Abstract Text

Metallic nanoparticles, used since antiquity to impart intense and vibrant color into materials, have more recently become a central tool in the nanoscale manipulation of light across a range of chemical sciences and engineering applications. This interest has led to a virtual explosion of new types of metal-based nanoparticles and nanostructures of various shapes and compositions, and has given rise to new strategies to harvest, control, and manipulate light based on these structures and their properties. By assembling metallic nanoparticles into useful building blocks, a striking parallel between the plasmons of these structures and wave functions of simple quantum systems is universally observed. [1] Clusters of metallic nanoparticles behave like coupled oscillators or antennas, introducing effects characteristic of systems as diverse as radio frequency transmitters and coupled pendulums into light-driven nanoscale structures. [2] Their unique light-controlling properties can be put to use in a multitude of ways: for detecting single molecules and following chemical reactions, for generation of hot electrons for color-specific photodetection[3] and photocatalysis,[4] and most recently, for high-efficiency solar steam generation poised to tackle our planet's energy and sustainability challenges.[5]

Session Title Accurate Mass Analysis of Environmental Samples and Food by both LC and GC/Q-TOF-MS

Abstract Title **LC/QTOF MS Analysis of Microcystins in Natural Waters**

Primary Author Ralph Hindle
Vogon Labs

Date: Sunday, March 08, 2015 - Afternoon

Time: 01:35 PM

Room: 238

Co-Author(s)

Abstract Text

Microcystins are formed by cyanobacteria during algal blooms, and are found all around the world. These liver toxins can contaminate drinking water supplies, and can be fatal for many species of animals, as well as humans. Data will be presented showing levels of some of the more widely-reported compounds, such as Microcystin-LR, but also the identification of different variants by interpretation of accurate mass fragmentation spectra using LC-QTOF.

Abstract Text

Comprehensive two-dimensional gas chromatography (GCxGC) used in combination with high-resolution mass spectrometry (HRMS) is a powerful tool for the analysis of complex mixtures. In this work, we analyzed a number of environmental samples by using GCxGC in combination with a new high-resolution time-of-flight (TOF) mass spectrometer. A composite mass spectrum for each sample was created by summing the mass spectra for all components in the GCxGC/HRTOFMS analysis. Afterwards, the Kendrick mass defect plots produced from these spectra facilitated the rapid identification of families of compounds based on their substituents which in turn helped guide the analysis of the chromatographic data. Additionally, tentative identification of specific contaminants was aided by database searches and elemental composition determinations from the accurate-mass data. The details of these results will be reported for this presentation.

Abstract Text

Analysis of commercial honey from different parts of the US was carried out using a simple sample preparation procedure. Raw honey samples were dissolved in water and directly injected into a liquid chromatography-quadrupole time-of-flight mass spectrometer (LC/Q-TOF-MS). A complex profile of compounds was obtained after processing the mass spectral data. Identifications of a few natural compounds were made by accurate mass measurements. Moreover MS-MS experiments were performed to elucidate structures of the found compounds.

Maple syrup samples from different regions were also analyzed and compared. Because of both grade and region, verification of maple syrup is difficult. Similarly to honey, analysis of maple syrup shows a complex profile of compounds. Direct analysis of real and imitation maple syrup easily distinguishes the two. Ratios of glucose to fructose can be used to distinguish the amount of natural sugar to process sugar in both types of maple syrup. Both adulteration and classification of the syrup by grade and region is more complex and requires data mining and multivariate statistical approach. This work examines the chemical profiling of syrups from different regions and grades. Identification of marker compounds for real maple syrup will be made by LC/Q-TOF-MS and compared.

Abstract Text

Current European Union regulations permit the use of GC/MS-MS and bioassay techniques only in feed and food samples. In this talk we will present a comparison of results obtained with official GC/HRMS methods, with a GC/HRMS TRACE GC 2000, Thermo Finnigan (Thermo Fisher Scientific), coupled with a MAT 95 XP Mass Spectrometer, and with a commercial GC/MS-MS Agilent 7000 Triple Quadrupole Mass Spectrometer interfaced to an Agilent 7890 GC (Palo Alto, CA, USA), for the dioxins analysis in typical air and soil environmental samples.

Most of the samples analyzed had congeners below LOD as they were real, everyday, environmental samples. A correlation between PCDD/F soil and air samples concentrations, expressed as WHO-TEQ, obtained by GC/MS-MS and GC/HRMS, despite the low PCDD/F concentrations, shows that data are in a good agreement.

A new monitoring strategy for dioxin in environmental samples could be proposed with new MS/MS instrumentation available. This would be a realistic, lower cost, higher throughput alternative to the GC/HRMS method at least as a screening method to classify a sample as compliant or suspected to be non-compliant.

Abstract Text

This abstract reports the identification of various surfactants in flowback and produced water samples from hydraulic fracturing resulting from natural gas production. The method uses an application of the Kendrick mass defect and liquid chromatography/quadrupole-time-of-flight mass spectrometry, including ion mobility. The Kendrick mass defect differentiates the various adducts of the ethoxylates, in particular, the proton, ammonium, and sodium adducts in both singly- and doubly-charged forms. ICP/MS is also applied to the flowback waters to identify constituents used in making up the cocktail for injection. The importance of the various identified surfactants will be discussed as well as procedures for removal of these compounds from flowback and produced water from hydraulic fracturing.

Abstract Text

There is increasing interest in the use of nanoparticles (NPs) for biomedical applications. In particular, nanobiophotonic approaches using fluorescence offers the potential of high sensitivity and selectivity in applications such as fluorescence-based bioassays and intracellular sensing. In this presentation, we focus primarily on the use of fluorescent silica NPs for these applications. We summarise the main synthetic approaches namely the Stöber and microemulsion processes and, in this context, we deal with issues in relation to both covalent and physical incorporation of different types of dyes in the particles. The important issue of NP functionalisation for conjugation to biomolecules is discussed and strategies for minimising non-specific binding are highlighted. We give examples of the use of silica NPs as fluorescent labels for bioassays and as carriers for analyte-specific dyes for intracellular sensing applications, in particular for optical oxygen and pH sensing. The use of the NPs for cell staining is also discussed in the context of cancer diagnostics. We conclude with some perspectives for the future in this area.

Abstract Text

Nanotechnology has emerged as enabling platform for using nanofabrication and nanoparticle formulations to improve the detection of chemical and biological processes. In particular, silica nanoparticles provide a versatile platform to boost the photostability and fluorescence quantum yields of near infrared (NIR) fluorescent dyes. We demonstrate the development of NIR fluorescent silica nanoparticles, which enhanced the brightness of NIR dyes by orders of magnitude. Coupled with exceptional photostability, these nanoparticles are useful for longitudinal assessment of the same sample or cell population without loss of fluorescence signal, ushering a new approach for monitoring dynamic processes in cells and living organisms.

Abstract Text

A practical method for bacterial separation remains a hindrance for the successful deployment of rapid detection methods from complex samples. We have developed core-shell nanoparticles containing 30% cobalt (w/w) in the final nanoparticle which have much shorter separation times than traditional iron oxide nanoparticles. The particles were bound to T7 bacteriophages in order to recognize and specifically bind to [i]E. coli[/i] cells. For comparison, the particles were directly compared to antibodies on both the magnetic nanoparticles as well as traditional micron-scale particles. The capture efficiencies of antibodies and bacteriophages on nanoparticles and microparticles for the separation of [i]E. coli[/i] K12 were determined. The results suggest that improvements can be made to magnetic separation by using phage for capture and by the use of nano-scale particles.

A paperfluidic device was constructed to detect the separated [i]E. coli[/i]. Here we report the development of a simple and sensitive antibody and Ru(bpy)₃²⁺-doped silica nanoparticle-labeled lateral flow assay which achieves low limit of detection. Following concentration, the nanoparticles and bacteria were incubated to allow completion of the bacteriophage infection cycle. The increase in free phage titer was then quantified fluorescently.

The 30 nm spherical Ru(bpy)₃²⁺-doped silica nanoparticles were prepared in aqueous medium by a novel method recently reported. The nanoparticles were modified anti-T7 antibodies. The experimental results showed that the lateral flow fluorescent assay developed was more sensitive compared with the traditional colloidal gold test strips. The limit of detection for the fluorescent lateral flow assay developed is approximately 10⁶ PFU fmoles as compared to approximately 10⁸ PFU for the colloidal gold. This correlated with a detection limit of approximately 10³ CFU/mL of [i]E. coli[/i].

Abstract Text

A series of silica-based near-infrared fluorescent (NIRF) nanomaterials have been developed using new approaches. The distinct features of these NIRF nanomaterials are 1) highly intense and photostable fluorescence signals, 2) tunable fluorescence wavelengths, and 3) low toxicity. Several metallic-based sandwich nanostructures were developed with various shapes and sizes for further enhanced fluorescence. The geometric, compositional, and dimensional effects of these NIRF materials on their fluorescence properties were studied, including fluorescence quantum yield, lifetime and wavelengths. These NIRFs were applied to biological applications including sensitive detection and imaging of trace analytes, and photothermal therapies. Nanomaterial-based photothermal therapy has shown great potential for efficient cancer treatment. The developed nanohybrids can generate significant amount of heat upon irradiation in the near infrared (NIR) region for inducing thermal cell death. The nanohybrids showed excellent in vitro biocompatibility as a promising hyperthermia agent.

Abstract Text

Fluorescent silica nanoparticles can be made using almost any kind of fluorophores that can be modified to have suitable functional moiety for covalent binding to silicates used in nanoparticle synthesis. Chemically stable visible fluorophores such as fluorescein is often utilized for this purpose. The NIR spectral region (650-900 nm) offers significant advantages among them lower background interference especially in biological samples. However NIR dyes have relatively lower fluorescent quantum yield as compared to visible fluorophores. Additional disadvantage of using NIR dyes is their relatively high sensitivity to microenvironmental changes such as solvent polarity or quenching. Self quenching may become a problem due to energy transfer for carbocyanines that are at high concentration in the silica nanoparticle. Self quenching can be significantly reduced by using dyes that have large Stokes' shift. This can be achieved by substituting meso position halogens in the NIR fluorescent carbocyanine dye with a linker containing amino moiety. This substitution can also serve as a linker to covalently attach the dye molecule to the nanoparticle backbone. Additional disadvantage of NIR dyes is their relative sensitivity to harsh chemical conditions present during silica nanoparticle synthesis. During the studies presented here we developed silica nanoparticles containing different covalently incorporated visible and NIR dyes. One application of these particles is for bright fluorescent labels to be used in immunochemistry, flow cytometry, etc. Covalently bound silica nanoparticles can be used as biomolecular labels after activation with aminoreactive surface moieties suitable for biomolecule labeling. Other biological and bioanalytical applications of fluorescence silica nanoparticles presented includes phagocytosis and related applications. Reverse micelle synthesis approach to this application is ideal due to easy control of particle size.

Abstract Text

Nitric oxide has been implicated in a number of physiological processes, including vasodilation, neurotransmission, sepsis, and wound healing. As a result, the quantification of nitric oxide and its analogs in vivo may lead to improved diagnosis and treatment. Our lab has previously described the fabrication of a microfluidic nitric oxide sensor platform capable of sensitive and selective detection of nitric oxide in biological fluids. Samples volume requirements (1.0 milliliters) circumvented using this device for wound fluid analysis. Furthermore, the first generation device only allowed for the detection of nitric oxide. In this presentation we will describe an improved microfluidic sensor that requires only 50 microliters of sample and allows for measurement of nitric oxide, nitrite, and S-nitrosothiols.

Abstract Text

One of the predominant challenges in systems-wide analyses is the broad-scale characterization of the molecular inventory in cells, tissues, and biological fluids. Advances in computational systems biology rely heavily on the experimental capacity to make panomics measurements, i.e. integrated metabolomics, proteomics, lipidomics, glycomics, etc., accompanied with fast minimal sample preparation, fast measurements, high concentration dynamic range, low limits of detection, and high selectivity. This confluence of figures-of-merit place demanding challenges on analytical platforms for such analyses. Ion mobility-mass spectrometry (IM-MS) provides rapid (ms) gas-phase electrophoretic separations on the basis of molecular structure and is well suited for integration with rapid (us) mass spectrometry detection techniques. Furthermore, the timescales of this multi-dimensional separation are well suited for combination with fast condensed-phase separations such as GC, SFC, and UPLC (min) for enhanced separation selectivity as the sample complexity becomes ever more challenging. This report will describe recent advances in IM-MS panomics measurement strategies in the analyses of complex biological samples of interest in systems, synthetic, and chemical biology. New advances in bioinformatics and biostatistics will also be described to approach biological queries from an unbiased and untargeted perspective and to quickly mine the data gathered to provide targeted and actionable information. Elucidation of biomolecular signatures specific to diabetic wound healing and in synthetic biological studies to decipher the prevailing biology in a variety of diseases and drug mode-of-action will be presented.

Abstract Text

Sol-gel processing is widely used to create low-k materials, thermal insulation, and stationary phases in the separation sciences. Xerogels, porous sol-gel derived materials formed by solvent evaporation at or near ambient conditions, are attractive platforms for chemical sensor development. We have devoted significant time and effort to elucidate the chemistry within hybrid silica-based xerogels as a means to intelligently guide materials development for use in areas ranging from chemical sensors to anti-fouling coatings. The speaker will summarize their research group's efforts to develop sensors for time-dependent cytokine and growth factor detection and imaging in model systems.

Abstract Text

Bacterial contamination of chronic wounds has long been a major concern – especially for those involved in the management of diabetic foot disease where delays in treatment can all too easily lead to life threatening complications. While there have been considerable advances in the development of wound dressings that aim to minimise bacterial contamination and aid the healing process, the majority tend to be inherently passive and possess little or no diagnostic capability.

Early identification of infection is imperative in the management of the diabetic foot in preventing limb threatening events, the need for hospitalisation and subsequent amputation but it is possible and, indeed probable, that individuals will only seek treatment once gross symptoms appear and an infection has taken a firm hold. There is a pressing need for more advanced materials that could not only provide the clinician with a detailed picture of the wound dynamics at the time of consultation, but which would periodically monitor the wound once they leave the hospital.

Conductive films capable of monitoring chemical changes within the wound fluid open up the possibility of remote monitoring of the wound thereby allowing much earlier referral and hence proffer a more effective treatment and a more positive outcome. The design of mechanically flexible composite film structures, their activation for electrochemical sensing and subsequent response to a range of wound biomarkers are described. Their assembly within conventional bandage as an integrated unit is demonstrated and their adoption for clinical use is discussed.

Abstract Text

Chronic wounds such as diabetic ulcers, venous leg ulcers and pressure sores are very difficult to heal and can last for months to years in spite of the numerous treatments currently available. Various wound biomarkers have been investigated as possible predictors of this healing impairment. Our preliminary human studies of wound fluid nitric oxide levels have suggested a correlation between wound progression (healing) or worsening and threshold levels of nitric oxide activity. We analyzed nitric oxide metabolites (nitrate and nitrite, NO_x) in human wound fluids and correlated these markers with wound healing status (progressing or worsening) based on patient's wound history. Samples were collected from patients with wounds of various etiologies and analyzed for NO_x. A laboratory method was developed to analyze NO_x which can detect at least 5 uM in samples as small as 10 ul. A nitrate-free sample collection device was identified to match the sensitivity of this new assay (most "nitrate-free" products tested contained nitrate levels higher than this detection limit when extracted in such a small volume). Data analysis from 50 wounds showed that NO_x allowed to discriminate between worsening and progressing wounds and suggested that a two cut-point diagnostic test using NO_x is better than a single cut-point test to identify progressing from worsening wounds. The method developed here can be used in the future to monitor NO_x levels in wounds producing enough exudate for its prognostic value or to monitor the response to a therapy. This could provide a useful tool to help guide treatment in wound care. Additional work is needed to get longitudinal data and a larger number of wound patients in each of the various chronic wound categories.

Abstract Text

Despite its effectiveness at removing background interferent signal from mass spectral analyses, FAIMS has yet to achieve wide-spread use for a number of factors. The first, and foremost, complaint is limited sensitivity. It is common to lose approximately ninety percent of incoming ion flux when FAIMS is implemented. Although the resulting signal-to-noise can be improved versus analysis without FAIMS, the loss in absolute ion signal does not allow for lower limits of quantitation in most cases. Second, the amount of time required for FAIMS separation, often between 50ms and 100ms, limits the number of data points available across a chromatographic peak. Third, a mixture of nitrogen and helium is generally used as FAIMS gas. While it has been shown that helium in the transport gas offers beneficial results, the reduced worldwide availability of helium, and its resulting cost, is a mark against FAIMS. Finally, FAIMS analysis has been mostly limited to liquid flow rates at microliters per minute and above. This is due to the desolvation gas flowing into the source region deflecting the electrospray plume away from the entrance of the device. This is overcome when using ionization sources that are aided by a sheath gas to push through the countercurrent desolvation gas. However, nanospray generation in front of the entrance plate has been difficult to date. Here, we will discuss modifications to a set of cylindrical FAIMS electrodes that address each of the previous factors limiting FAIMS analysis. The resulting nanospray friendly instrument is capable of transmission efficiencies greater than fifty percent with residence times lower than 20ms without using helium or dopants.

Abstract Text

Glycosaminoglycans (GAGs) are an important class of carbohydrates that are involved in a number of key biological processes. Their biosynthesis occurs as a number of sequential enzymatic processes in the Golgi apparatus. Because these are non-template events, GAGs are produced as a heterogeneous mixture of molecular sizes and compositions. Their analysis is challenging both because of the complexity of the mixture of structures that are present in a sample as well as the lability of their chemical features, specifically sulfation. There have been many recent advances in "sequencing" purified GAG oligomers by tandem mass spectrometry. To examine mixtures of GAGs, there needs to be some separation of the components prior to MS analysis. On-line HPLC, which works well for peptides, does not work so well with GAGs, as they are highly ionic, and not well separated by conventional reverse phase separations. As an alternative to solution-phase separations, we are developing gas-phase separation of GAGs based on differential ion mobility. We find FAIMS to provide excellent resolving characteristics for GAG oligomers, ionized by electrospray ionization in negative ion mode. FAIMS can resolve fine structural differences, such as the epimeric sugar residues, glucuronic acid from iduronic acid, in tetrameric oligomers. This presentation will describe the recent progress in applying FAIMS to the analysis of GAGs using FTICR mass spectrometry.

Abstract Text

The design of a DMS cell is flexible and can be tailored to the performance requirements of targeted applications. The focus of this presentation will be on the specific design elements of a DMS/MS system, how they affect performance, and how they can be balanced to achieve the appropriate performance trade-offs. Particular emphasis will be given to how factors such as DMS gap height and residence time affect key figures of merit, including resolution, peak capacity, transmission, and analysis speed. Examples of separations will be provided with a range of different mobility cell dimensions and geometries. In addition, modeling results will be provided to describe the development of simulators of ion motion, whose ultimate value can be envisioned for aiding in DMS instrument design optimization and creating reference libraries of differential mobility for a large number of chemical species for chemical identification purposes. In particular, the use of simulators to improve our understanding of fringing field effects and temperature gradients will be discussed.

Abstract Text

A unique feature of differential ion mobility spectrometry (FAIMS) is a strong dependence of separation performance on the buffer gas composition. In that aspect, FAIMS is distinct from conventional IMS but resembles liquid chromatography, where the species resolution is sensitive to the chemistry of mobile and stationary phases and is often optimized by their tailoring. However, FAIMS differs from chromatography in that the choice of gas also greatly affects the overall separation peak capacity. This talk will discuss our systematic effort to maximize the FAIMS resolving power and resolution of specific targets by rational gas formulation. We shall focus on the advantages of buffers rich in helium and particularly hydrogen, especially for analyses of protein conformers in comparison with smaller ions such as peptides, lipids, and amino acid isotopomers. The limitations of approach for larger macromolecules imposed by the peak broadening due to conformational diversity will be explored.

Abstract Text

Environmental research continues to expand beyond traditional, regulated contaminants to emerging contaminants, such as pharmaceuticals, perfluorinated compounds, nanomaterials, flame retardants, drinking water disinfection by-products (DBPs), hormones, siloxanes, UV filters, algal toxins, naphthenic acids, benzotriazoles, artificial sweeteners, antimony, perchlorate, musks, and prions. These are now frequently being found in water samples, including rivers, lakes, ground water, and drinking water. Moreover, understanding their fate and transport in the environment and in wastewater/drinking water treatment is vitally important, and as such, one of the major trends continues to be in identifying their transformation products. Because environmental samples are inherently complex mixtures with trace-level contaminants, the development of sensitive and modern analytical tools has been key for their identification and measurement. This presentation will provide an overview of emerging contaminants and the modern tools used to measure them. This will include a discussion of high resolution mass spectrometry (MS), liquid chromatography (LC)/MS/MS, gas chromatography (GC)xGC-MS, direct sampling ionization-MS techniques, NMR spectroscopy, and halogen-specific total organic halogen (TOX) analysis, as well as current extraction technologies.

Abstract Text

Micro-total-analysis systems positively influence the cost, availability and range of applications of environmental analysis. Highly portable, energy efficient field analysis systems, monitoring networks, and remote/autonomous devices can all be realized through miniaturization.

This work presents the design, fabrication and application of the components of an integrated field-portable analysis device for water quality monitoring. Micro-fabricated components include filters, mixers, reagent reservoirs, and detection zones. Detection is accomplished using stand-alone, low-cost hardware and the on-board optical hardware of a smartphone. The presentation includes an overview of design elements, fabrication methods, and integrated device models.

An application to be discussed is analysis of environmental water for evidence of hydraulic fracturing (fracking) contaminants. While fracking has made shale gas accessible and economical, large quantities of wastewater are produced over the lifespan of a well: drilling and fracturing a Marcellus shale well requires 14,000-17,000 m³ of water. Within one year of well completion, 10-25% of the water returns to the surface as a concentrated brine. 55-80% of this returned water is reused for other wells, leaving a substantial amount of wastewater. New approaches are needed to assess and ensure compliance and safety as these valuable natural resources are utilized. Constituents such as bromide, strontium, and barium are characteristic of the wastewater generated by Marcellus shale gas extraction, and are of particular interest as early indicators of wastewater leaks and for tracking the movement of produced waters.

Our progress toward the ultimate goal of a versatile, portable, simple, stable, adaptable, low-cost monitoring platform will be highlighted.

Abstract Text

In recent years, chemicals of emerging concern have been associated with adverse effects observed in aquatic organisms throughout the world. These include feminization of male fishes, reduced reproductive success, immunosuppression and behavior changes. However, the specific causes and sources associated with these responses are often difficult to identify. Many of these chemicals, such as synthetic hormones, pharmaceuticals, personal care products were produced to have biological effects. They act through interaction with hormone receptors, often involving complex feedback mechanisms and hence may elicit nonlinear dose responses. Aquatic organisms are exposed to complex mixtures of these as well as legacy contaminants that may also have endocrine-disrupting effects. These complex mixtures may contain compounds with additive, synergistic or antagonistic activity and can have biological effects at concentrations below or close to the current level of detection. Hence, biological effects monitoring is increasingly used to identify potential problems. Bioindicators, such as intersex (testicular oocytes), vitellogenin (a yolk precursor) in the blood of male fishes, altered plasma hormone concentrations, increased susceptibility to infectious disease, microscopic changes in gonads and endocrine glands, and changes in gene expression profiles of wild fishes have been developed and used in numerous monitoring and assessment projects. In addition, extracts from discrete and time integrated water samples can be screened for hormone (estrogenic, androgenic, thyroid, corticosteroid) activity using in vitro cell-based assays such as the BLYES (bioluminescent yeast estrogen screen), transgenic zebrafish embryos or nuclear translocation assays. These methods are considerably cheaper and quicker than comprehensive chemical analyses and can better focus the choice of analytes in water, sediment or fish tissue.

Abstract Text

Endocrine disrupting contaminants that enter the water system through ineffective wastewater treatment and as run-off, impair reproduction, interfere with development, and are associated with obesity and cancer in humans. Fish are indicators of environmental exposure that is hazardous to humans, and chemical biomarkers in fish are correlated to early stages of dysfunction. Circulating steroids are critical biomarkers of endocrine disruption because they are a direct measurement of hormonal imbalance initiated by endocrine disrupting contaminants. Capillary electrophoresis is utilized to rapidly quantify steroid hormones circulating in only 5 microliters of plasma in order to identify endocrine disrupting chemicals that elicit a physiological response. Multiple steroidal compounds are captured, concentrated and assayed using a high-throughput label-free electrophoresis separation based on pH mediated stacking. With this new technology, nanomolar detection of steroid hormones is achieved with UV-visible absorbance. When the microscale method is used to profile steroids in individuals, the change in steroid levels is easier to quantify and observe. The technology is utilized to demonstrate how chemicals and chemical mixtures interfere with interrelated steroid pathways. The effects of solvents used in the literature to solubilize and deliver chemicals are also evaluated.

Abstract Text

High sensitivity, high mass accuracy mass spectrometry has transformed the way we examine biological and biomedical questions. With modern analytical tools, proteome-wide studies of protein post-translational modification and single amino acid polymorphisms (SAAPs) are enabled. Expression levels are accurately quantified by single reaction monitoring (SRM). Furthermore, with the recent integration of the ENCODE data into our proteomic workflow, we can identify the unknown human proteins at an accelerated pace. By use of databases that contain predicted sequences of known and novel proteoforms, we identified dozens of SAAPs in proteins derived from glioma stem cells that may be associated with glioma pathology, and novel alternative spliceforms derived from fusions between known and previously unknown exons. The identification of an overexpressed metabolic protein, BCAT2 T186R, has opened up studies of a target never associated with glioma pathology. Integration of RNA-Seq data and proteomics has allowed us to determine the roles of SAAPs and novel fusion proteins in GSC pathobiology. Bioinformatic searches of ENCODE data translated into a searchable database for proteomics (proteoENCODE db) yielded eighty-one chimeric peptides in GSCs. These results will allow further studies of proteins' role in pathogenesis, tumor recurrence, and resistance to chemotherapy and radiation. The next step is to validate and quantify their expression by SRM across our biobanked cell lines, at baseline conditions and following standard-of-care treatments. We expect that among the newly identified proteins, new therapeutic targets and biomarkers will be established. Our results are enabled by modern mass spectrometric methods and the development of databases that include the complexities of protein features. Our results serve to demonstrate how improved analytical methods have translated into increased ability to produce breakthrough discoveries in cancer research.

Abstract Text

Protein footprinting coupled with mass spectrometry has emerged in recent years as a valuable tool to study protein structure. Several footprinting techniques, such as hydrogen deuterium exchange and oxidative labeling, have been successfully used to identify protein-protein and protein-ligand interactions in varying protein systems. To date, these footprinting methods have been performed on relatively pure proteins [i]in vitro[/i]. The development of an [i]in vivo[/i] footprinting method would provide a powerful platform to study proteins in their native cellular environment. The coupling of footprinting with high resolution mass spectrometry allows for data to be analyzed on the amino acid residue-level. We have developed an [i]in vivo[/i] oxidative labeling method, based on the footprinting method fast photochemical oxidation of proteins (FPOP). Oxidative labeling is advantageous for [i]in vivo[/i] labeling owing to its irreversible nature, which allows for purification of the proteins of interest from the cell membrane prior to MS analysis. [Several parameters were optimized for the development of [i]in vivo[/i] FPOP, including hydrogen peroxide concentration and quenching conditions. Mass spectrometry on digested cell lysates demonstrate that several proteins within the cell are oxidatively modified. A comparison of the extent of oxidative modification to regions of solvent accessibility of several proteins whose structure has been solved by high resolution methods revealed that [i]in vivo[/i] FPOP successfully characterizes solvent accessibility. These data demonstrate the feasibility of [i]in vivo[/i] FPOP as a tool to analyze protein structure within cells.

Abstract Text

This presentation will provide several examples of how we re-discover, objectively learn, and generate new hypotheses using ultrahigh specificity technology. For example, it is often thought that a Western Blot is a gold standard for the specific detection of a protein and that quantitative Western blotting provides quantitative information. Mass spectrometry is inherently specific and can be quantitative over 5 orders of magnitude. Moreover, it provides us with untargeted yet specific data enabling new discoveries and hypotheses to be generated. Examples from several different areas of biology will be presented including ovarian cancer and lignin biosynthesis.

Abstract Text

Proteomics allows the simultaneous detection of thousands of proteins and can give dynamic information about underlying mechanisms of disease. Using a transgenic mouse model, our group has gained insight about the proteome of Alzheimer's disease in systemic tissues. In order to follow protein changes with disease progression and from many biological replicates, has required the development of novel sample multiplexing methods. These sample multiplexing methods rely on precursor isotopic labeling and isobaric tagging methods and take advantage of mass spectrometry to keep track of sample origin and relative sample quantity. Here we will briefly present these methods and discuss how they have been used to understand the complexity of Alzheimer's disease.

Abstract Text

Measuring diagnostic panels of multiple proteins promises future personalized early detection and therapy monitoring of cancer. Levels of biomarker proteins in patient serum can provide a continually updated record of disease status. Research in electrochemical detection of proteins has produced exquisitely sensitive approaches. Most utilize ELISA-like sandwich immunoassays incorporating various aspects of nanotechnology. Several of these ultrasensitive methodologies have been extended to microfluidic multiplexed protein detection. To achieve clinical or point-of-care (POC) use, simplicity and low cost are essential. In multiplexed microfluidic immunoassays, required reagent additions and washing steps pose a significant problem calling for creative engineering. We will discuss two microfluidic systems utilizing strategies to solve these problems to detect 4 protein biomarkers in serum. The first involves a sample-reagent delivery system feeding an ECL detection chip built with carbon nanotube forests in microwells, and using RuBPY-loaded antibody-coated silica nanoparticles for detection. The second example involves on-line capture of analyte proteins on antibody-enzyme-coated magnetic beads with detection on an 8-electrode antibody decorated chip. Applications to development of diagnostic protein panels for prostate cancer and oral mucositis during radiation therapy and validation with patients serum samples will be discussed.

Abstract Text

Microfluidic paper-based analytical devices (mPADs) have gained attention as an alternative format for microfluidic analysis because of their low cost, flexibility of analysis methods, and wide range of potential applications. While mPADs have utilized a variety of detection methods, colorimetric reactions have been the most common. However, electrochemical detection with mPADs (ePADs) provides an attractive alternative to colorimetric methods because it is more sensitive, selective, and can access a wide range of analytes. Here recent research from our group on portable ePAD development and chemistry will be discussed for four different ePAD configurations with an emphasis on two projects: detection of pollutants in water, and analysis of enzymatic reactions specific to microbe detection. The first ePAD design incorporates novel carbon paste microelectrodes to detect organic pollutants such as pesticides. Second, an ePAD utilizing a simplified method for incorporating carbon electrodes has been developed and used to measure pesticide contamination marker, p-nitrophenol, in ground water. By coupling this system with a built in QR code, it is possible to provide simple and rapid assessment of pollutant levels. Third, a flow injection analysis-like ePAD system will be presented. This ePAD sandwiches Au microwire electrodes between layers of paper to create a flow through analyzer. The physical shape of the pumping region allows for steady-state flow with multiple sample injections. Finally, carbon paste ePAD detection of enzymes associated with E. Coli and Salmonella will be presented as a first step towards analysis of bacterial loads in food and water.

Abstract Text

The ability to provide real-time information about an individual's response to therapeutics has the potential to revolutionize healthcare by offering personalized treatment. Drugs with narrow therapeutic windows become toxic or ineffective if over- or under-dosed thus reducing efficacy. Maintaining the most efficient dosage, personalized to the patient, can maximize efficacy of treatment and ultimately patient outcome. Current methodologies for monitoring therapeutics are cumbersome (requiring tens of minutes to hours) and are often performed removed from the point of care. Biosensors represent a promising alternative but often fail to respond to specific targets when challenged in biological sample matrices. This failure is typically a result of biofouling, which masks the true sensor response. This talk focuses on the rational design and tuning of electrochemical, aptamer-based sensors for the detection of therapeutic levels of the antibiotic tobramycin directly in blood. The RNA aptamer-based sensors are coupled with biocompatible hydrogel membranes to enable long-term stability in this complex biological matrix.

Abstract Text

To understand the molecular basis of brain functions, researchers would like to be able to quantitatively monitor neurochemicals in vivo. However, the chemical and physiological complexity of the central nervous system (CNS) presents challenges for the development of these analytical methods. We used the redox nature of neurochemicals at the electrode/electrolyte interface to form a basis for selectively monitoring neurochemicals. In this presentation, I would introduce the recent process in our group on in vivo monitoring ascorbate in rat brain.

1) Carbon nanotubes (CNTs) provide an electrode/electrolyte interface for the selective oxidation of ascorbate and, based on this, we have developed both in vivo voltammetry and an online electrochemical detecting system (OECS) for continuously monitoring ascorbate in CNS.

2) By using the CNT-based OECS, we compared the dynamic regional changes of extracellular ascorbate level in four different brain regions 1 h after global cerebral ischemia induced by two-vessel occlusion (2-VO). We also compared the change in the level of ascorbate in the different ischemia model (i.e., two-vessel occlusion (2-VO) and left middle cerebral artery occlusion (LMCAO) in striatum.

3) We also demonstrated the validity of the OECS for ascorbate detection as a platform for in vivo evaluation of neuroprotective efficiency of antioxidants by studying the dynamic change of hippocampal ascorbate during the acute period of cerebral ischemia and its responses to intravenous administration of antioxidants including ascorbate and glutathione.

Abstract Text

Surface enhanced Raman spectroscopy (SERS) has been developed for a variety of bioanalytical applications requiring the rapid sensitive and highly specific identification of molecular components in human body fluids. SERS can be exploited for novel diagnostic of urinary tract infections (UTI) that does not require cell growth which is the slow step (one to three days) in current gold-standard strain specific determinations of causative bacteria. A bacterial enrichment procedure based on filtration and centrifugation, a portable Raman microscope, a reference library and associated identification software are the key components of this methodology that results in strain specific bacterial identification of bacteria in spiked human urine samples is accomplished in less than one hour by this SERS methodology. The observed bacterial SERS signatures are dominated by purine metabolic products of the bacterial cells. Robust antibiotic specific bacterial identification can be accomplished with this technique.

Tumor cells are well-known to exhibit high metabolic rates compared to normal, non-pathogenic cells. Characteristic SERS vibrational signatures due to molecules like adenine, hypoxanthine and NADH appear over the course of several hours from single cancer cells and the time dependence of these signatures are found to be different for pathogenic and nonpathogenic cells. Thus these SERS may be used for in vitro single cell cancer detection as well as fundamental studies of the effects of genetic or proteomic manipulation for cancer therapy efficacy evaluation.

SERS has also been developed for the trace detection and identification of human body fluids such as blood, semen, vaginal fluid and saliva for on-site detection and identification for forensic applications. SERS is found to be a sensitive and specific method for the evaluation and identification of human body fluids and mixtures which provide important timely evidence for crime scene investigators.

Abstract Text

There is a significant effort to utilize surface-enhanced Raman scattering (SERS) for medical and biomedical diagnosis and theranosis in recent years. One of the areas where has been a substantial research effort to use SERS for microorganism detection and identification. The SERS spectra acquired from whole microorganisms can be used for their label-free detection and identification. Although a capture scheme utilizing an antibody or an aptamer is necessary for their detection, it may not be need at a clinical setting and only microorganisms collected from the culture media might be satisfactory for the microorganism identification. The primary goal in clinical microorganism identification is the speed and the reliability. In this presentation, the current status and potential of the technique for clinical microorganism identification will be discussed.

Abstract Text

Flame retardant chemicals are often added to resins and polymers used in consumer products to reduce their flammability. Their increasing use over the past decades has led to increasing concentrations of several classes of flame retardants in both the environment and in human tissues. However, identifying consumer products that contain these chemicals, and understanding their links with human exposure, has been particularly challenging. To this end we have developed mass spectrometry-based approaches to identify flame retardant additives in polyurethane foam and textiles. Using a combination of gas chromatography low-resolution mass spectrometry and liquid chromatography high-resolution mass spectrometry, we have developed a screening method to detect the presence of 12 different organic based flame retardants that are commonly used in polyurethane and textiles. To date we have analyzed approximately 250 polyurethane foam samples and 6 textiles samples. The most common commonly detected chemicals in foam are tris (1,3-dichloro-isopropyl) phosphate (TDCPP), tris (1-chloro-isopropyl) phosphate (TCPP), a suite of polybrominated diphenyl ethers (PBDEs), and a mixture of brominated aryl esters and aromatic organophosphate chemicals associated with several different commercial mixtures. Textile materials in contrast primarily contained either tetrabromobisphenol A (TBBPA) or hexabromocyclododecane (HBCD). These chemicals are frequently identified in indoor dust and recent studies have identified these chemicals, or their metabolites, in human tissues. This presentation will provide an overview of the methods used to identify flame retardant chemicals in these samples and how their relative detection frequency corresponds to the detection and relative abundance of these compounds in human tissues.

Abstract Text

Numerous examples from the literature concerning environmental contaminants like antibiotics, surfactants, and pesticides suggest that biological effects can be expected within families of closely related structures, with differences in chemical structure modulating the degree and character of induced bioactivity. The possibility for conserved bioactivity within transformation products generated by either environmental or engineered mechanisms implies that characterizing the the environmental significance of these products needs both chemical and biological approaches to fully understand environmental risk. To investigate the formation of bioactive transformation products within families of potent steroid hormones used as veterinary and human pharmaceuticals, we first used spectroscopic and spectrometric techniques, including high resolution, accurate mass spectrometry to initially characterize transformation products. For selected examples of major products, NMR techniques and organic synthesis was used for structural elucidation and the creation of pure standards for subsequent biological assessment. Product mixtures and isolated products were then evaluated with bioassay techniques including both in vitro and in vivo systems. These data indicate that for a number of steroid pharmaceuticals, we can expect the formation of at least some highly bioactive transformation products arising from typical environmental mechanisms. Although contaminant transformations can reasonably be expected to reduce bioactivity within a single endpoint, product bioactivity can span several different receptor endpoints and magnitudes. Thus, a comprehensive analysis of both product bioactivity and stability is sometimes needed to improve our assessment of environmental risk by specifically accounting for transformation products and non-target receptor interactions for potent pharmaceuticals.

Abstract Text

Recent studies have suggested that hydroxylated metabolites of polybrominated diphenyl ethers (OH-PBDEs) accumulate in human serum at levels similar to or greater than their parent PBDEs, and have the potential to cause endocrine disruption. Conventionally, gas chromatography/mass spectrometry (GC/MS) after derivatization is used to analyze for OH-PBDEs. However, there is a need for the direct analysis of OH-PBDEs at relatively low concentrations in environmental and biological samples. Therefore, we explored the use of supercritical fluid-based Ultra Performance Convergence Chromatography coupled to Time of Flight Mass Spectrometry (UPC²/TOF MS) towards a non-targeted analysis to identify metabolites formed during in vitro metabolism of PBDE-100 by a recombinant human cytochrome P450 (CYP2B6). Without prior derivatization, five monohydroxylated metabolites were effectively separated by UPC². Additionally, MS^E, which records data without discrimination or pre-selection, was used to generate and analyze the accurate masses of fragment ions containing bromine isotopic patterns. UPC²/TOFMS proved effective in the targeted analysis of OH-PBDEs in human serum samples.

Abstract Text

Biomolecules are abundant in the natural environment due to organism wastes and breakdown products. A number of “pollutant” biomolecules, however, can cause public health problems when present in drinking water. Genetic material that contains antibiotic resistance genes (ARGs), for example, may lead to the spread of antibiotic resistance in pathogenic bacteria. Likewise, virus particles with intact genomes can cause a range of diseases when ingested. The drinking water industry relies heavily on disinfecting treatments to destroy these biological contaminants. Interestingly, research has suggested that some disinfecting treatments (e.g., chlorine, chloramines) can actually lead to bacterial populations with increased antibiotic resistance. And although the reactivity of virus proteins with disinfectants has been reported, a thorough understanding of the fate of virus genomes during disinfection is still lacking.

Typically, virus nucleic acids and bacterial antibiotic resistance genes (ARGs) are assayed and quantified with PCR-based methods. Although these methods can be quantitative and can identify regions where nucleic acids have incurred damage, they do not identify the specific location (i.e. nucleotide) in the virus genome or ARG sequence where chemical modifications have occurred and they cannot detect the specific chemical modifications.

Here, we have employed nucleic acid mass spectrometry techniques to study the reactions that take place in virus genomes and bacterial ARGs during common disinfecting treatments. Both MALDI-TOF and Orbitrap MS analyses have been applied in order to identify regions in viral RNA and in bacterial plasmids containing ARGs that are most susceptible to chemical oxidants and UVC. We compare the degradation data collected with mass spectrometry to the degradation data collected with qPCR and to the loss of virus infectivity and ARG transformation efficiency.

Abstract Text

The rates at which different wastewater treatment plant (WWTP) microbial communities biotransform specific substrates can vary by orders of magnitude. However, it is unclear what factors lead to differences in specific biotransformation rates. We hypothesized that differences in taxonomic composition among WWTP communities may be predictive of the differences in the rates of some types of biotransformations. Here we present a novel framework for establishing predictive relationships between specific bacterial 16S rRNA sequence abundances and biotransformation rates. We selected ten WWTPs with substantial operational variation and measured the *in situ* ammonia biotransformation rate constants in nine of them. We also selected ten micropollutants that undergo different types of biotransformations and measured biotransformation rate constants in batch reactors seeded with each of the ten WWTP microbial communities. We isolated total RNA and analyzed 16S rRNA sequence reads. We then developed multivariate models between the measured abundances of specific 16S rRNA sequence reads and the ammonia and micropollutant biotransformation rate constants. We constructed model scenarios that systematically explored the effects of model regularization, model linearity and non-linearity, and aggregation of 16S rRNA sequences into operational taxonomic units (OTUs) as a function of sequence dissimilarity threshold (SDT). For ammonia biotransformation rate constants, a large percentage of model scenarios resulted in well-performing and significant models at intermediate SDTs of 0.13-0.14 and 0.26. The 16S rRNA sequences consistently selected into the well-performing and significant models at those SDTs were classified as *Nitrosomonas* and *Nitrospira* groups. We then extend the framework by applying it to the biotransformation rate constants of the ten micropollutants. We identified phylogenetic groups that were robustly selected into all well-performing and significant models constructed with biotransformation rate constants of isoproturon, propachlor, ranitidine and venlafaxine. These phylogenetic groups can be used as predictive biomarkers of WWTP microbial community activity towards these specific micropollutants. This work is an important step towards developing tools to predict biotransformation rates in WWTPs based on taxonomic composition and was supported by grants from Eawag (Category: Seed) and the Korean-Swiss Science and Technology Cooperation.

Abstract Text

Water and wastewater disinfection processes can aid in minimizing the transport of antibiotic resistant bacteria (ARB) within environmental systems. However, the antibiotic resistance genes (ARGs) associated with such ARB may in some cases “survive” disinfection and remain capable of disseminating resistance traits to downstream bacterial communities via horizontal gene transfer processes (e.g., natural transformation). Using a combination of culture-based assays and quantitative real-time PCR (qPCR), we have confirmed that ARGs in extracellular and intracellular genomic DNA of an antibiotic resistant [*Bacillus subtilis*] strain remain nearly 100% intact and capable of conferring resistance traits to non-resistant [*B. subtilis*] strains via natural transformation following treatment with disinfectants exhibiting negligible direct reactivity toward DNA (e.g., NH_2Cl , ClO_2), even at exposure levels far beyond those achievable in practice. In contrast, DNA-reactive disinfectants such as HOCl, O_3 , and UV_{254nm} light are capable of degrading and eliminating the transforming activity of ARGs under practical conditions. Following exposure to each disinfectant, measurements of residual ARG transforming activity generally correlate well with qPCR measurements for amplicons of sufficient size (~800 bp) and base content to accurately capture damage capable of yielding elimination of ARG transforming activity, suggesting that qPCR analyses alone may be sufficient to confirm elimination of ARG transforming activity during the use of such disinfectants in water and wastewater treatment. While this work primarily addresses engineered water treatment applications, the general approach applied here can also be adapted to characterize the fate of ARGs during exposure to commonly-used healthcare disinfectants, as well as during natural attenuation processes (e.g., solar irradiation) relevant to environmental aquatic systems.

Abstract Text

The occurrence of human and veterinary pharmaceuticals in the environment has been a subject of concern for the past two decades because many of these emerging contaminants have been shown to persist in soil and water. This concern has accelerated recently as improvements in analytical methods coupled with larger scale surveys revealed the broad range of apparently persistent pharmaceuticals that are cycling through our local wastewater-to-drinking water cycle. While recent studies indicate that pharmaceutical contaminants can pose long-term ecological risks, many of the investigations regarding risk assessment have only considered the ecotoxicity of the parent drug, with very little attention given to the potential contributions that metabolites and other transformation products may have. The scarcity of available environmental data on the transformation products of pharmaceuticals in the environment can be attributed to the difficulty in analyzing trace amounts of previously unknown compounds in complex sample matrices. However, with the advent of highly sensitive and powerful analytical instrumentation that have become available commercially, it is likely that an increased number of pharmaceutical transformation products will be identified and included in environmental risk assessment. This presentation will focus on the applications of liquid chromatography/ mass spectrometry on the analysis of pharmaceutical contaminants in the influent and effluent of wastewater treatment systems. It is also intended to provide specific strategies to facilitate identification of unknown contaminants in wastewater samples.

Abstract Text

Quantum Cascade Lasers (QCL) were first realized over 20 years ago at Bell Labs, yet the technology is just now starting to find commercial applications in analyzers and instruments. As a semiconductor technology producing mid-IR light of high spectral power density and radiance, the potential for compact, high power, high-resolution devices are promising. Tiny in size at the millimeter scale, these devices are fabricated from existing semiconductor processes that promise low costs in quantity. Despite their small size, low power efficiency (~1%), thermal management challenges, and mechanically driven external cavities used for wavelength selection represent challenges to their use in handheld devices. However, the technology continues to evolve and new approaches to wavelength tuning and power efficiency should make them viable candidates for handheld devices. In this paper we will review the current state of QCL technology and explore the future of these novel devices.

Abstract Text

The overall size of Laser Induced Breakdown Spectroscopy (LIBS) Instrumentation has been steadily shrinking over the last decade resulting in the introduction of several handheld units within the last two years. In designing any handheld instrument, trade-offs in features and functions must be made in order to accommodate the “handheld” size and form factor. We have carefully considered typical LIBS features including laser power/rep-rate, laser rastering, time-gating, spectrometer resolution/range, argon purge, data processing/OS and battery lifetime in the development of the SciAps LIBS handheld system. In this presentation, we will review those considerations along with the subsystem development paths followed to realize those requirements. Selected examples of collected data will be presented from a variety of sample types including some quantitative studies.

Abstract Text

X-ray fluorescence (XRF) spectrometry is a mature technology for elemental chemical analysis, dating from the early 1900s. Field portable XRF is a more recent development, a little more than 40 years old. The last two decades were signified by the rapid pace of development in handheld XRF analyzers, large isotope based two-component systems of the early nineties were replaced by the lightweight; X-ray tube based one-piece handheld devices. Small silicon detectors and miniature x-ray tubes combined with the modern microprocessor and battery technologies made this evolution possible. The latest major development was the introduction of silicon drift detectors around five years ago, which improved the speed of analysis and light element performance significantly.

It is estimated that more than 50 thousand of handheld XRF analyzers are presently used throughout the world. The majority of them is used for analysis and identification of metal alloys, but handheld XRF technology has become an important tool also in many other diverse applications ranging from ore exploration to screening toys for hazardous elements. Speed of a single analysis, which translates into a large number of tests, its non-destructive character and the economics of use, are key features that have made handheld XRF analyzer a tool of choice for so many applications.

Handheld XRF is today clearly a mature analytical method, but this doesn't mean that pace of development would have slowed down. In this presentation, we briefly review the evolution of handheld XRF and look at the science and technology of the latest generation of handheld XRF analyzers, their new applications and new analytical capabilities. In addition to ever improving analytical performance, latest technology provides smart connectivity and other new features in smaller and lighter package, making the handheld XRF technology more powerful and versatile analytical tool than ever before.

Abstract Text

Much of the miniaturization of handheld spectrometers has come from existing technology or laboratory instrumentation being shrunk to the size of an acceptable portable solution. Examples of this would be IMS, Raman, FT-IR, AFP, Chemiluminescence and Near-Infrared. Colorimetric Detection is well established as a manual technique but the application of making it Automated (without the use of the user's eye) for detection is rather new; especially the miniaturization and reliable detection utilizing a spectrometer with applied algorithms based on expected colorimetric reactions. It could be said that it is the automating of a chemist mixing chemicals to produce a calculated result. Colorimetric Detection has been around for many years and has undergone many iterations of development to keep up with the times and additions or variations of explosives, drugs, and other items of interest. Whereas other Handheld Spectrometers already have the semi-complete spectrum and require the library or instrumentation to be tuned to these molecules or signals, colorimetric spectrometers require a chemical reaction to be developed that creates a unique color but ignores other non-wanted items ie interferences from reacting in the visible or near visible color spectrum. Automating this is where the techniques and instrumentation become vital to the detection capability. Repeatability and chemical delivery are key and critical to making the handheld device reliable. The advantage of automated colorimetric technology is that the reaction is quite rugged and happens reliably and tolerates a variety of conditions and while it requires a finesse delivery of chemicals, the reaction is rugged and dependable allowing the Handheld automated colorimeter to be dependable and portable in many environments.

Abstract Text

Mass spectrometry is crossing the handheld chasm. Novel micro-scale ion-trap geometries have recently been demonstrated operating at pressures 3-4 orders of magnitude higher than conventional ion trap mass spectrometers, and these pressure regimes fundamentally alter vacuum pumping burdens enabling to self-contained MS systems weighing 2-4 pounds with continuous flow rates of >3 sccm. The theory and history of these micro-scale trap advances will be reviewed, along with recent engineering and performance achievements leading to the integrated handheld systems in the field today. Tradeoffs in performance, size and automation will also be reviewed in the context of results and examples from prominent high-throughput public/private safety applications.

Abstract Text

New drug applications (NDAs) and accelerated new drug applications (ANDAs) require the applicant to provide acceptable analytical methods to assay the product for the active pharmaceutical ingredient (API) and for related manufacturing impurities and degradants. Analytical methods need to be robust, accurate and suitable for use by the applicant and the regulatory agency. Method validation can be aided by the use of quality by design principles to demonstrate the robustness of the method. Commonly encountered reviewer observations regarding validated methods submitted to the U.S. Food and Drug Administration will be discussed.

Abstract Text

Bioanalysis provides critical data for toxicokinetic, pharmacokinetic and pharmacodynamics studies. The demand for reliable bioanalytical methods continues to grow as a result of changing regulatory requirements and the desire to improve pharmacokinetic-pharmacodynamic predictions in humans. In addition, the challenges are ever increasing as there are an increasing number of peptide and protein drug candidates which require more bioanalytical resources. LC/MS/MS is still the most widely used technique to quantify small molecule compounds in biological matrixes and is gradually supplanting ligand binding assays for quantification of some peptide and protein drug candidates due to increased selectivity and dynamic range.

We have been working to develop processes that can be implemented to support GLP methods for small and large molecules. We have automated sample processing for both types of analytes using protein precipitation, solid phase extraction, liquid-liquid extraction and immunoaffinity purification. In addition to sample processing, we have improved post acquisition processes through implementation of electronic notebooks and new tools to automatically generate validation and bioanalytical reports. We have streamlined a drug candidate method development process to leverage knowledge from discovery methods that could then be applied toward development of robust methods for the support of preclinical (GLP) and clinical studies.

We will present an overview of the current state at our department and provide examples of challenges we faced along the way: adsorption of peptides during sample processing, accommodating different sample preparation methods into a single robotic method, and ensuring method ruggedness for small and large molecule analyses.

Abstract Text

Febuxostat is a novel non-purine selective inhibitor of xanthine oxidase (XO), which is used for the treatment of gout. In the present study, a rapid and sensitive liquid chromatography-tandem mass spectrometry (LC-MS/MS) method for simultaneous determination of febuxostat and its three active metabolites, hydroxylated febuxostat 67M-1 and 67M-2, carboxylic acid 67M-4 in human plasma has been developed and validated for the first time. After addition of internal standard (IS) losartan, plasma samples were pre-treated by one-step protein precipitation with methanol. Febuxostat, three metabolites and the IS were separated on a ZORBAX SB- C18 column (50mm×4.6mm, 5µm) using gradient elution with a mobile phase consisting of acetonitrile, water and formic acid. Detection was performed on a triple quadrupole tandem mass spectrometer by selective reaction monitoring (SRM) mode to monitor the precursor-to-product ion transitions of m/z 317 → 261 for febuxostat, m/z 333 → 261 for 67M-1 and 67M-2, m/z 347 → 261 for 67M-4 and m/z 423 → 207 for I.S. respectively using a positive electrospray ionization (ESI) interface. The total run time was about 12 min per sample. The method was validated over the concentration range of 10–20,000 ng/mL for febuxostat, 1.0–270 ng/mL for 67M-1 and 67M-2 and 0.8–250 ng/mL for 67M-4 respectively. The extraction recoveries of all the analytes at three concentration levels were consistent. The intra-day and inter-day precisions of the investigated components exhibited an RSD within 14.7%, and the relative errors ranged from 4.3% to 5.1%. The proposed method has been successfully applied to a clinical pharmacokinetic study of febuxostat in Chinese volunteers after oral administration of a single dose of febuxostat at 40, 80 and 120 mg.

Abstract Text

Drug metabolite detection and characterization are an integral part of the drug discovery and development processes. High resolution mass spectrometry (HRMS) has emerged as the primary analytical tool for metabolite identification during the evolution of LC/MS technology in the past decade. In addition to the advances of HRMS instrumentations, newly introduced data acquisition and data mining algorithms made it happen. The metabolite identification process by HRMS usually involves three steps: (1) data acquisition to collect full MS and MS/MS spectra of metabolites, (2) data mining to find metabolite ions and retrieve their MS/MS spectra from acquired datasets, and (3) data interpretation for metabolite structure assignment. Selective detection of minor or trace amounts of metabolites in the presence of high levels of background noises and endogenous components is a challenging task. Furthermore, detection of totally unknown drugs, metabolites and other xenobiotics in complex biological systems is even more challenging. In this presentation, advantages and limitations of various data acquisition and data mining tools in analysis of totally unknown xenobiotics will be compared. Examples will be illustrated to demonstrate of the effectiveness of background subtraction and metabolomic approach. Future application of these technologies to the detection of various xenobiotics, such as herbal medicines, designer drugs, abused drugs and environmental components will be discussed.

Abstract Text

A new and aggressive focus on medicine – personalized – is emerging. Prevention and early diagnosis of disease appear to be the straightforward path toward accurate and efficient healthcare. Early detection of disease will lead to earlier treatment and followed by a response-guided medication regiment that will lead to more effective treatment. The unique opportunities for analytical technology to enable personalized medicine via early detection and response-guided medication appear to have relevance in for laboratories that require high throughput drug analysis. Recent experiences and perspectives, derived mainly from the clinical laboratory environment, will be shared in order to describe unique workflows that feature: fully integrated and automated platforms from sample handling to information out; no sample preparation; no reagent preparation; pre-validated and optimized analytical methods that require little-to-no training; and laboratories filled exclusively with FDA approved analyzers. Specific examples will be presented to demonstrate how analytical platforms such as a mass spectrometer can be transformed into a clinical analyzer – the molecular microscope and molecular plate reader – to enable unprecedented levels of high throughput drug analysis, and perhaps, the future of personalized medicine.

Abstract Text

A clear understanding of the absorption and metabolism of a traditional Chinese medicine (TCM) is very important in its clinical use and pharmacological research. To find more of the absorbed constituents and metabolites of a TCM, a novel strategy was proposed. This strategy consisted of three steps, including (1) the construction of a digital library of PRR, which included the parent compound database, the known metabolites database, the characteristic neutral losses database, (2) searching the absorbed constituents and metabolites by comparing the extracted ion chromatograms (EICs) and base peak chromatograms (BPCs) of the test group with those of the control group and collected the related information, and (3) the identification of absorbed constituents and metabolites. The absorbed constituents and known metabolites were identified with the digital library described above. The unknown metabolites were elucidated in several steps: first, the conjugation type was identified according to the characteristic neutral losses in MS; second, the skeleton structure was elucidated by querying the CAS Registry and other bioinformatic tools using the molecular formula; third, the proposed structure was further confirmed by MSn fragment ions and maximum UV absorption; and finally, the exact conjugation site was determined for some metabolites based on the ClogP and predominant conjugation site.

This strategy was first applied to screen and identify the absorbed constituents and metabolites of a commonly used TCM Paeoniae Radix Rubra (PRR) decoction and paeoniflorin in rats. In total, 13 new absorbed constituents and 90 new metabolites of PRR decoction were detected. Among these metabolites, the structures of 70 metabolites were identified, and the conjugation types and structure skeletons of the other 20 metabolites were preliminarily determined. These findings enhance our understanding of the metabolism and Effective forms of PRR decoction and paeoniflorin.

Abstract Text

Hepcidin is a 25-amino acid peptide hormone with 4 cysteine bridges. It is produced in the liver to regulate iron homeostasis. Hepcidin is excreted to urine during chronic renal inflammation because of incomplete or impaired reabsorption. The level of urinary hepcidin-25 has been identified as a potential biomarker for kidney damage in previous reports. Because of the structural similarity between hepcidin and its metabolites (hepcidin-20, 22 and 24), an LC-MS assay would easily provide better specificity than a ligand binding assay. In this work, a sensitive and robust LC-MS/MS assay has been developed and validated to measure hepcidin in human urine over the concentration range of 0.5 to 500 ng/mL. Special procedures have been used to overcome challenges such as matrix effect, absorption and carryover that were encountered during the assay development and validation. The assay has been validated to support clinical research.

Abstract Text

It is well-known that transporters play a vital role in the ADMET profile of many drugs. Because of this, it is necessary to develop and implement panels of relatively high-throughput (HT) transporter inhibition assays to screen for potential liabilities earlier in drug discovery in an effort to inform lead chemotype selection. Using a 384-well format, these inhibition assays can be conducted in freshly-plated cryopreserved cell lines and/or vesicular systems expressing the transporter of interest. Currently, many of these assays use microplate-based scintillation counting to assess probe substrate transport, but in order to reduce the cost and waste streams associated with using radiolabelled drug substrates, a MS-based solution is necessary. Analysis with traditional LC-MS/MS allows the use of clinically-relevant probe substrates to assess compound inhibition of transporter activity, but typically does not offer the throughput needed to support the high sample volumes associated with an early liability screen.

One solution for improving throughput is to couple SPE with MS detection using a RapidFire™ (RF) system. By using ultrafast RF analysis, it is possible to easily support multiple transporter inhibition assays in early drug discovery. Hepatobiliary transporter inhibition assays have been developed for OATP1B1 and NTCP using the RapidFire platform. RF methods are inexpensive when compared to radiolabeled assays and are much faster than traditional LC-MS/MS methods, yet demonstrate similar sensitivity, selectivity, reproducibility, linearity and robustness. Validation with reference compounds demonstrates that these assays are robust, reproducible, and generate data consistent with literature, LC-MS/MS, and radiometric values. Implementing this type of HT-assay panel may facilitate informed clinical candidate selection and could establish a foundation upon which one can build a better understanding of the role that transporters play in ADMET biology.

Abstract Text

Differential mobility spectrometers provide characterization and separation of gas ions derived from sample vapors based on field dependent mobility coefficients between 10 to 150 Townsend at ambient pressure in air. In a tandem configuration, DMS analyzers can be used to transmit ions selectively through the analyzer according to field dependent behaviors described in dispersion plots, or plots of ion current, compensation field, and separation field. Since ions exhibit field dependent mobility with distinctive dispersion plots, one combination of separation and compensation fields will filter or remove all ions in a DMS stage except those with a favorable match in differential mobility to the two fields. In purified air at 1 to 100 ppm moisture, field dependences can be significant between 50 to 150 Td and two DMS stages can remove all ions except those with favorable matches to two combinations of separation and compensation fields. Since filtering occurs based on non-linear dependences of mobility with separation fields, the tandem DMS detector is more than a sequential filter and holds implicit selectivity rooted in hydration of ions. Response in the tandem DMS begins with chemical ionization processes which are simplified by chromatographic pre-separation and the tandem DMS provides a measure of selectivity not attainable with single stage mobility detectors and with theoretical response times of ~10 ms. The addition of either ion fragmentation or vapor modifiers between the first and second DMS stages can provide a further level of selectivity for targeted substances.

Abstract Text

Ion mobility techniques (IMS, AIMS and DMS) share simplicity, high speed, and a broad range of scientific and analytical capabilities for detection of trace individual chemicals in mixtures. Nevertheless experience shows that analytical power of standalone mobility based instrument's is insufficient to satisfy current, enhanced requirements when they used in harsh environment conditions, e.g., airport, shopping malls and subway systems. In such environments, the false alarm rates of the ion mobility analyzers become too high, due to the presence of numerous interferences in the raw, real-world samples. One of effective ways to enhance the performance of analysis is to add orthogonal chemical characterization by combining the other well developed analytical methods to ion mobility measurements. Integrating two orthogonal physical-chemical views of analyte and interferences usually enhances the analytical performance of the combined system. According to its principle of operation, the DMS sensor can operate in two regimes: a) as a spectral detector and/or b) it can be used as a tunable non-distractive ion pre-filter for selection of specific ion species. This provides flexibility to build different hyphenated systems on the basis of DMS with many analytical systems.

In this talk, we will overview and present descriptions and analytical characterization of existing hybrid systems which were developed, tested, and produced on the basis of a planar DMS design sensor. These are the following hyphenated systems: a) GC-DMS, b) DMS-AIMS, DMS-DMS, DMS-IMS2, and DMS-MS. The current prototypes have high sensitivity (ppb level) and enhanced robustness for operation in field conditions for a wide range of chemicals including CWA simulants, explosives, TICs and TIMs, and environmental pollutants.

Abstract Text

Environmental monitoring for manned spaceflight has long depended on archival sampling, which was sufficient for short missions. However, the longer mission durations aboard the International Space Station (ISS) have shown that enhanced, real-time monitoring capabilities are necessary in order to protect both the crewmembers and the spacecraft systems.

Over the past several years, a number of real-time environmental monitors have been deployed on the ISS. Currently, volatile organic compounds (VOCs) in the station air are monitored by the Air Quality Monitor (AQM), a small, lightweight gas chromatograph-differential mobility spectrometer. For water monitoring, real-time monitors are used for total organic carbon (TOC) and biocide analysis. Presently, no information on the actual contaminants contributing to the TOC value is provided.

An improvement to the current state of environmental monitoring could be realized by modifying a single instrument to analyze both air and water. As the AQM currently provides quantitative, compound-specific information for VOCs in air samples, this instrument provides a logical starting point to evaluate the feasibility of this approach. The major hurdle for this effort lies in the liberation of the target analytes from the water matrix.

In this presentation, we will discuss our recent studies, in which an electro-thermal vaporization unit has been interfaced with the AQM to analyze target VOCs at the concentrations at which they are routinely detected in archival water samples from the ISS. We will compare the results of these studies with those obtained from the instrumentation routinely used to analyze archival water samples.

Abstract Text

Introduction: Under ideal circumstances the species that arrive at the detector during an ion mobility experiment represent the starting conditions. However, the presence of metastable species and solvating neutrals are experimental realities that result in deviations from the ideal. Despite these challenges, ion mobility-mass spectrometry (IMMS) systems represent a powerful tool to probe gas-phase equilibria and in some cases the thermochemistry of systems. This work details the experimental subtleties of implementing the Fourier transform IMMS experiment which eliminates the observation of reaction intermediates and simplifies spectral interpretation. Specifically, we demonstrate the utility of this approach to characterizing gas-phase ion clustering behavior with the standard DMMP and an unknown system using tributyl-phosphate (TBP).

Methods: Fourier experiments were conducted using an atmospheric pressure IMMS system operated at WSU. The drift tube of this system operates at a range of temperatures from 100–250°C with electric fields below 3Td. Following ionization using electrospray and a desolvation period, DMMP and TBP and ions were gated into the 23 cm-long drift tube connected to a TOF mass spectrometer. Following an experimental design analogous to Tabrizchi the drift gas was modified with neutrals using a custom drift gas inlet. Signal averaging experiments used gate pulse widths of 210 ns and analogous FT spectra were obtained by sweeping the ion gate frequency from 10–10,000 Hz over the period of 1s.

□

Preliminary Data: Serving as a thermometer ion the dimer of DMMP was observed in the IMS-TOF when the drift gas was modified with the neutral analyte. During the standard signal averaging mode a pronounced tail is traced between the monomer and dimer, however, under the FT-IMMS mode of operation these reaction intermediates are removed. Observation of the TBP dimer has been achieved and a detailed characterization of this clustering equilibria underway.

Abstract Text

Ion Mobility Spectrometry is the leading technology for trace detection to prevent unauthorized transport and use of dangerous materials to include explosives, toxic chemicals, illegal drugs and other forms of contraband. The primary complaint by users of IMS detectors, or any trace detection technology, is false alarms. By measuring the mobility to an improved accuracy of an order of magnitude, effective resolution of ion mobility spectrometers can be improved while maintaining high sensitivity without expensive hardware modifications.

Accurate and precise reduced ion mobility constants, K_0 , are being obtained for target compounds with accurate and precise measurements of temperature, pressure, electric field strength (voltage and ion drift distance), and drift gas water concentration in positive and negative ionization modes – precision and accuracy of measurements is an order of magnitude better than literature values. Parametric measurements are made using commercial NIST-traceable sensors. Ion mobility constants are determined using a new, precisely constructed, ion mobility spectrometer interfaced to a time-of-flight mass spectrometer. Accurate, precise ion mobility constants result in greater spectrum peak capacity and narrowing detection spectrum “windows” to reduce potential for false alarms – detection sensitivity is not affected. Narrow windows can be incorporated in fielded detection instruments using only software and firmware modifications, significantly less expensive than hardware modifications required to achieve similar results.

Details of the construction of ion mobility spectrometer, precision and accuracy of parametric measurements, and experimental methods will be described. Target compounds include TNT, 2,4-DNT, NG, EGDN, DMNB; chemical warfare agent simulants methyl salicylate (MES), dimethyl methylphosphonate (DMMP), thiodiglycol (TDG); proposed IMS standard analyte di-tert-butyl pyridine (DtBP).

Abstract Text

The growing interest in high resolution multi-dimensional separation is driving the development of advanced instrumental platforms that can directly handle complex samples. With the recent development of ambient-pressure high-performance ion mobility spectrometry (HPIMS), ion mobility separation alone offers meaningful analytical performance comparable to chromatography. In many on-site analytical needs, standalone IMS systems are used as an alternative to HPLC. When combined with HPLC as a detector, HPIMS can identify UV transparent compounds and offer a complimentary separation capability for coeluting compounds. The combination of HPLC-HPIMS delivers two dimensional separation based on orthogonal separating principles, providing a simple, low cost, compact analytical system to common analytical laboratories.

On the other hand, when HPIMS is coupled with mass spectrometry (MS), ion mobility spectrometry adds tremendous value to the analysis of species that were either previously may lead to undesirable, highly complex spectra. As ion movement within the IMS drift tube is governed by its size/cross-sectional area, effective separation of molecules with slight structural differences such as conformers, isobars, and isomers can be achieved. In order to maximize the advantages of this technology, we have developed, evaluated, and introduced an ambient pressure IMS device that readily integrates with the ion trap MS line of Thermo Scientific instrumentation (i.e. LTQ Velos, Orbitrap).

Abstract Text

Ion Mobility Spectrometers (IMS) are often used as trace detectors for explosives and can be found at many airports. The different time of flight of ions is used in order to differentiate between all kinds of explosives. Some military used explosives have nearly no vapor pressure and require special sampling methods. Therefore a thermal desorption unit is needed in order to vaporize explosive residues which have to be sampled by wipe pads in advance. In addition, higher operating temperatures in the detector are required. Many explosives are based on nitrogen-oxide compounds, which can be detected in the negative mode of the IMS. New peroxide based explosives, now often used in terrorist attacks due to their simple manufacture, have a much higher vapor pressure and have to be detected in the positive mode of the IMS. A new double tube IMS was developed in order to detect positive and negative ions simultaneously. IMS systems at airports are used without any pre-separation. A very fast analysis is possible, but the identification of the explosives is sometimes difficult and even more problematic are false alarms. This is why different detection technologies are often combined in order to gain selectivity. Another fast and selective technology is Raman spectroscopy. Especially the surface enhanced Raman spectroscopy (SERS) is a suitable detection technology because of the low detection limits, similar to IMS. In Raman spectroscopy the identification of explosives is based on their molecular vibrations, which is an orthogonal technique to the IMS. Therefore, a novel approach based on a combination of IMS and SERS in one instrument for the simultaneous detection of all kind of explosives will be presented. The technology and first results will be discussed.

Abstract Text

Traditional time of flight Ion Mobility Spectrometers operate by making a measurement of the velocity with which ions generated from a sample travel through a linear electric field, typically 250 V/cm. The velocity with which an ion travels from an ion gate to a collector (a distance referred to as the “drift region”) is usually reported as the “reduced mobility”. The mobility of an ion is determined by its mass, its charge and its collisional cross sectional area. As such, ions generated from different compounds can be differentiated from one another based on the reduced mobility measurement.

Problems can arise when different compounds give rise to ions with very similar or identical mobilities, and the spectrometer is unable to distinguish between them. In order to eliminate the prospect of a false negative the spectrometer is usually programmed to alarm if any ion which matches the target compound mobility is detected. This subsequently can lead to false positive alarms.

☐

Ion Modification is a new technology which can be used to substantially reduce the likelihood of false positive alarms. An IMS which utilises Ion Modification technology incorporates additional electrodes within the drift region, upon which a high amplitude high frequency waveform can be applied. The waveform subjects the ions to an electric field vastly higher than the normal IMS field. Under these conditions, the energy of the ion/gas collisions are sufficiently high for chemical rearrangements to take place, such that new ions are formed. The new ions typically have a higher mobility than the parent ion.

☐

In the majority of cases, a modified ion from a target compound has a different mobility to a modified ion from an interferent. As such, activation of the ion modifier can lead to differentiation between compounds that otherwise could not be differentiated in a traditional IMS.

The technique has been shown to have utility in improving the detection of many classes of compounds.

Abstract Text

The ability to obtain accurate and reliable data is an essential aspect of scientific research. Recent trends have sought to minimize cumbersome and expensive instrumentation in efforts to free-up crucial laboratory space and finances. The Qubit[registered] quantitation platform is an inexpensive, versatile, and straightforward alternative to a benchtop fluorometer. Currently, the Qubit[registered] Fluorometer is used in conjunction with kits for the quantification of DNA, RNA, microRNA, and proteins. These quantitation kits provide unparalleled accuracy, sensitivity and selectivity for the target analyte in as little as 20 minutes. The Qubit[registered] programs utilize an algorithm that, after a quick 2-3 point user calibration, directly reports data in terms of concentration. To expand the breadth of the Qubit platform, we have recently established application notes for cholesterol and glucose detection. The programs for these detection assays can be easily uploaded to the Qubit[registered] instrument using a USB drive. Both assays combine the resiliency of Amplex[registered] Assay kits offered by Life Technologies with the ease of use offered by the Qubit[registered] Fluorometer. Using the MyQubit software and web tool, we have established several additional Qubit[registered] assays that utilize existing Amplex[registered] Assay kits, as well as other popular detection assays. Here, we will highlight the user-friendly nature of the "create-your-own-app" format and outline how any user can convert their detection method to an intuitive Qubit[registered] assay. Overall, we will demonstrate how the Qubit[registered] platform is a cost-saving replacement for a traditional benchtop instrument that has the versatility to work with any fluorescence detection scheme.

Abstract Text

The general benefits of working at higher than ambient temperature, including shorter analysis time, higher efficiency and lower column and system pressures, equally apply to the separation of low- and high-molecular mass compounds. In this presentation we will examine the impact of working at elevated temperature on the retention of globular proteins, monoclonal antibodies and peptides during the lifecycle of columns packed with 3.4 micron, 400 angstrom pore size, C4 alkyl-bonded, superficially-porous particles. Short 2.1mm ID columns were subjected to aqueous acetonitrile/trifluoroacetic acid mobile phase gradients at temperatures up to 90 °C for 15-60,000 column volumes, during which repeated injections of protein and peptide standards were made. Our findings suggest that at 75-90 °C the columns last longer for the analysis of globular proteins and monoclonal antibodies than for peptides in terms of the stability of retention time, while efficiency and peak shape were not or only minimally impacted. While a modest decline in retention time was observed for proteins, peptides showed a more pronounced loss of retention during long term gradient operation, a result that is expected by differences in their gradient steepness parameters. At 35 °C we did not observe a decline in retention time, nor were peak shape and efficiency impacted for any of the biomolecules studied. The results of our studies illustrate the importance of optimizing temperature when performing biomolecule separations and will prove beneficial to analysts who are tasked with finding optimum conditions for the separation of proteins or peptides during drug development and biomarker research.

Abstract Text

Monoclonal antibodies (mAbs) are the most prominent class for protein therapeutics because of their high specificity, excellent biocompatibility and effectiveness against autoimmune disorders, cardiovascular diseases, infectious diseases, and cancer. The proliferation of monoclonal antibody therapeutics and their susceptibility to various biochemical modifications has highlighted the importance of characterizing these highly heterogeneous products for their safety and efficacy.

Hydrophobic interaction chromatography (HIC) is a technique for separation of proteins including monoclonal antibodies, and has been widely used as an orthogonal method to size exclusion chromatography and ion exchange chromatography for analysis of mAb and related substances, such as succinimides, fragments, oxidants, C-terminal lysine modification, and drug conjugates, to monitor the stability and potency of the drug.

Here we introduce a new family of HIC columns designed for mAb analysis. They exhibit desired and complementary selectivity, excellent recovery, high efficiency, and chemical stability. The effectiveness for mAb separation has been demonstrated by examples including antibody-drug conjugates (ADCs), antibody fragments, oxidized mAb, PEGylated mAb, antibody aggregates and fusion protein.

Abstract Text

In this study, a relatively simple workflow for confident identification of compounds was developed and tested on a variety of cannabis samples. Analyses included a combination of complementary hard and soft ionization methods coupled to high performance time of flight mass spectrometry, as well as, effective data processing for characterization of samples. In general, GC-TOFMS profiling of materials was an effective way to determine the relative concentration of active components, as well as, characterize anthropogenic materials in cannabis samples. Instrumental analyses were fast, reproducible and provide excellent chromatographic resolution. High resolution time-of-flight mass spectrometry (HRT) resulted in additional benefits such as robust formula determinations for fragment, quasi-molecular and adduct ions, as well as, increased selectivity that resulted in reduction of background interferences. HRT data acquired over a large mass range was probed multiple times via targeted or untargeted processing methods. Data were searched against well-established nominal mass libraries (e.g., NIST 14, Wiley 10) to facilitate confident identification of components. These results were corroborated using formulae generated from the high resolution, accurate mass data (< 1 ppm). Where possible, standards were analyzed for unequivocal confirmation of chemical formulas and their proposed structures.

Abstract Text

Exposure of DNA to oxidative stress is responsible for the formation of 8-oxo-7,8-dihydro-2-deoxyguanosine (8-oxodG). 8-oxodG is genotoxic and can cause cancer. It is considered to be the biomarker of oxidative stress. In this current research work a new immobilization approach has been developed for the fabrication of ECL sensors for oxidative DNA damage. Composite films containing Os(bpy)₂phen-COOH-Nafion-Graphene (OsNG) were assembled by drop casting on the pyrolytic graphite to develop sensors that selectively detect 8-oxodG in intact ds-DNA. The stability and reproducibility of the composite films were investigated. The electrochemistry and electrochemiluminescence (ECL) of composite films containing OsNG were also studied using sodium oxalate as a co-reactant on a pyrolytic graphite electrode. A hydrophobic cation like Os(bpy)₂phen²⁺ could be easily incorporated into the hydrophobic nafion films, however the uptake rate of Os(bpy)₂phen²⁺ was observed to be relatively slow. Immobilization of graphene on the electrode resulted in the high peak current and ECL intensity of Os(bpy)₂phen²⁺, which could be due to the greater accessibility of the ion exchange sites in the composite film, hence leading to a faster rate of diffusion of Os(bpy)₂phen²⁺ in the films. Sensor arrays were fabricated on the graphite electrode using a print and peel method. OsNG composite and the oxidized DNA films were assembled on these arrays and were finally housed in a microfluidic device, which was used to detect DNA oxidation caused by Fenton's Reagent. This simple approach could further be used to detect Copper-mediated oxidative DNA damage caused by metabolites of pollutants and drugs.

Abstract Text

While liquid chromatography is the most common liquid separation technique for hydrophobic analytes, nonaqueous capillary electrophoresis (CE) has advantages for some analyte classes including better separation quality, quicker separation times, and more economical use of samples and solutions. Nonaqueous CE can be coupled with mass spectrometry, and moving the separation to a microfluidic chip can further enhance the speed and quality of separations. In this study, a fully nonaqueous separation buffer system is used for high quality separations of phospholipids. This separation buffer is then used on an electrospray ionization microchip electrophoresis device for coupling the liquid separation to mass spectrometry. Initial work focused on developing a proper buffer system for nonaqueous CE of phospholipid standards. Surprisingly, N-methylformamide (NMF) shows substantial solvation ability and electroosmotic flow, even in the absence of supporting electrolyte. Electrophoretic separations on a microchip were performed with fluorescently labeled phospholipids yielding a baseline separation of a quaternary lipid mixture with a full separation in less than two minutes. Coupling of the microchip electrophoresis separation with electrospray ionization mass spectrometry is accomplished using a second make-up flow channel prior to electrospray at a monolithically integrated electrospray tip. Currently, the coupling of the separation and ESI is being optimized for high quality separation with mass spectrometric, label-free detection of lipid species from NMF. Further work will target biological fluids to detect and quantify known lipid disease biomarkers and discover new potential disease biomarkers.

Abstract Text

In critically ill patients, life-threatening changes of vital conditions may occur within seconds. Some of these changes translate into breath VOC profiles. Non-invasive real time monitoring might become possible when breath resolved determination of VOCs could be realized through direct mass spectrometry.

Breath from 12 mechanically ventilated patients was analyzed continuously by means of PTR-ToF-MS during one hour immediately following cardiac surgery. For safety reasons, a 6m long heated silicosteel transfer line was used for breath sampling.

Through optimization of operational parameters a time resolution of 200ms could be realized for PTR-TOF measurements. Thus, breath resolved detection of more than 300 mass traces was possible without interference with mechanical ventilation and without need of additional equipment. Identification of alveolar and inspiratory phases was performed by a custom-made algorithm. Detection limits (for continuous monitoring) were in the low ppbV / high pptV range. Exogenous contaminants (anesthetics, disinfectants) could be identified by comparison of breath phases. Analyzing specific markers, representing aspects of metabolism (acetone), cardiac output dependency (isoprene) or oxidative stress (aldehydes) we were able to monitor (patho)physiological processes non-invasively. During a lung recruitment maneuver isoprene concentrations decreased by 52% whereas PCO₂ only decreased by 13%, acetone decreased by 26%. After lung recruitment acetone had decreased by 14 %, whereas isoprene and CO₂ increased by 4% and 9%.

Continuous VOC monitoring by PTR-TOF enables immediate recognition of physiological or therapeutic effects in ICU patients. In a perspective non-invasive real-time monitoring of breath biomarkers may act as tool to observe patients' clinical conditions.

Abstract Text

Ion-selective electrodes (ISEs) and reference electrodes (REs) are used to determine the concentrations of target ions in sample solutions. Recently, paper-based potentiometric sensors with conventional ISEs and REs have been developed to detect the concentrations of various ions (K^+ , Na^+ , Ca^{2+} , and Cl^-). In this work, we simplify the design by using all-solid-state ISEs and REs to replace conventional electrodes and fabricate a paper-based all-solid-state potentiometric ion-sensing platform. This ion-sensing platform contains an ion-selective membrane and a reference membrane, both doped with a well-defined redox couple and contacting with colloid-imprinted mesoporous carbon as solid contact. With these devices, no external reference solutions are needed and sample volumes as small as one droplet can be achieved, which greatly simplifies the operating procedures and minimizes human errors. Furthermore, these miniaturized sensors are portable, disposable and inexpensive, making them promising commercialized ion sensors for clinical analysis.

Abstract Text

Detection and quantification of biological material is integral to biomedicine, clinical diagnostics and forensic science. We have previously developed a label-free DNA detection modality through bead aggregation, which has been firmly established at previous conferences[1,2] and in two recent seminal papers[3,4]. The dual-force aggregation (DFA) system allows for the multiplexed, rapid detection and quantitation of non-specific DNA via chatrope-driven aggregation (CDA). The purpose of this research is to adapt and demonstrate the capability of the DFA system in clinical (cell counting) and forensic (buccal swabs and rare samples) applications.

Here, we show that the DFA system and CDA provide a simple, rapid, and accurate method for white blood cell (WBC) counting. The number of cells in a sample can be obtained by back calculating from the DNA concentration that is determined from the degree of bead aggregation. To date, in a comparison with traditional WBC counting methods, the DFA system provided accurate WBC counts within an average of 430 cells/ μ L and a median of 197 cells/ μ L of clinical values in less time, with only 10 μ L of whole blood.

In addition to clinical applications, we have applied the system to buccal swab and rare blood sample analysis for forensic applications. With a newly adapted extraction procedure, DFA has shown effectiveness in quickly, and accurately, quantifying buccal samples prior to STR analysis. Further, the newly improved sensitivity of the DFA method[4] shows promise quantifying and extracting rare blood samples from fabric and other materials.

Abstract Text

A fully integrated, small surface plasmon resonance (SPR) sensor has been developed for the therapeutic drug monitoring (TDM) of methotrexate (MTX) levels in actual clinical samples. The SPR instrument is based on the wavelength interrogation configuration with sequential lighting of the measurement channels. We have implemented a novel method with this instrument which provides direct readout of MTX concentrations in patient's serum on a SPR sensor. The developed method consists of employing folic acid functionalized gold nanoparticles (Fa-AuNP) in competition with MTX for a specific number of its targeted enzyme, human dihydrofolate reductase (hDHFR) immobilized on the sensor surface. The sensor was calibrated with spiked MTX samples in a pool of serum from healthy patient, providing a model to mimic real clinical samples analysis. Nonspecific adsorption from serum components has been reduced by an anti-fouling peptide monolayer. Preliminary data with actual clinical samples from a local hospital shows good agreement between the SPR method and LC-MS/MS and Fluorescence Polarization Immunoassay (FPIA). Ultimately, our work will focus on integrating our SPR based sensing platform for rapid and direct analysis of sera MTX levels in patients under chemotherapy in hospital laboratories. We also demonstrate that the SPR instrument is suited for monitoring ligand-receptor interaction in drug design, to identify pheromones and to quantify hormones.

Abstract Text

Atmospheric Methane is one of the key greenhouse gases for global warming. The urban methane concentrations are influenced by the anthropogenic emission of methane that originates from livestock, landfills, rice paddy fields, energy production and sewage treatment.

The challenge in accurate monitoring of the atmospheric methane using infrared absorption based techniques are the low detection limit requirement and selectivity in the presence of varying concentrations of water. In the proposed solution tunable quantum cascade laser source operating at the mid-infrared range is combined with cantilever enhanced photoacoustic detection scheme [1] [2] [3] . This achieves ppb-level detection limit and high selectivity due to the possibility of performing measurement at lowered pressure.

The conclusion of the suitability of the tunable quantum cascade laser combined with cantilever enhanced photoacoustics in monitoring the atmospheric concentrations of methane in the presence of interfering gas components and changing ambient conditions will be presented based on the measurement results and user experience.

Abstract Text

Carbon Capture and Storage (CCS) technologies aim to reduce the release of greenhouse gases (especially CO₂) generated from fossil fuel combustion. Air Liquide is a key contributor to the evolution of such CCS technologies in the field of oxycombustion, actively participating in collaborative projects for the development and improvement of CO₂ Compression and Purification Units (CPU). Reliable analysis of the impurities through the whole process plays a key role to demonstrate the capabilities of oxycombustion. A mobile laboratory featuring analyzers for all major flue gas components and key impurities has been designed and installed at the Callide Oxyfuel demonstration site and connected to more than twenty different sampling points on the CPU. Different types of analyzers such as multi-component analyzers based on NDIR, FTIR and chemiluminescence were used to determine the effluent compositions at different steps in the process.

The CPU installed at the Callide power station has been operated since Q4 2012 (currently more than 3500 hours of operations) and has been optimized in order to improve plant reliability. Data were collected during two analytical campaigns (2013 and 2014) to evaluate the CPU performances. The results have been used in data reconciliation models and helped to better understand the process to further improve subsequent demonstration designs.

This presentation will illustrate the complexity of impurity measurements in CO₂ rich streams with results from the test campaigns carried out in 2013 and 2014 at the Callide Coal-fired power station (Queensland, Australia).

Abstract Text

Aqua sphere is threatened by both organic and inorganic pollutants. Adsorption of pollutants on activated carbon is one of the various successful remediation processes. Activated carbons produced from various raw materials are usually selective for any one type of pollutants. This study focuses on activation processes that can prepare activated carbon from a single substrate which is selective for both types of pollutants. Three types of activated carbons were produced from the same substrate and compared with the commercial activated carbon (CAC) for adsorption properties. AC – 01 was prepared by treating raw material with sulfuric acid at 250°C, treatment of AC – 01 with aqueous NaOH yield AC - 02. Heating AC – 01 at 850°C in an inert environment produced AC - 03. Lead(Pb), cadmium(Cd), methyl blue(MB) and xylenol orange(XO) were selected pollutants for this study. It was observed that activated carbon produced at high temperature was selective for organic pollutants whereas low temperature activation yielded carbon selective for inorganic pollutants. Trend of percent removal for CAC was XO (99%) > MB (90%) > Cd (20%) > Pb (11%). The trend for AC – 03 was XO (18%) > MB (35%) > Pb (13%) > Cd (4%). Adsorption trend was reversed for AC – 02 that is XO (2%) < MB (13%) < Pb (93%) < Cd (93%). For AC – 01 the respective percent removals were XO (0%) < MB (5%) < Cd (38%) < Pb (79%). A blend of produced activated carbons can be effective for removal of both types of pollutants.

Abstract Text

Historically, infrared (IR) spectroscopy methods were widely used for quantifying oil, grease and hydrocarbons in water samples. Infrared spectroscopy allows for fast and easy measurement of these types of samples. Various IR methods were used globally according to local regulations or protocols. Prior to the Montreal Protocol in 1989 prohibiting the use of chlorinated solvents, most of the IR methods involved the extraction of hydrocarbons in water samples used carbon tetrachloride, CCl₄, as the extraction solvent. Alternative methods were required to replace these methods, with many laboratories moving away from IR methods. Some of these methods, such as EPA 1664, still use hazardous solvents for the extraction of hydrocarbons from water samples, prior to gravimetric measurement.

A solvent-free IR method, ASTM D7575, is presented that uses an IR-transmitting membrane material that will extract and retain the hydrocarbon species as a known quantity of water sample is passed through it. The membrane is contained with a filter extraction device, called the Extractor, which has a standard Luer lock fitting for processing water samples through the membrane. After the sample is processed, the membrane is then dried by using compressed dry air. Once dry, the Extractor device is placed directly in the IR beam of the spectrometer and the hydrocarbon content determined based on a set of hydrocarbon calibration standards. The paper describes the development and implementation of a workflow to simplify the analysis process, will show examples of measurements, and also highlight some of the significant advantages of this method for this type of analysis.

Abstract Text

The determination of sulfide and cyanide is of great importance in various samples ranging from environmental, food, chemical, pharmaceutical, food to clinical samples. Due to extremely high toxicity, many worldwide regulatory organizations set their maximum contaminant levels for cyanide and sulfide at very low concentrations. To determine the concentration of cyanide and sulfide accurately and precisely at single low ppb, it is required to develop a reliable analytical method with a limit of detection at sub-ppb levels and free from matrix interferences.

In this paper, we discuss methods in which sulfide and cyanide are separated by using anion-exchange columns and detected by pulsed amperometric detection (PAD) with a thin-film disposable silver working electrode. The advantages of a new separation method using Thermo Scientific Dionex IonPac® AS7 columns and eluents containing oxalate in combination with low concentration of hydroxide and ethylenediamine (EDA) are presented. The possible interference of other species, such as halogens, thiocyanate, thiosulfate and transition metals are discussed and evaluated. Also discussed is the analytical performance of the PAD detection method using the disposable silver electrodes. The new method provides detection limits of 0.1 ppb for sulfide and 0.2 ppb cyanide using a 25 µl injection volume. Calibration plots for sulfide and cyanide are linear from their respective detection limits up to 1,000 ppb. Reproducible long-term performance is demonstrated using repetitive injections of low concentration of sulfide and cyanide.

Abstract Text

Global concern is growing over the amount of pollution in the atmosphere and the effect on human health. A major source of pollution is particulate matter (PM), solid or liquid particles suspended in the atmosphere. They have the potential for causing health problems in humans due to inhalation of the particles. The smaller the particles, the further they can get into the respiratory system. PM2.5 (particles less than 2.5 micrometers in size). is of particular concern and has been the subject of many health studies linking it to respiratory diseases and increased occurrences of lung cancer. The major sources of PM2.5 are industrial combustion, road transport (from diesel emissions), burning of fossil fuels and small-scale waste burning.

The reference method for measuring PM2.5 is a manual gravimetric method. Samples of PM are taken by pumping ambient air through a size-selective inlet followed by a filter. The concentration of PM is determined by measuring the change in mass of the filter before and after the sampling, and combining the result with the volume of air. Although this method is capable of measuring the total amount of PM2.5 it is not capable of identifying the chemical identity of the materials.

This paper describes the use of the technique of infrared imaging for the detection, identification and quantitation of the different chemical species present in the PM2.5, providing significant information in determining the source of the particulate matter.

Abstract Text

Wireless air quality networks have become more affordable in the last years. Low cost wireless technology has been matched with low cost gas sensors that are proving reliable at the ppb concentration levels- recent urban air quality networks have proven that the gas sensors have the required stability, selectivity and sensitivity. The missing requirement was a low cost particle monitor to report on PM1, PM 2.5 and PM10.

An Optical Particle counter (OPC) using a laser source has been used for many years in atmospheric chemistry studies of aerosols and particulates in the stratosphere and troposphere. This design was modified for the Heathrow project and recently commercialised for use in urban air quality networks such as the CITISense European project.

We discuss here results from recent urban air projects and laboratory validation of the OPC.

Laboratory validation at Manchester and co-location with AQMs at Cambridge provide us with quantifiable limits on PM and particle size distribution errors. Errors as particle count is translated into particle mass and errors in PM1 calculations will also be discussed.

Correlation of particulate results with CO, NO, NO2 and O3 concentrations gives more information than from any single or coupled measurements, with the fast time resolution telling more about local and background pollutants.

Abstract Text

This project involves constructing and characterizing a fluorescence spectrometer. An average fluorescence spectrometer consists of a light source, excitation monochromator, sample holder, emission monochromator, detector, and a computer and processor. This device is designed to be smaller and portable by eliminating some components from a commercial design. The schematic this fluorescence spectrometer includes a wavelength specific ultra violet LED, a 1mm inner diameter capillary as the sample holder, a wavelength specific photodiode as the detector, and microcomputer as the processor. This set up was characterized using a set of quinine standards. As this setup is wavelength specific, future plans include designing the instrument in such a way that both the light source and detector can be interchangeable or allowing for several sources/detectors to be available in a near simultaneous fashion. This would allow for the possible analysis of other controlled substances to be used for forensic field work, the analysis chlorophyll to be used for biology field work, the ability to monitor protein-protein interactions, and the analysis of various samples in the environment. Future plans also include using an iPhone/iPad application as the computer and processor in order to make the instrument completely wireless.

Abstract Text

Cerebral Ascorbic acid (AA) detection has become a hot topic in the biological and analytical sciences since AA not only act as a water soluble organic antioxidant protecting oxidative stress but also involve in enzymatic step as a cofactor and is a specific electron donor for enzymes during carnitine biosynthesis, norepinephrine biosynthesis, amidation of peptide hormones, and tyrosine metabolism. Many elegant methods that have been developed for detection of AA including. Compared with well-established HPLC or GC-MS assay, enzymatic method, capillary electrophoresis and electrochemistry approaches, fluorescence probes sensing ones have attracted rising attention due to their considerable research space and intrinsic advantages such as high sensitivity and selectivity and direct monitoring in live cells, tissues, and animals. Herein, we report a novel and efficient fluorescence probes synthesized by tris (tris(hydroxymethyl)aminomethane)-derived carbon dots (CDs)-modified hexagonal CoOOH nanoflakes (Tris-derived CDs-CoOOH) for monitoring of cerebral AA. The as-prepared Tris-derived CDs as the signal output are fabricated by one-step pyrolysis strategy, then hybridized with CoOOH nanoflakes to form the fluorescence probe Tris-derived CDs-CoOOH. The luminescence of the Tris-derived CDs can be efficiently quenched by CoOOH via Förster resonance energy transfer (FRET) and then by specific redox reaction between CoOOH with AA making high selective to detect AA. The Tris-derived CDs-CoOOH probe show a linear range from 100 nM to 20 μ M with the detection limit 10 nM and such high sensitivity makes it applicable for determination of cerebral AA in a rat brain.

Abstract Text

Whooping cough is highly contagious. *Bordetella pertussis* (*B. pertussis*), the pathogen that causes whooping cough and is considered life threatening to young children, has been at the forefront of the nation's attention due to the recent outbreaks. Current diagnostic methods for *B. pertussis* are slow (e.g. bacterial culture), or require expensive and bulky equipment (e.g. qPCR). Therefore, we developed a low-cost PDMS/paper hybrid microfluidic biochip (Figure 1) integrated with loop-mediated isothermal amplification (LAMP) for the rapid, sensitive and instrument-free diagnosis of *B. pertussis*. Paper placed in each LAMP zone of the hybrid biochip serves as a 3D substrate for preloading and protecting LAMP primers for the subsequent LAMP reaction. Based on the recovered fluorescence of calcein, the fluorescence indicator of LAMP detection, visual detection has been successfully achieved just by using a portable UV light pen. An instrument-free direct pathogen detection approach has been achieved avoiding the use of centrifuge or laborious sample preparation processes. The limit of detection of *B. pertussis* is about 5 copies per LAMP zone within 1 hour. This low-cost hybrid microfluidic biochip provides a simple but sensitive approach for rapid *B. pertussis* diagnosis, which has a great potential for point of care detection in resource-limited settings. Financial supports from the NIH and UTEP MRAP are gratefully acknowledged.

Abstract Text

Water-soluble conjugated polymers with unique structure have attracted much attention because of their good light-harvesting ability and signal amplification properties, which exhibits the broad applications in biosensor, diagnosis of pathogenic microorganisms and tumor cells, detection of disease-related biomarkers, cell-imaging, drug screening and delivery, photodynamic therapy, etc. Recently, we have devoted ourselves to the design and synthesis of water-soluble conjugated polymers and their applications in biosensors and biochemical analysis. A series of conjugated polymers have been synthesized, such as neutral water-soluble conjugated polymers PPP-OR10, cationic conjugated polymers PFPB, etc. The new biosensing mechanisms have been studied, and new analytical methods have been investigated for detection of enzyme activity, including adenosine deaminase, alpha-chymotrypsin, restriction endonucleases, etc. as well as real-time monitoring of the cleavage of ssDNA by S1 nuclease and phosphorylation of glucose by hexokinase. Our results indicated that these methods are sensitive, cost-effective, simple and rapid without any excess operation, such as separation, denaturation, further reaction, washing steps, etc. Furthermore, the studies are contributed to the WSCPs-based biosensor development, and provide new platforms for biosensors. In future, it is still promising to explore more novel applications by designing and synthesizing novel WSCPs.

Abstract Text

Multilayers composed of weak polyelectrolytes (PEMs) exhibit tunable properties making them ideal for use in applications such as drug uptake and selective delivery, separations, and water purification. In order to optimize devices for these applications, an understanding of mass and charge transport in PEMs is required. We have directly measured the interaction of monovalent ions with a multilayer of poly(acrylic acid) and poly(allylamine hydrochloride) and found it to be multimodal, pH tunable and charge dependent. Fluorescence microscopy and single molecule tracking were used to determine the presence of two primary transport modes: 1) adsorption, characterized by periods of immobilization in a subresolution region, and 2) diffusion trajectories characteristic of hopping ($D \sim 10^{sup}-9[/sup] cm[²[/sup]/s) likely due to intermittent surface interactions. Radius of gyration evolution analysis was used along with simulated trajectories to demonstrate the coexistence of the two transport modes in the same single molecule trajectories. For both anionic and cationic probe molecules, the hopping transport mode could be reversibly switched on and off by changing the solution pH. These results confirm the previously suggested hopping mechanism for the interaction of charged molecules with PEMs and offer insight into the role of electrostatics and nanoscale tunability of transport in weak polyelectrolyte multilayers. This work was funded by the National Science Foundation (CBET-1134417, CHE-1151647, and 1333651), the National Institutes of Health (GM94246-01A1), and the Welch Foundation (C-1787).$

Abstract Text

To self-assemble one-dimensional DNA building blocks into two- and three-dimensional nanostructures via DNA/RNA nanotechnology has led to broad applications in bioimaging, basic biological mechanism studies, disease diagnosis, and drug delivery. However, the cellular uptake of most nucleic acid nanostructures is dependent on passive delivery or the enhanced permeability and retention effect, which may not be suitable for certain types of cancers, especially for treatment in vivo. To meet this need, we have constructed a multifunctional aptamer-based DNA nanoassembly (AptNA) for targeted cancer therapy. In particular, we first designed various Y-shaped functional DNA domains through predesigned base pair hybridization, including targeting aptamers, intercalated anticancer drugs, and therapeutic antisense oligonucleotides. Then these functional DNA domains were linked to an X-shaped DNA core connector, termed a building unit, through the complementary sequences in the arms of functional domains and connector. Finally, hundreds (100-200) of these basic building units with 5'-modification of acrydite groups were further photo-cross-linked into a multifunctional and programmable aptamer-based nanoassembly structure able to take advantage of facile modular design and assembly, high programmability, excellent biostability and biocompatibility, as well as selective recognition and transportation. With these properties, AptNAs were demonstrated to have specific cytotoxic effect against leukemia cells. Moreover, the incorporation of therapeutic antisense oligonucleotides resulted in the inhibition of P-gp expression (a drug efflux pump to increase excretion of anticancer drugs) as well as a decrease in drug resistance. Therefore, these multifunctional and programmable aptamer-based DNA nanoassemblies show promise as candidates for targeted drug delivery and cancer therapy.

Time: 03:45 PM

Room: 264

Co-Author(s)

Abstract Text

Biochemists are investigating detection methods for biological samples such as protein and DNA. In this study, we have designed and synthesized three fluorescent molecular probes based on dansyl fluorophores; i) fluorescent molecule possessing both Zn(II) complexes and dansyl moieties for total protein electrophoretic analysis (Probe 1), ii) fluorescent oligonucleotides (ONTs) prepared from nonnucleoside amidite block of dansyl fluorophore to detect target DNA (Probe 2), iii) fluorescent reagent using FRET between cyanopyranyl group and dansyl fluorophore for the detection of proteins (Probe 3) to reduce the background fluorescence from dansyl group and achieve highly sensitive detection.

Probe 1, which produced strong fluorescence on the addition of proteins, allowed 1-step protein staining (SDS-PAGE Staining & Detection) and shortened the operating time (35 min) with high sensitivity (limit of detection: 1.0 ng or less). Fluorescence intensities of Probe 2 specifically increased by the presence of adjacent guanosine residues but, significantly reduced in a dansyl-flipping duplex with good linear relationship between fluorescence intensity and target DNA concentrations. These changes were caused by solvatochromism effect due to the number of guanine which is hydrophobic functional group and the external environment change around dansyl residue.

Fluorescence quantum yield of Probe 3 itself ($[\Phi] < 0.001$) was about 100 times lower than those of Probe 1 and Probe 2 due to the fluorescence quenching of dansyl group by cyanopyranyl group, whereas fluorescence intensity of Probe 3 increased upon binding to BSA ($[\Phi] = 0.49$). These phenomena demonstrated the highly sensitive detection of proteins (limit of detection: 0.1 ng on the electrophoretic gel).

These results proved that above three fluorescent probes could be useful for a convenient and highly sensitive detections of protein and DNA in biochemical and medical fields.

Abstract Text

DNA micelle flares are sphere-shaped DNA-lipid structures formed by hydrophobic interactions between the lipid tails coupled to single DNA strands. Compared to other sphere-shaped nucleic acids, DNA micelle flares have high cellular permeabilities and low critical micelle concentrations, making them potential carriers for cancer drugs. For this purpose, the particles must remain stable under various conditions dictated by the drug, such as low pH and in organic solvents. In this work, the basic properties of DNA micelles have been studied using fluorescence, static light scattering and UV-Vis detection for systematic investigations of enzyme resistance, complementary DNA binding affinity and micellar melting temperature. Additional studies have included measurements and comparisons of aggregation number and critical micelle concentration of micelles of different lengths. Results have shown that micelles have better enzyme resistance towards DNase I and Exo III compared to molecular beacons containing the same base pairs. The critical micelle concentration is below 5nM for all the micelles being tested and the aggregation number remains stable for micelles of different DNA lengths. The stability of DNA micelles in low pH conditions has also been verified.

Abstract Text

Determination of blood alcohol concentration (BAC) is one of the most common analyses performed within forensic laboratories. This analysis most commonly utilizes headspace sampling, followed by gas chromatography combined with flame ionization detection (GC-FID). Amongst the many instrumental parameters, helium has historically been the chosen carrier gas, largely based on convenience and the potential safety issues associated with Hydrogen. According to the Van Deemter Equation, hydrogen has proven to reduce run times due to its high diffusivity and high optimal linear velocity. A potential issue due to the emerging helium shortage, and increasing cost, has led to the evaluation of using hydrogen supplied through a generator system for application to this routine analysis.

The goal of this research is to investigate the differences in chromatography and efficiency of BAC determination when either helium or hydrogen is used as a carrier gas. Quality by design (QBD) will be implemented in order to determine the appropriate corresponding BAC instrumental parameters when converting to hydrogen as a carrier gas. This presentation will discuss the differences in efficiency between helium and hydrogen as applied to the Van Deemter equation, as well as their safety within this application. Additionally, resolution and overall chromatographic performance will be thoroughly discussed. Finally, the degree of uncertainty at the common threshold of 0.08 g/dL and method detection limits will be reported in order to determine a reporting threshold.

Abstract Text

Cellular fatty acid profiling is a valuable tool for identifying the species/strain of bacteria within a forensic sample as well as the culturing conditions used in the laboratory. However, traditional fatty acid analysis involves lysing the organism to extract membrane phospholipids. This often prevents other types of chemical or genetic analyses from being performed on the same sample. The goal of this study was to investigate extracellular fatty acid profiles as a forensic signature for *Bacillus* spores. Extracellular reservoirs can be extracted from the cell non-destructively thereby preserving the rest of the cell for other techniques. To test this, six strains of *Bacillus* organisms (*Bacillus cereus* T-strain, *Bacillus cereus* 14579, *Bacillus anthracis* 690, *Bacillus anthracis* 0517, *Bacillus thuringiensis* HD1 and *Bacillus thuringiensis* HD522) were cultured in three separate medium formulations: milk-digest, meat-digest, and yeast. Fatty acids from the cell surface were extracted in acetone, converted into fatty acid methyl esters, and profiled by GC-FID.

Results showed that the types and relative abundance of fatty acid structures on the spore surface could be used to determine the species/strain and the growth medium used to prepare an unknown *Bacillus* sample. Specific fatty acids were also unique to certain strains, aiding taxonomic characterization (e.g., 16:1 ω 6 in BtHD522). Distinct variation in 17:0anteiso, 14:0iso, and 17:1iso ω 3 markers was indicative of growth medium. Discriminant function analysis using these variables provided clear separation of nutrient source for each strain. These non-destructive methods could provide novel data streams during a forensic investigation while permitting further sample analyses.

Abstract Text

The US Environmental Protection Agency Method 8095 gives guidelines for the use of gas chromatography with electron capture detection (GC-ECD) for explosive residue analysis. There have since been advances that may increase sensitivity or detection. Previous gas chromatographic studies on explosives analysis focus on variables like column chemistry, inlet temperature, injection methods, & detector variability[1,2]. Amid these studies are none focused on effects of surface deactivation, inlet liner geometry or guard column length for the gas chromatographic explosive analysis. While studies mention using deactivated inlets the chemistry of this surface & inlet liner geometry hasn't been studied. Thus, a study on the combination of inlet geometry, stationary phase chemistry & guard column length is useful. The goal is to find more efficient chromatography parameters for explosives analysis. The main focus is optimization of deactivation chemistry applied to inlet liner geometry & columns. Determination of the ideal method for gas chromatographic analysis of explosives with improved sensitivity, especially with more thermally unstable analytes will be discussed. Ultra high purity liquid chromatography (UHPLC) with time-of-flight mass spectrometry (TOFMS) & direct sample analysis (DSA) with TOFMS will be used to decide if better selectivity can be obtained. Currently, ion mobility spectrometry is used but it has high false-positive rates[3]. Since TOFMS can be a highly selective method, we will discuss if LC-TOFMS & DSA-TOFMS is more selective & feasible as a reliable explosives testing device for law enforcement.

Abstract Text

Petroleum and petroleum-based products are ubiquitous and include, gasoline, diesel, kerosene, jet fuels, oils and lubricants – among others. Effective monitoring, measurement and analysis of these products are essential. One compound which has been difficult to determine in petroleum products is water. The water content affects the refining, performance and overall quality of the product. It also is considered a parameter that affects the purchasing/sale of these products. The complex matrix leads to many side reactions with traditional methods for water determination. For instance, in the Karl Fischer titration, the presence of sulfur containing compounds leads to an over estimation of water content. Other methods like loss on drying are difficult since it determines the mass of all volatile components and is therefore not specific to water. We have developed a sensitive, accurate headspace gas chromatographic method utilizing the novel dielectric barrier ionization detector for the determination and quantification of water. The water is chromatographically separated from any volatile compounds alleviating problems associated with complex matrices and other volatile components. This leads to a method that is rapid, precise and not affected by side reactions or matrix effects.

Abstract Text

Fossil fuels such as diesel fuel and jet fuel are some of the most important sources of energy in today's society. Both the performance and emission properties of these types of fuels are influenced by their group-type composition (i.e. saturates, mono-, di-, tri- and polycyclic aromatics). Since there is such a widespread use of diesel fuels government limits on the poly aromatic hydrocarbon content of diesel fuels are becoming increasingly stringent. ASTM: D5186-03 is a test method that determines the aromatic and polynuclear aromatic content of diesel fuels and aviation turbine fuels by supercritical fluid chromatography (SFC).

However, access to SFC instrumentation is increasingly difficult to obtain, while gas chromatographic (GC) instrumentation is commonplace. Furthermore, the the "bio" component of biodiesel does not necessarily elute quantitatively from the columns used in the SFC method. Previously, GC separations requiring multidimensional separations and/or mass spectrometric detectors (that give non-uniform responses) have been used to achieve group-type separations. The recent introduction of ionic liquid (IL) columns for use in GC presents an opportunity for the development of a conventional GC separation that may deliver a suitable group-type separation for certain petroleum samples. Group-type separation through the use of IL columns in conjunction with a GC-UV-FID to will be explored in this research. Initial studies demonstrate the potential of GC-UV-FID to differentiate the few overlapping aromatic and saturate responses that remain for diesel-range fuels.

Abstract Text

The petroleum industry has a need to enhance the accuracy of the boiling point distribution received from method ASTM D7169. The accuracy is compromised by solvent interference in the C4 to C8 boiling point range. The proposal from ASTM is to report the distribution from C9 minus from a DHA analysis which separates the carbon disulfide (CS₂) peak on one gas chromatograph (GC), and merge the results received from a classical D7169 for C9 plus from another GC which requires two GCs.

This paper will discuss innovative techniques demonstrating the ability to meet the goal of improved accuracy on one GC instead of two reducing costs and bench space. It will save time by reducing sample preparation and data processing enhancing productivity.

With the use of multi-dimensional GC, improvements in columns, and innovative capability, a method for the C1 to C100 analysis of a crude oil was developed with enhanced accuracy on one GC.

Additional improvements are the ability to attain more information from crude other than boiling point distribution, such as:

- Quantitate n-paraffins below C8
- Improve wax profile
- Separate bio-markers such as pristane and phytane
- Determine crude quality
- Resolve Benzene and Toluene for quantitation

Abstract Text

As LPG is transported through pipelines, hoses, and tanks it comes into contact with many contaminants, potentially resulting in a heavy residue in the LPG. This residue, when left unchecked can harm seals, valves, and even engines. Understanding the composition of this residue is important to determine the source of problems. In addition to LPG, there are many other pressurized gases that require investigation.

This presentation discusses an accurate and precise technique, answering the question is there contamination, and if so, how much of this contamination is present.

This presentation will demonstrate the ability to analyze for the hydrocarbon range between C6 through C44 in pressurized gas using sorbent tube technology, thermal desorption, and gas chromatography. This ability to analyze this broad hydrocarbon range in gases is advantageous in many petrochemical and environmental matrices. Many of these matrices will be discussed in addition to LPG.

Co-Author(s) Leonard M. Sidisky, Robert Shirey

Abstract Text

There has been a growing trend in bioanalysis toward the utilization of micro extraction techniques for sample isolation and transportation. Not only are there ethical advantages for test subjects, but there is also an interest in cost reduction associated with sampling. This study explores the utility of biocompatible solid phase microextraction (BioSPME) as a viable means for sample preparation in bioanalysis. A model set of compounds is used to explore the utility of BioSPME across a range of biological matrices. The unique feature of the BioSPME technique is that enables direct analysis of biological samples without the need for protein precipitation, centrifugation or digestion. The BioSPME technique allows for isolation of target analytes while minimizing coextraction of sample matrix allowing for more sensitive and robust bioanalysis.

Abstract Text

The average age of many large power transformers around the globe is reaching 40 or more years. Due to cost and today's growing demand for power, many countries are choosing to maintain rather than replace transformers. Maintaining power transformers involves routine testing of the transformer oil to monitor the furan levels present, with the intent to provide assurance of both transformer safety and power supply reliability to communities across the globe. Unexpected failures of power transformers can lead to significant costs - a replacement transformer, environmental cleanup from the failure, as well as potential financial penalties for not delivering power to communities. With these financial and safety factors in mind, testing of aging power transformers is increasing significantly using the traditional manual ASTM D5837 solid phase extraction procedure of the sampled transformer oil. Frequency and number of samples tested is growing, leaving many power companies and contract laboratories searching for new automated solutions that use the ASTM procedure to offer simplicity and efficiency versus hiring and training more laboratory chemists. This application presents data to compare automated and manual solid phase extraction ASTM D5837 testing procedures to offer a simplified and more efficient approach for workflow, accuracy, precision, and operator time.

Date: Sunday, March 08, 2015 - Afternoon

Time: 02:10 PM

Room: 267

Co-Author(s) Leonard M. Sidisky, Yong Chen

Abstract Text

A new line of fibers that contain an overcoating-layer of a proprietary PDMS over an adsorbent fiber coating has been developed. The primary advantage of adsorbent based fiber coatings is that the porous materials retain analytes more tightly than adsorbent type fiber coatings. This analyte retention advantage may become a disadvantage if the fiber has to be immersed in a complex matrix sample. The properties of adsorbent coatings that retain analytes tightly also may tightly retain nonvolatile components in the matrix. This can result in fouling of the fiber coating and shorten the lifespan of the fiber. By applying a layer of PDMS coating over the adsorbent coating, many of the large components in the matrix are repelled, while the smaller analytes of interest can pass through the outer PDMS layer and be retained by the adsorbent.

This presentation will compare the lifespan of overcoated fibers to adsorbent fiber coatings without the PDMS overcoat layer out of complex matrices such as fruit juices. The effect of the matrix on the lifespan of the coatings will be demonstrated with pictures and data. The effectiveness of the overcoated fibers from a variety of matrices will be presented. Because the PDMS overcoating slightly changes analyte uptake kinetics, data will be shown that compare the differences. Also, we will share some tips on how to use the overcoated fibers more effectively.

Abstract Text

QuEChERS (Quick, Easy, Cheap, Effective, Rugged, Safe) is an extraction technique that combines a liquid-liquid microextraction and a dispersive solid phase extraction cleanup. This technique has been used primarily for the extraction of pesticides from food products and applied to a wide array of pesticides in a multitude of food matrices including fruits, vegetables, teas, fatty food products, and more. This presentation will discuss an overview of QuEChERS and its methodology as it pertains to the extraction of glucocorticoid steroids such as prednisolone, hydrocortisone, dexamethasone, and methylprednisolone from water and herbal medicinal products (HMPs). These steroids are frequently used in adulteration of HMPs to speed the healing process; thus it is necessary to develop an analytical method to detect the presence of these illegal adulterants. Both gas chromatography triple quadrupole (GC/MS/MS) and two-dimensional gas chromatography time of flight mass spectrometry (GCxGC-ToFMS) were used for the analysis of these steroids once extracted from water and herbal medicines using QuEChERS. The optimization of both instruments, such as MRM parameters for GC-MS/MS and modulator parameters for GCxGC-ToFMS will be discussed as well as optimization of the QuEChERS extraction for these steroids.

Abstract Text

Solid phase microextraction (SPME) is a fast, easy, and reliable technique used for extraction of analytes from various matrices such as waste water, air, etc. The extraction phase for an SPME fiber can be either a solid or a liquid. Liquid coatings such as PDMS yield good linear ranges and show no competitive displacement effects, but the extraction process is slow. On the other hand, solid coatings such as DVB-PDMS offer faster extractions and better selectivity, but exhibit competitive displacement effects. Recently, our group has developed a novel, sputtered SPME coating. These coatings are thin (ca. 1 μm), porous, and do not require any adhesive for attachment to the substrate. The resulting fibers have yielded good extraction efficiencies for mixtures of alkanes and alcohols. We expect these novel fibers to be robust and compatible with numerous organic solvents. With regards to thermal stability, the fibers will be exposed to different temperatures: 260, 280, 300, and 320 °C for a specific period of time and their extraction performance will be evaluated. The longevity of the fibers will be determined by monitoring the extraction efficiencies of the fiber after each extraction at a specific temperature until there is a decrease in the extraction capability of the fiber.

Abstract Text

Since its inception in 2007, the HybridSPE technology has demonstrated to be an instrumental platform for mitigating ion suppression/matrix interference in LC/MS applications. Peer review publications on this technology have stemmed across a broad range of disciplines from clinical applications to various “omics” fields. The utility of the technology stems from the ability harness the selective Lewis Acid/Base affinity of the Zirconia-Si particles towards electron rich phosphate moieties for both reduction of biological matrix interference and targeted isolation of phospholipids. This presentation serves as an overview of peer reviewed journal publications where the HybridSPE platform has been implemented in various disciplines for targeted isolation, enrichment, depletion and profiling of phospholipids.

Abstract Text

Dietary supplements are a rapidly growing segment of the food and beverage industry around the world but particularly in the United States. The ingredients which make up the composition of these supplements are sourced from around the globe making testing of these products of critical importance. A new USP method 2232 is in the process of final approval which will standardize the testing of these materials. Closed vessel digestion is listed as a way to prepare samples using Method 2232 and microwave digestion provides a rapid preparation step as compared to other techniques. Limited sample size has prevented its use for some applications especially for infant formula. We will show the possibility of preparing a wide variety of supplements and infant formula samples in a microwave system using sample sizes of up to two grams. We will illustrate the step wise approach required to prepare these samples as well as show recovery data for reference materials as well as spike recoveries for both volatile and non volatile elements.

Abstract Text

A drug delivery system or a formulation typically consists of several ingredients, the compatibility of which can influence its biological activity and its shelf life. Therefore, investigation of interactions between active pharmaceutical ingredients (APIs) and excipients is important during the development process of new drugs to achieve a finally acceptable drug product stability. Due to its sensitivity to changes in composition and structure, differential scanning calorimetry (DSC) is a fast and reliable method to detect incompatibilities; with thermogravimetric analysis (TGA) it is possible to quantify volatile products and TGA-FTIR (thermogravimetric analysis combined with Fourier transform infrared spectroscopy) allows identification of the evaporating gases. These methods were used to investigate binary mixtures of ibuprofen – an analgesic – and magnesium stearate, a widely used anti-caking agent.

Abstract Text

The interior of cells consists of a heterogeneous mixture of macromolecules that are tens to hundreds of times more concentrated than the dilute conditions used in most biophysical studies. Both theoretical and experimental evidence suggests that enzymes behave differently under such conditions resulting in changes to stability, diffusion, aggregation, association, and ultimately function. To better understand how macromolecular crowding affects enzyme kinetics, we used spectrophotometric assays to measure the Michaelis-Menten parameters for the enzyme yeast alcohol dehydrogenase (YADH) in the absence and presence of crowding agents. These crowding agents vary from inert sugar polymers, such as dextran, to charged proteins, such as BSA. Our results show that crowding enhances the binding affinity of YADH for both of its substrates while decreasing the maximum reaction rate. Furthermore, the extent of these effects depends on the dextran concentration but not the size of the polymers.

Since diffusion plays such an important role in enzyme kinetics, we have also used electrochemical methods to measure diffusion coefficients of small molecules in crowded solutions. These electrochemical measurements both complement the kinetic studies and offer a more general insight into diffusion in crowded media. Again, the concentration of the crowding agent more than its size plays a role in determining the diffusion coefficient. Comparing these values to the solution viscosities revealed that dextran solutions do not obey Stokes-Einstein. Thus, this work provides insight about protein movement within the densely packed cellular environment.

Abstract Text

For properly maintaining the operation of the waste water treating facilities, in-situ analysis of the water quality is very important. Ammonium-nitrogen has been used as an index of the water pollution because it is formed when the organic compound in water is corrupted and decomposed.

Ammonium-nitrogen in the water treating process is oxidized to nitrite-nitrogen (NO₂), then to nitrate-nitrogen (NO₃). Thus the concentration of ammonium-nitrogen has been utilized as an index to show the nitrification process condition in the biological reactors in the sewage treatment plants and/or septic tanks. Meanwhile, ammonium-nitrogen is also used as an effective water quality index to determine the chlorine injection rate in the disinfection process by chlorine. In this way, measurement of ammonium-nitrogen is commonly done for daily monitoring and diagnosing the condition of waste water plants.

In this report, we describe the development of a new ammonia analyzer using a coulometric titration method. We will show that this new method is considerably faster and easier to use while the data shows very high correlation when compared to conventional methods. The measurement principle will also be described.

Abstract Text

Extended HPLC system operation during overnight or weekend operation requires either a sufficient volume of solvent or operator intervention to prevent the system from running dry.

In this report, we describe the development of a new sonic level sensor that fits into the HPLC solvent reservoir cap. The sensor employs sonic wave technology that can monitor the level of solvent in a maximum of four solvent reservoirs. We will describe in detail the real-time monitoring of the solvent level and will show other safety features like shutting down the HPLC pump should solvent levels become critically low.

Abstract Title **Evaluation of the Mutagenic Activity Due to Heavy Metals of Water Collected From the Cauca River in the City of Cali, Columbia by Using the Ames Test**

Primary Author Fernando E. Larmat
Universidad del Valle

Date: Sunday, March 08, 2015 - Afternoon
Time:

Room: Outside of Great Hall A

Co-Author(s) Alejandro Soto

Abstract Text

The Cauca River is an important hydric and economic resource for the Republic of Colombia and especially for the City of Cali because it provides the water for human consumption. Unfortunately, there are several sources of contamination from agricultural, industrial and domestic residual waters. This has resulted in widespread heavy metals contamination and it is well known that these metals can be introduced in the food chain by several species of native fish.

In this work the mutagenic activity of the Cauca River water due to the presence of heavy metals (Hg, Pb, Cr and Cd) was evaluated in the urban area of the city of Cali by the Ames test. Samples of crude water were taken at five different places during dry and rainy seasons. The metals were extracted from water samples using the Amberlite XAD-16 resin. The concentrations of heavy metals were measured by Atomic Absorption Spectrophotometry and mutagenicity was evaluated using the TA98 and TA100 strains of *Salmonella typhimurium* with and without the S9 enzymatic activator to simulate the effect of contaminants in the liver of mammals.

The results showed mutagenic activity with Mutagenicity Indices (MI > 2.0) in three of the five points evaluated: The El Hormiguero bridge (MI = 3.6), the mouth of southern collector channel (MI = 2.9) and the mouth of the Cali River (MI = 2.7). These sampling points in turn presented the highest total concentrations of heavy metals in the extracts. The determination and analysis of spatio-temporal variation of the mutagenic effects obtained was done by conducting multifactorial variance analysis of MI, finding that the effect of sampling season (dry or rainy season) contributes significantly to the variability of MI unlike the sampling points.

Co-Author(s) Alexander Fialkov, Bogdan Belgorodsky, Tal Alon

Abstract Text

GC-MS with Cold EI is based on interfacing the GC and MS with supersonic molecular beams (SMB) along with electron ionization of vibrationally cold sample compounds in SMB in a fly-through ion source (hence the name Cold EI). The Aviv Analytical 5975-SMB GC-MS with Cold EI provides enhanced molecular ions, significantly extended range of compounds amenable for analysis, much faster analysis and lower limits of detection particularly for difficult to analyze compounds. However, in order to convert GC-MS with Cold EI into ideally suitable solutions for challenging applications we further developed and combined it with several additional enhancement technologies including:

- A. A unique low thermal mass fast GC enables sub one minute full analysis cycle time with short standard fused silica capillary columns.
- B. Open Probe Fast GC-MS with Cold EI enables the provision of real time analysis with separation and library identification including with minimal or no sample preparation.
- C. ChromatoProbe sample introduction device serves as an effective MS probe and as manual thermal desorption unit for dirty samples analysis with minimal or no sample preparation and with enhanced sample integrity.
- D. Pulsed Flow Modulation GCxGC was combined with GC-MS with Cold EI for the combination of improved separation with best identification and the elimination of ion source peak tailing and second column peak fronting.
- E. Improved sample identification was achieved via TAMI software that provides improved quadrupole mass accuracy and combined with isotope abundance analysis it provides elemental formulae and is automatically linked with the NIST library.

Abstract Title **Manganese Based Magnetic Nanoparticles for Electrochemical Immunosensing**

Primary Author Amos Mugweru
Rowan University

Date: Sunday, March 08, 2015 - Afternoon

Time:

Room: Outside of Great Hall A

Co-Author(s)

Abstract Text

Silica-coated core-shell magnetic nanoparticles, having both the properties of magnetic nanoparticles as well as specifically tailored chemical properties, are important for biomedical applications. In this study manganese based magnetic nanoparticles (MNP) were synthesized using micro-emulsion and then used as support for other nonmaterial's including silica. These nonmaterials were characterized using X-ray Diffraction (XRD) and Scanning Electron Microscope (SEM) and DLS. To demonstrate usability of these nonmaterials, anti-human IgG, was immobilized on the surface of the nanoparticles. The immunological reaction with the human IgG antigen was then carried out on the surface. Detection of the anti-human IgG reaction with the antigen on the manganese based magnetic nanoparticle was followed using electrochemistry. This approach provides an immunosensor with a low antigen detection limit and provides a platform for several applications in protein analysis.

Primary Author Ryan Brennan
Glass Expansion

Date: Sunday, March 08, 2015 - Afternoon
Time:

Room: Outside of Great Hall A

Co-Author(s) Jerry Dulude

Abstract Text

While ICP-OES technology has undergone considerable developments on the spectrometer side, challenges related to the sample matrix still remain. For example, oil analysis by ICP-OES can be challenging due to use of organic solvents. When organic solvents are introduced into the plasma the temperature gradient along the axis of the ICP torch increases more significantly. This increase in the temperature gradient can lead to premature failure of the standard quartz ICP torch. Oil analysis also often requires labor intensive sample preparation with volatile organic solvents. In this paper we will present two sample introduction components specifically designed to increase both the speed and accuracy of oil analysis by ICP-OES. An enhanced productivity system eliminates the need for manual dilutions by incorporating three precision syringe drives and a switching valve, allowing for a sample of undiluted oil to be diluted in-line with kerosene and precisely delivered to the ICP spectrometer. A fully ceramic demountable torch, comprised of a sialon outer tube eliminates premature ICP torch failure and improves long-term signal stability.

Abstract Text

A novel simple, direct and selective stability-indicating GC-MS procedure was developed for the determination of the antihistamine drug dimenhydrinate (DMH) in presence of six of its related substances and potential impurities, namely, diphenylmethane, diphenylmethanol, benzophenone, orphenadrine, caffeine and 8-chlorocaffeine. The method involved resolution of the underivatized compounds using a trifluoropropylmethyl polysiloxane (Rtx-200) capillary column and the mass spectrometric detection was carried out in the electron-impact (EI) mode. Excellent baseline separation of DMH and the cited related substances was achieved in less than 15 min. Quantification of the parent drug DMH was based on measuring its peak area. The reliability and analytical performance of the proposed method were statistically validated with respect to linearity, range, precision, accuracy, specificity, robustness, detection and quantification limits. Calibration curve of DMH was linear over the range 50–500 $\mu\text{g/mL}$ with $r^2 = 0.9982$. The proposed method was successfully applied for the assay of DMH in tablets dosage form with recoveries not less than 96.80%.

Abstract Text

We report on the application of photomicroscopy for kinetic measurements of the heterogeneous reaction of cinnamyl chloride on indium metal in solvent/water mixes for four different solvents. In some cases, the reaction is predominantly diffusion controlled, for others it is kinetically controlled, and for yet others, it is mixed. For each solvent mix we measure rates of reaction at different convection rates. We simulate the results using a mixed diffusion- and kinetic-control model in which the heterogeneous rate constant and diffusion coefficient are the only variables. We show that the reaction rate increases as the percent water increases, but in most cases depends only slightly on the type of organic solvent. Perhaps more importantly, we show that the modelling of the data allows a wider range of heterogeneous rate constants to be measured than possible with a simple analysis of the data.

Abstract Text

Based on the geometrical arrangement of the stationary phase, there are planar- and column chromatographic techniques. Planar chromatography operates with liquid mobile phase. Mobile phase progress takes place as consequence of several types of internal or external forces. Internal force is capillarity what forwards the solvent system (mobile phase) on the dry stationary mobile phase. External forces can be gravity, electric field, centrifugal force and a pump that force flow the mobile phase. The generally used version of planar (thin-layer) chromatography (TLC) utilizes ascending direction of development when mobile phase starts to run on a dry stationary phase. However, the constantly decreasing flow velocity of the mobile phase front is determined by the vapor phase and its saturation. It is the major reason that exerting of external forces of mobile phase progress has widely been suggested and used. Descending mode of development utilizes gravity for development. Supply of mobile phase by centrifugal forces gives an easy way of technical arrangements. Circular form of developments is reached and its application includes both analytical and preparative aims. Decreasing speed of front progress is resulted from circularity. Forced-flow development of planar chromatography is also possible using pump(s). Both circular and linear shape of mobile phase front can be generated using a special chamber called OPLC (overpressured-layer chromatographic set-up). Another way of mobile phase movement is planar electrochromatography. Basic theoretical rules, numerical formulas, advantages versus disadvantages of the various set-ups, and practical solutions will be given together with mode of optimizations.

Abstract Text

Some drugs and other xenobiotics contain either N-, O- or S-methyl group in their chemical structures. Their metabolism can yield desmethylated product together with formaldehyde. Their ADME (absorption-distribution-metabolism-excretion) is generally followed using reversed-phase high performance liquid chromatography (RP-HPLC). So can be done to localize the site of their desmethylation metabolism. The fragment metabolite (here, the formaldehyde) should also be determined in the compartment of question. Rats were intraperitoneally treated with ¹⁴C-methyl labeled selegiline (radiolabelled L-deprenyl). Distribution of the radiolabelled drug was followed by autoradiography to indicate organs and tissues of interest. Various tissues were dissected and serum was prepared following 15, 30 and 60 minutes following treatment and radioactivity was determined after dissolving one part of the samples using Soluene. Another part of the dissected tissues was homogenized and the formaldehyde and the deprenyl+methamphetamine contents were determined using RP-HPLC. Quantitative determination of formaldehyde required its derivatization using 2,4-dinitrophenyl hydrazine (DNPH), and the DNPH-formaldehyde adduct was subjected to RP-HPLC. Both ultraviolet absorbance and the radioactivity in the collected fractions were monitored to identify the formaldehyde content metabolically generated from radiolabelled L-deprenyl.

This project has been supported by the Hungarian National Granting Agency (grant No.: OTKA 100155). Animal treatment followed the ethical regulations.

Abstract Text

In the case of reversed-phase liquid chromatography (RPLC), aqueous solutions of methanol or acetonitrile are frequently used as the mobile phase solvents. On the other hand, it was hard to use water as the mobile phase in RPLC systems because of the tangle of alkyl ligands on the stationary phase surface. It is required to clarify the chromatographic behavior in the RPLC systems using water as the mobile phase.

Chromatographic behavior in RPLC systems using water as the mobile phase was experimentally studied on the basis of the moment analysis. The values of retention equilibrium constant (K) and surface diffusion coefficient (D_s) were respectively measured as the equilibrium and kinetic parameters for the RPLC systems. Additionally, the temperature dependence of K and D_s was analyzed to determine the heat of retention (Q_{st}) and the activation energy of surface diffusion (E_s) by the van't Hoff and Arrhenius plots, respectively. It was concluded that chromatographic behavior in the RPLC systems using water as the mobile phase was similar to that in the RPLC systems using the mixtures of organic solvents and water.

In this study, the intermolecular interactions between solute molecules and alkyl ligands on the stationary phase was also analyzed by molecular orbital (MO) calculations. The interaction energy estimated by the MO calculations was comparable with the value of Q_{st} experimentally measured. It was demonstrated that computational chemistry was one of useful strategies for the analysis of chromatographic behavior.

Abstract Text

In this interdisciplinary study, Chemistry and Art faculty and students collaborated to analyze, characterize and digitize artifacts from the Earlham College Art Collection. The goal of this project was to better characterize the uses and limitations of handheld spectrometers to obtain chemical information about art objects that can only be analyzed within our Art Collection. A total of 106 Chinese and African ceramic objects were analyzed by handheld INNOV-X alpha 6500 X-Ray Fluorescence spectrometer (hh-XRF) and by Diffuse Reflectance Infra-Red Spectroscopy (DRIFT) using a handheld 4100 Agilent ExoScan Series FTIR analyzer. Principal component analysis (PCA) was performed on all unglazed specimens using the log-scaled concentrations for Zr, Rb, Sr, Ti, Fe and Mn, and was able to differentiate the African objects from the Chinese objects. In the African group (56 objects), PCA using Zr, Fe, Rb and Sr showed six distinct clusters. In the Chinese group (50 objects), PCA using Zr, Rb and Sr also showed six distinct clusters that correlated well with the different time periods. From the Chinese glazed specimens, we were able to identify two distinct types of glazes: one heavy in Ca and one heavy in Pb. The Pb glaze on the Han Dynasty model stove matched that of a vase of uncertain origin, which reclassified the vessel's place of origin. DRIFT analyses were used to estimate the firing temperature of the ceramics objects. The SiO-stretching bands indicated that the West African objects were fired at lower temperatures (500 to 600 °C) than the Chinese objects (600 to 900 °C).

Abstract Title **Analysis of Fatty Acids in Archaeological Pottery Fragments Using GC-MS**

Primary Author Timothy J. Ward
Millsaps College

Date: Sunday, March 08, 2015 - Afternoon

Time:

Room: Outside of Great Hall A

Co-Author(s) Amanda Kaminski, Diane J. Ward, Sara Barker

Abstract Text

Organic residues in archaeological pottery fragments were analyzed using gas chromatography-mass spectrometry (GC-MS) to determine fatty acid ratios (C12-C22), which allows for the identification of food groups. Combined with ethnography and anthropological research, the extracted fatty acid ratios can be useful in determining specific foods and uses of the vessels through the food groups consumed. Pottery sherds from the Pacific Northwest were subjected to analysis by GC-MS. Prior to analysis, pottery sherd samples were crushed and subjected to a chloroform/methanol extraction and derivatized. Sample preparation included precautions to eliminate and account for potential contamination from outside sources.

Abstract Text

Particle simulation methods that have been developed for separation science research can be broken down into two general classes: transport and molecular simulation.

Transport particle simulation methods utilize stochastic simulation of diffusion and may include convection and retention (1). These are utilized to solve transport problems where boundary conditions may be exceedingly complex and may involve simple or complex flow fields.

Particle simulation methods used in molecular simulation include the Configurational Bias Monte Carlo Method in the Gibbs Ensemble (CBMC/GE). CBMC/GE has been used to model solute-solvent-retentive interactions and accurately determine the mechanism and energetics of reversed-phase liquid chromatography (2-4).

Examples from the literature where transport simulation has been utilized to solve important practical problems in field-flow fractionation, capillary electrophoresis, chromatographic transport in packed beds and pore transport in chromatographic particles will be discussed.

Abstract Text

Short columns of both superficially porous and totally porous sub-2 μm particles allow very fast separations, but practical limitations and other disadvantages of such small particles can be problematic. While sub-2 μm particles have demonstrated their utility in research studies, columns of larger particles are often better suited for most every-day applications. Superficially porous particles (SPP) in the 2.5 - 2.7 μm range provide nearly the same efficiency and resolution of sub-2 μm totally porous particles (TPP), but at one-half to one-third of the operating pressure. This performance advantage shown by these sub-3 μm SPP has led to the introduction of sub-2 μm SPP as a natural extension of this technology. However, the efficiency advantages of these very small particles often are not fully realized due to the difficulty of packing these very small particles into homogeneous beds. Additionally, the negative effects of extra-column volumes in most instruments cause peak broadening that is especially detrimental to the very low volume, narrow peaks that elute from high efficiency, small particle columns. The new 2.0 μm SPP described in this report provide most of the advantages and minimize most of the disadvantages of columns packed with sub-2 μm particles. The characteristics of these 2.0 μm SPP are described and studies comparing some present sub-2 μm SPP and TPP commercial columns for efficiency, column bed homogeneity and stability are presented. Several applications demonstrating the utility of 2.0 μm SPP will be shown.

Abstract Text

Multidimensional Chromatography is a technique that keeps evolving. It is now well-recognized that the comprehensive version of two-dimensional chromatography can offer much larger peak capacity and has the ability to resolve complex samples where one-dimensional techniques lack the resolving power. This increased resolving power has been exploited for samples of both synthetic and biological origin.

In Multidimensional Chromatography, sample components are fractionated by two different column functionalities resulting in two different types of retention mechanisms. To achieve successful resolution of complex samples, dissimilar retention mechanisms are required to spread the separation into an area-based representation of zones.

The advantages of increased peak capacity, improved resolution and ability to handle complex samples in an efficient manner in our opinion far surpass the disadvantages of instrumentation complexity and time investment necessary to develop more than one separation procedure essentially at the same time.

This presentation will review the evolution of the technology, and will discuss the utilization of newer coupling approaches for the solution of complex problems related to samples of industrial and biological origin. Examples using gas and liquid phase separations will be presented, and the importance of the data obtained in the context of problem solving will be discussed.

Abstract Text

The characterization of conjugation sites in monoclonal antibodies (mAb) is critical in the early drug discovery phase since site-specific conjugation improves in-vivo stability and drug efficacy. The analysis of bioconjugates from in-vivo pharmacokinetic (PK) samples is useful for the determination of degradation and drug optimization for improved half-life. The complexity of identifying Lysine (Lys) conjugation sites lies in part to the large number of Lys residues present on the mAb scaffold. This has posed technical challenges to standard peptide mapping approaches. Therefore, an alternative strategy intended for a high throughput analysis has been investigated by coupling immuno-affinity capture coupled to reversed-phase liquid chromatography with mass spectrometry (2DLC/MS) detection. In this work, I will present methodology and examples of how 2DLC/MS was used to determine sites of conjugation for both an azetidinone (AZD) and N-hydroxysuccinimide (NHS) linker, as well as, the analysis of PK samples for determination of sites of degradation and optimization for improved half-life.

Abstract Text

Liquid chromatography in all of its forms has proven to be an invaluable analytical technique over the past 3+ decades. As the separation challenges have increased over this time, practitioners and theoreticians alike have worked hard to develop and implement new approaches to meet these challenges. One major challenge is the separation of greater numbers of analytes in samples of ever-increasing complexity, and statistical considerations indicate that in most circumstances what is needed is a significant increase in peak capacity.

Comprehensive two-dimensional separations can provide a much higher peak capacity and greater probability of resolving the components in a given sample than conventional one-dimensional separations. However, the required instrumental setup is more complex and analysis times can be considerably longer.

Sequential-elution liquid chromatography (SE-LC) is a mobile-phase-centered approach to increasing the peak capacity and probability of a successful separation that only requires conventional HPLC instrumentation. In SE-LC, a sample comprised of different classes of compounds is introduced into a chromatographic system that is highly retentive for all compounds because of a weak mobile phase that is initially employed. The highly-retained compounds are then subjected to a sequence of mobile phases, each of which is designed to elute one class of compounds. The result of SE-LC is the sequential elution and separation of the sample components by class and also within class, i.e., each compound within a category is also separated from other compounds in the same category.

The theory of SE-LC is summarized and the results of numerous experiments utilizing different combinations of sequential, selective elution modes with several distinct columns or serial combinations of columns are reported for different samples containing various types of ionizable and neutral compounds. Pharmaceutical and other applications are discussed.

Abstract Text

The concept of personalized medicine is predicated on an ability to comprehend a patient's disease state in a highly informed manner that ideally illuminates an effective, molecularly-targeted treatment strategy. A growing body of evidence suggests that the simultaneous measurement of multiple unique biomolecular signatures from a single sample would be incredibly enabling in achieving such an informative diagnosis. Unfortunately, this is an analytical feat that currently not possible using established methods, thereby limiting the implementation of informative molecular diagnostic and theragnostic strategies in the clinical management and treatment of disease.

In response to these and other bioanalytical challenges that would benefit from high sensitivity, high level multiplexing capability, and scalable and cost effective sensor fabrication, our group has developed a biomolecular analysis platform based upon silicon photonic microring resonators. We have demonstrated the capabilities of this platform as applied to the detection of DNA, RNA, and protein biomarkers of disease, and have also shown its versatility in the facile screening of multiple types of biomolecular interactions. This talk will describe our efforts to develop this emerging platform in the context of creating multiplexed detection solutions for a range of challenges both in clinical diagnostics and fundamental biophysical interaction monitoring.

Abstract Text

We have recently obtained over 10,000 peptide identifications and over 2,000 protein identifications from a HeLa cell line using capillary zone electrophoresis in a single 100-minute analysis. These data are a 10-fold improvement in identifications using capillary zone electrophoresis over the previous state-of-the-art. We employed an electrokinetically-pumped nanoelectrospray interface to couple the electrophoresis capillary with an Orbitrap mass spectrometer. Based on these results, capillary zone electrophoresis is competitive with liquid chromatography for deep proteomic analysis.

Abstract Text

Microfluidics can be used to control multiple flows in single channels under conditions which prevent mixing of the flows. As we learn to direct and shape one fluid using another, an entirely new set of potential capabilities begins to emerge for optical components and sensors. Liquid waveguides can move light around corners and focusing cells in front of a laser beam can produce a microflow cytometer for point-of-care diagnostics or analysis of algae on unmanned underwater vehicles. Polymerizable streams can be used to fabricate fibers with predefined shape and highly consistent sizes over many meters in length. With sheath flow, we have aligned molecules within a subsequently polymerized matrix to create a fiber with optical anisotropy [1]. We have embedded metal nanoparticles in polymer fibers to control the color of the fibers and the plasmon resonance of the nanoparticles [2]. We can polymerize shaped fibers containing cells or decorated with recognition molecules to make filters that can simultaneously act as sensors [3]. Finally, we have demonstrated the integration of both bacteria and mammalian cells into hydrogel fibers [3,4]. Control of porosity and chemistry is essential to provide for cell viability. The bacterial can be used to detect environmental hazards such as arsenic or mercury, while the mammalian cells can be used to develop tissue-on-chip models, providing opportunity for imaging cellular interactions in three dimensions [5].

Abstract Text

The multiplexed detection of nucleic acids and proteins via bioaffinity adsorption onto biopolymer microarrays has become a mainstay tool for biological researchers throughout the world, and Surface Plasmon Resonance Imaging (SPRI) is an established optical detection method for in situ multiplexed bioaffinity measurements that works very well and nanomolar concentrations or higher. In this talk, we describe the development of new SPRI methods that can detect and identify nucleic acids and proteins at picomolar and even femtomolar concentrations. These include (i) a near infrared SPR microscope for single nanoparticle-enhanced SPRI and digital bioaffinity adsorption measurements, and (ii) coupling SPRI with surface enzyme chemistries and on-chip templated biosynthesis the on-chip, and (iii) the application of single nanoparticle SPR microscopy to detect the uptake of bioactive peptides into single hydrogel drug delivery particles. These new SPRI ultrasensitive biosensing methods for detecting multiple DNA, RNA and proteins at extremely low (picomolar to femtomolar) concentrations will facilitate the identification of better biomarkers for early disease detection and strategies for post-treatment patient monitoring.

Abstract Text

Protein separations represent a major technological challenge because of the multiplicity of forms that exist for even one protein. Electrically driven separations, which are mainly electrophoretic sieving and isoelectric focusing, have been widely used for decades, but they suffer from low throughput and are cumbersome in integrating with other separations and with detection. Yet the simplicity of separating using a voltage rather than a pump should make these methods easy to automate and integrate with mass spectrometry. What has been lacking is a medium that is easier to use than gels. We have been exploring silica colloidal crystals as the replacement medium, giving faster separations with higher resolution than gels, and in this work we discuss integration with detection methods as well as automation.

Abstract Text

Often new Mass Spectrometer instrument design begins development as a proof-of-concept or rapid prototypes in order to demonstrate a new advance in technology. An unnecessarily large fraction of such new designs under-perform when applied to field analysis due to factors unrelated to the new technology. Yet, end-users unfamiliar with the technology tend to view the technology itself as the failure. This talk will review some basic design concepts to consider at the onset of prototype development that can mitigate risks of reduced performance, or failure, in the field. Topics include reviews of design best practices for electrical, mechanical, fluid, and material system aspects. Additional topics will focus on human factors issues such as - ease of operation (especially by non-experts), ease of maintenance, and damage mitigation.

Abstract Text

Recently, a backpack MS and a desktop Mini 12 MS systems have been developed and characterized for in-field chemical detection and point-of-care applications, respectively. In this presentation, a set of technologies recently developed will be introduced, which have been used to enable new capabilities or improve the functions of these miniature ion trap MS systems. A dual-LIT (linear ion trap) configuration has been implemented with the discontinuous atmospheric pressure interface (DAPI), which enables MS/MS analysis of multiple precursor ions with a single introduction of ions generated at atmospheric pressure. The scan speed of the miniature ion trap MS systems is thereby significantly improved when using ambient ionization source for analysis of non-volatile compounds. Prototype miniature pumps with new pumping technologies have also been tested for the miniature ion trap instruments. A 350g scroll pump developed by Creare provided adequate pumping for backing up the turbo pump, while operating extremely quite in comparison with the diaphragm pumps popularly used in the miniature MS systems. Development of sampling probes were also explored with several different designs, including the integration of a 130g turbo drag pump to a handheld unit along with a coaxial low temperature plasma source and a vacuum manifold containing a DAPI and a rectilinear ion trap. The synchronized discharge ionization method took advantage of the periodical pressure variations with the DAPI operation and enabled high sensitivity analysis of the volatile organic compounds in air. This method has been recently applied to detection of explosives and pesticides of low volatility. The recently developed slug flow microextraction nanoESI method has been shown to be powerful for direct analysis of biofluid samples. Its application to the analysis of drugs in urine and blood samples as well as the evaluation of the enzymatic functions will be introduced.

Abstract Title **The Liquid Sampling-Atmospheric Pressure Glow Discharge (LS-APGD): A Pragmatic Ion Source for Field-Based Elemental/Isotopic MS**

Primary Author R Kenneth Marcus
Clemson University

Date: Monday, March 09, 2015 - Morning

Time: 09:45 AM

Room: 238

Co-Author(s)

Abstract Text

While the immediate concerns that come to mind regarding the concept of field-deployable MS instrumentation are the vacuum and power requirements, one must remember that there is no mass spectrum to be obtained without an ionization source that can vaporize/ionize the sample at hand. In the case of organic vapors, the energy-input required can be as simple as a filament or radioactive (beta particle) emitter. When one turns to sample forms wherein elemental/isotopic information is needed, the power requirements immediately go up as the sample must ultimately be degraded down to the atomic level; this is after whatever energy is required to affect the sampling and vaporization steps. The liquid sampling-atmospheric pressure glow discharge (LS-APGD) holds a unique position among the other atmospheric pressure glow discharges as it has demonstrated abilities in atomic emission, elemental mass spectrometry, molecular mass spectrometry, and ambient desorption mass spectrometry. These base capabilities are multiplied as the sample forms that are amenable to analysis include liquids, bulk solids, solution residues, and aerosols generated by laser ablation. This versatility is affected on a very small platform, with minimal supporting utilities. Specifically, the plasma is ignited between an electrolytic solution that is introduced at flow rates of 10-200 microliters/min at discharge currents of <60 mA, and d.c. powers of <50 W. The discharge volume is set by the electrode gap, but is usually on the order of 1 cubic millimeter. Importantly, ion sampling from the LS-APGD microplasma does not bring along the pumping overhead of high temperature/high gas flow plasmas such as ICP sources. It is believed that the LS-APGD microplasma holds a unique place among its peers and warrants investigation as a field-deployable ionization source for environmental and national security applications.

Abstract Text

Fieldable or portable analysis techniques are sought for in many environmental, and national security application areas. The development of new, robust approaches that provide smaller, simpler, cost-effective and analytical useful and defensible results remains a challenge however. This talk will survey these needs and provide concepts and ideas for unique, new approaches to fieldable MS that include development of new ionization mechanisms and sources as well as new MS separation technologies.

Abstract Text

The oil and gas industry, and organizations that environmentally monitor deep ocean and coastal regions, have a need to detect and characterize light hydrocarbons in these regions. Hydrocarbons can enter the water column through natural seepage from the sea floor, or through unintended leaks and spills from drilling operations and transportation of oil and gas to shore. The ability to perform this analysis in situ greatly enhances achievable spatial and temporal densities. In addition, real-time, in-water chemical measurements allow for rapid decision-making, provide adaptive sampling strategies, and offer the possibility of tracking chemical gradients to trace leaking chemicals to their source. SRI International's in situ membrane introduction mass spectrometry (MIMS) instruments can quantitatively detect light hydrocarbons in water at trace levels, while simultaneously monitoring the concentrations of all light, stable dissolved gases to a depth of 2000 meters.

We will discuss the design and operational parameters of our new in situ MIMS instrument, which is deployable on underwater platforms, such as the Bluefin BF-12 autonomous underwater vehicle (AUV). We will also present results from recent deployments of our MIMS systems to characterize hydrocarbon seeps and other features in the Gulf of Mexico, the Santa Barbara Channel, and Tampa Bay.

Abstract Text

The Air, Climate, and Energy (ACE) and Chemical Safety for Sustainability (CSS) programs at the U.S. Environmental Protection Agency (EPA) encompass broad-based research that includes assessment of the health and environmental impacts of anthropogenic and manufactured chemicals. One component of these programs is to develop efficient and accurate analytical methods for testing the relative toxicity and potential health effects of chemicals (and chemical mixtures) and to ultimately guide chemical prioritization for more detailed evaluation and regulation. Currently, high-throughput in vitro methods using specific targeted adverse outcome pathways (AOPs) are implemented at the cellular and molecular level with liquid phase micro-fluidics including liquid chromatography-tandem mass spectrometry (LC-MS/MS) analyses. New methodology is now under development to implement gas phase probe molecules for assessing specific metabolic pathways that have already been well defined in human or mammalian models and apply semi-real time detectors (optical or MS) to in vitro measurements. We propose two probe molecule and metabolite pairs that could be used for in vitro assessment of perturbations in specific liver enzyme systems: methyl-tertiary butyl ether (MTBE) metabolism to tertiary butyl alcohol (TBA) via CYP2A6 and sevoflurane metabolism to hexafluoroisopropanol via CYP2E1 in flow through-reactors using human cell lines. We expect to extend the gas-phase probe methodology to airway epithelial cells and analyze carbon monoxide (CO) production via heme oxygenase (HO) activity.

Abstract Text

Chemical analytical procedures for *in vitro* analyses of biological media typically involve considerable time-consuming steps that limit sample throughput. Such constraints can be reduced by use of real-time mass spectrometry for both *in vitro* and *in vivo* analysis. The technique of proton-transfer-reaction mass spectrometry (PTR-MS) is a chemical ionisation based tool that allows for rapid and direct detection and quantitation of gas-phase volatile organic compounds (VOCs). Depending on the medium, this can be made either *in vivo* or *in vitro*. Probative analysis of exhaled breath gas for biomarkers, for example, can be made at a breath-by-breath frequency and deliver immediate chemical information that can be utilised for adverse outcome pathways (AOP) studies. On the other hand, *in vitro* analysis of other bodily media, e.g. in the form of the detection of VOCs in the headspace of fluids such as blood, urine or saliva, can offer rapid analytical throughput of samples for correlation with *in vivo* data to establish chemical pathways. This presentation will introduce the technology of PTR-MS, outline latest developments, and discuss potential applications for AOP assessments.

Abstract Text

Exhaled human breath consists of mixtures of molecules derived from the human exposome and from normal and abnormal physiologies. The advantages of breath over other bodily fluids are that it can be collected multiple times non-invasively from infants or adults without posing any risk to the patient or the person collecting the sample. Breath can be sampled or collected easily anywhere: in a physician's office, in a clinic, in the field or in the home. Real-time monitors are currently being developed and these devices may be well-suited for field and epidemiological studies, particularly for studies in developing countries where collecting blood and urine samples are difficult without refrigeration.

If inexpensive portable real-time monitors can be developed for point-of-care testing then patients can be provided important information immediately and treatment initiated. Real-time breath analysis is ideally suited to personalized medicine, which is the future direction for clinical medicine. Moreover if devices are portable, simple to operate and relatively inexpensive then chronically sick patients could monitor their progress in their home and thereby minimizing their exposure to infections during routine visits to clinics.

Currently, breath analysis can be used to monitor disease progression, or monitor therapy. Breath analysis could be used for phase 1 and phase 2 clinical trials to monitor new drug therapy or to detect potential adverse effects. Since breath analysis is non-invasive and can be performed easily, it allows larger numbers of study subjects to be studied. Using larger numbers of study subjects, unusual adverse effects are more likely to be identified. This presentation will discuss the various analytical approaches that are being used to develop real-time breath monitors with particular emphasis to the use of mid-infrared QC lasers "Personalized medicine using mid-IR spectroscopy".

Abstract Text

Exposure to inorganic arsenic (iAs) early in life is associated with adverse health effects in infants, children, and adults, and yet the biological mechanisms that underlie these effects are understudied. The objective of this research was to examine the proteomic shifts associated with prenatal iAs exposure using cord blood samples isolated from 50 newborns from Gómez Palacio, Mexico. Levels of iAs in maternal drinking water (DW-iAs) and the sum of iAs and iAs metabolites in maternal urine (U-tAs) were determined. Cord blood samples representing varying iAs exposure levels during the prenatal period (DW-iAs ranging from <1 to 236 μ g/l) were analyzed for altered expression of proteins associated with U-tAs using a high throughput, antibody-based method. A total of 111 proteins were identified that had a significant association between protein level in newborn cord blood and maternal U-tAs. Many of these proteins are regulated by tumor necrosis factor and are enriched in functionality related to immune/inflammatory response and cellular development/proliferation. Interindividual differences in proteomic response were observed in which 30 newborns were "activators," displaying a positive relationship between protein expression and maternal U-tAs. For 20 "repressor" newborns, a negative relationship between protein expression level and maternal U-tAs was observed. The activator/repressor status was significantly associated with maternal U-tAs and head circumference in newborn males. These results may provide a critical groundwork for understanding the diverse health effects associated with prenatal arsenic exposure and highlight interindividual responses to arsenic that likely influence differential susceptibility to adverse health outcomes.

Abstract Text

While chronic disease and cancers are caused by both genetic and environmental factors, it has been estimated that 70-90% of disease risk is due to differences in environments. To investigate the role of the environment in disease etiologies, untargeted approaches are needed that can compare chemical profiles across groups in an unbiased fashion. Candidate biomarkers identified in such studies can then be targeted in population-based studies using simple blood collection methods, such as dried blood spot (DBS) sampling. While it is currently not possible to measure all chemicals in the human body in single experiments, important classes of reactive chemicals can be targeted. Here we report a novel approach using protein adduct (addition product) profiles as molecular fingerprints of environmental exposures, called "adductomics". Because protein adducts persist in the blood for the life span of the protein, adducts represent an integration of exposures occurring over weeks to months (e.g., mean residence times are 28 days and 63 days for human serum albumin (HSA) and hemoglobin, respectively). Consequently, protein adducts serve as ideal biomarkers for measuring exposures to environmental chemicals when chronic exposure scenarios are of greatest interest. Once discordant adducts are identified in discovery-based experiments, we then apply targeted protein adduct methods to dried blood spots (DBS), which can be collected using a simple and minimally-invasive finger prick. To achieve unparalleled analytical sensitivity using extremely small volumes of blood, adducts will be quantified using a state-of-the-art Agilent 6490 QQQ mass spectrometer with a nano-chip HPLC interface. This analytical platform permits biomarker detection down to the attomolar concentration (10-15 mol/L) using micro-liter blood volumes that can be obtained from a single 3 mm punch of dried blood.

Abstract Text

We show that mediator-tethered atomic force electrochemical microscopy (Mt/AFM-SECM), a local probe technique based on the direct contact between surface-confined redox-labeled molecules and an incoming microelectrode, complemented by redox-immunolabelling enables mapping the distribution of proteins on the shell of individual viruses. The perfectly ordered and known viral architecture allows single protein resolution to be demonstrated. This result makes Mt/AFM-SECM a powerful tool for viral nanotechnology as it allows both the topography but also the function (e.g. redox function) of functionalized viruses to be simultaneously characterized at the individual virus scale.

Abstract Text

Most research on nanoparticle (NP) collisions with an ultramicroelectrode (UME) has been with “hard” NPs (e, g., metals, oxides, organics, and polymers). Recently, collisions of “soft” NPs, like emulsion droplets, biological cells, and viruses, have been described. The electrochemical response and the frequency of collisions allow one to extract information about the NPs and even study electrode reactions in fL and aL droplet reactors. An overview of this field will be given and recent advances described.

Abstract Text

In the first part of this lecture, I will provide some background material on the basic physical concepts underlying molecular plasmonics with an emphasis on SERS and LSPR spectroscopy. Next, I will turn to the area of single particle surface enhanced Raman spectroscopy (SPSERS). In this section I will provide some answers for several fundamental questions such as: (1) what is the largest possible enhancement factor (EF) and (2) what nanostructure produces the largest EF. Our approach to answering these questions involved the development of new tools using single nanoparticle SERS and single nanoparticle LSPR spectroscopy spatially correlated with high resolution transmission electron microscopy (HRTEM).

In the second part of this lecture, I will discuss very new results in single molecule SERS (SMSERS) and single molecule tip-enhanced Raman spectroscopy (SMTERS). These include: (1) the first SMSERS study involving nanofabricated surfaces rather than chemically synthesized nanoparticles; (2) a simultaneous isotopologue and bianalyte experiment; and (3) the study of isotopologues and fluctuation analysis in SMTERS.

Abstract Text

In the atomic spectrometry community, the use of plasma sources has become associated almost exclusively with elemental analysis. This trend is not surprising; after all, inductively coupled plasmas, glow discharges, and microwave-induced plasmas offer outstanding figures of merit for the determination of metals and metalloids. However, in other fields, these same sources, suitably modified, and others such as corona discharges can be used not only to ionize samples but also to desorb and fragment them. These alternative plasmas therefore offer promise for molecular and speciation analysis. In this presentation, the focus will be on plasma sources that are capable of molecular characterization and speciation. The first source is intended for the simultaneous emission-based examination of spots on a two-dimensional (planar) chromatographic plate, such as one from thin-layer chromatography or two-dimensional gel electrophoresis. Coupled with a monochromatic imaging spectrometer, the glow-discharge source enables the simultaneous detection and quantification of spots that hold metal-containing proteins or those stained with silver, gold nanoparticles, or metal-containing affinity tags used to identify functional groups. A second source is based on the flowing afterglow produced by an atmospheric-pressure glow discharge (APGD). Simple in design, construction, and operation, this source can ionize vapor-phase samples or can be used to volatilize solution or solid samples directly and to ionize the resulting molecules. The resulting mass spectra are amazingly simple, and consist mainly of the molecular ion or protonated molecular ion. Because of this spectral simplicity, simple mixtures of compounds can often be characterized without a prior separation. The plasma source is therefore useful for speciation analysis and for the burgeoning technique of ambient desorption-ionization mass spectrometry.

Abstract Text

Laser Induced Breakdown Spectroscopy (LIBS) is a convenient and powerful analytical tool for direct and fast elemental analysis at atmospheric pressure for samples of virtually all kinds. However, LIBS generally provides only elemental information of a given sample but not its isotopic constitutions. The development of the Laser Ablation Molecular Isotopic Spectrometry (LAMIS) technique allows isotope analysis by laser ablation.

The LAMIS technique measures the molecular spectra of those radicals that are produced when the ablated materials expand into the atmosphere. It is implemented similar to conventional LIBS elemental analysis, and can be measured simultaneously with LIBS under the same laser pulse. Because isotope shifts in molecular spectra (LAMIS) are orders of magnitude larger than those in atomic spectra (LIBS), it is possible to determine isotopes at atmospheric pressure by an all-optical means. Some previously published LAMIS works include isotopes from carbon, boron, hydrogen and strontium.

In this presentation, the theoretical principles of LAMIS will be overviewed, and the current status (e.g., analytical figures of merit as well as challenges) of this technique will be discussed. In addition to chemical analysis, LAMIS can also be used for fundamental studies in laser-induced plasma. For example, we recently employed the LAMIS technique to clarify the mechanisms leading to the formation of C_2 and CN molecules during laser ablation of an organic compound in ambient air, which also will be presented in this talk.

Abstract Text

The recently introduced strategy for the analysis of rare earth-tagged antibodies in tissues using laser ablation-cy-TOF has gained a lot of attention due to the fast multielement imaging capabilities under atmospheric conditions. The method requires fast transport of laser-generated aerosols into the cy-TOF where quasi simultaneous detection of all isotopes of interest takes place. Furthermore, the spatial resolution for discrete sampling of the tissue has to be in the order of 1 micron to provide insights into the antibody distribution within single cells.

The research reported in the presentation will focus on various inhouse built laser ablation systems and ablation cell geometries suitable for fast screening of tissue are available and that the wavelength of the laser for tissues is less crucial as reported for geological samples. In addition, some attempts towards quantitative analysis will be discussed.

Abstract Text

Glow discharge optical emission spectroscopy (GDOES) has been historically used for direct bulk analysis and depth profiling of solid samples. Recently, the capabilities of GDOES have been expanded such that laterally resolved information can be obtained from within the sample sputtered area. This is achieved by collecting the emitted light with a spectral imaging system and by operating the GD in pulsed mode and under high pressures. The potential impact of the new capability becomes apparent when one recognizes that traditional elemental mapping techniques are throughput limited such that large area samples require many hours for measuring an elemental landscape with sufficient pixel density. On the other hand, GDOES elemental mapping has shown it can yield chemical composition landscapes with several orders of magnitude faster acquisition times than traditional techniques. As a result, elemental mapping of large area samples has the possibility of being a tool for routine analysis and diagnostics, as opposed to being limited to fundamental studies. Currently, protocols are being developed for its use with biological thin sections which will open the development of imaging methods for molecules used for therapeutic compounds, contrasting agents, toxicology studies, and many more. Recent advances will be presented.

Abstract Text

The road to a healthy, prosperous future for humankind and nature as a whole is dependent scientific discovery to understand processes on a molecular level and to develop approaches to improve the symbiotic relationship between humans and nature. At the heart of these discoveries is the need for powerful analytical instrumentation to view natural processes of the past and to project a path of the future. One particular area of the analytical sciences, atomic spectroscopy, has been essential to understanding modern (<100 years ago) biological processes as well as that from the distant past (>100,000 years ago). Yet, this area is often labelled as a “mature field,” which implies there is nothing left to discover or no more problems to solve. As will be demonstrated here, there is still a need for better (i.e. faster, robust, portable, sensitive, etc.) tools to quickly provide a comprehensive assessment of species in a sample in situ.

☐

This presentation will focus a novel plasma source capable of providing molecular, structural, and atomic information of species when coupled with mass spectrometry. In this plasma-based ambient mass spectrometry experiment, the source directly removes molecules from a sample surface, ionizes the species, and transfers these ions into a mass spectrometer. The separation power and sensitivity of the mass spectrometer is used to resolve individual components in a complex mixture. By adjusting the operational mode of the plasma source, the produced mass spectra selectively consist of intact molecular ions, electron ionization (EI)-like fragments, or bare atomic ions. This plasma source can also be coupled with electrospray ionization to enhance atomic and molecular detection of large biomolecules. The plasma source design and operation will be presented as well as representative applications and mass spectra. Lastly, approaches to process and deconvolute complex mass spectra generated by this system will also be presented.

Abstract Text

In 1970, essentially all infrared spectrometers that were sold to analytical chemistry laboratories were based on grating monochromators. By 1980, FT-IR spectrometers had made a large impact on the market and within a few more years, scanning grating spectrometers had become obsolete. After a brief introduction to the types of FT-IR spectrometers that were developed in the 1960s, I will describe the factors that gave rise to the capability to measure mid-infrared spectra rapidly and at reasonably high resolution. These factors included the report of the fast Fourier transform in the mid 1960s by Cooley and Tukey and the subsequent development of three items of hardware: minicomputers, small helium-neon lasers and the triglycine sulfate (TGS) pyroelectric bolometer. The first instrument to incorporate all these components was the Digilab FTS-14. Although each of these items has been replaced by higher-performance analogues, today's FT-IR spectrometers bear a striking resemblance to the FTS-14, which can, I believe, be called the first FT-IR spectrometer of the modern era. In this talk, I will describe the development of this instrument in 1969 and 1970 and relate some of the events that occurred in this period.

Abstract Text

Cells must acquire significant quantities of metals ions for use in a multitude of essential processes. While fluxes of alkali and alkaline earth metal ions play well-established roles in controlling cellular physiology, recent studies have shown that dramatic time-dependent fluctuations in intracellular transition metal concentrations control key steps in development, proliferation, differentiation and growth. Major barriers to understanding these processes include the low sensitivity of methods for determining concentration changes in small volume elements and maintaining the integrity of subcellular metal distributions during sample preparation. Here we address these issues and correlate results from several different ultrasensitive methods for direct analysis of changes in metal concentrations in single cells and in subcellular compartments, some as small as 250 nm diameter vesicles. Quantitative single cell X-ray fluorescence microscopy (ACS Chem Biol, 2011,15;6(7):716) and tomography experiments (Nature Chemistry, in press) at the APS (Argonne National Laboratory) open the door to the discovery of new signaling roles for zinc fluxes. Even higher spatial resolution of zinc distributions is achieved using a Hitachi 2300 STEM microscope equipped with dual EDS detectors. Finally new fluorescent probe molecules deployed in live cell confocal fluorescence experiments complement these physical methods and reveal how fluxes of billions of zinc atoms in the time course of seconds to hours are used by the cell to control key physiological decisions at the earliest stages of mouse, cow and primate development, including oocyte maturation, fertilization and early embryonic development. Thus, zinc fluxes involving the movement of from millions to billions of metal ions between compartments of a single cell, or between the intracellular and extracellular environment are emerging as key cell cycle regulatory events in biology.

Abstract Text

The detection and quantification of biological trace metals is of critical importance for a comprehensive understanding of metal homeostasis in cells, tissues, and whole organisms. To this end, we designed and optimized water-soluble fluorescent probes for sensing Cu(I) and Zn(II) within a biological environment. Systematic optimization of the ligand architecture as well as electronic tuning of the fluorescence reporter were key for realizing a Cu(I)-selective probe with a 180-fold fluorescence contrast and a limit of detection in the parts-per-trillion concentration range. To take advantage of two-photon excitation microscopy, which offers reduced phototoxicity, improved depth penetration, and negligible background fluorescence, we developed an emission ratiometric Zn(II)-selective fluorescent probe with optimized non-linear optical properties. The water-soluble probe retains a balanced two-photon cross section upon Zn(II) binding and responds with a strong shift of the emission band suitable for ratiometric imaging of labile zinc pools in live cells and tissues. As a complementary approach we employed synchrotron X-ray fluorescence (SXRF) microscopy and 3D microtomography to visualize and quantify the transition metal distribution in proliferating cells and in developing zebrafish embryos.

Abstract Text

Fluorescent ion indicator is defined and the question of why fluorescent ion indicator is answered. The advantages of fluorescence over other methods and criteria for a good indicator is presented briefly. Development of fluorescent ion indicators is presented with examples of the most important ions: Calcium, Sodium, Potassium, Magnesium and proton(pH). The future of fluorescent ion indicators and new developments from Teflabs concludes the presentation.

Abstract Text

Lead toxicity is one of the most common environmental problems, particularly in older cities. Complications due to lead exposure can affect virtually every soft tissue in the body. Thus, the ability of detect small amount of lead is of paramount importance. We have developed a new class of fluorescent molecules that can detect lead in solution. This molecule has a dithiolene-based binding site, and thus differs from other commonly used fluorophores with more hard donors such as oxygen or nitrogen. Our studies suggest that the molecule can serve as a sensitive and selective fluorescent sensor for lead in a wide pH range. In this presentation we discuss the details about the material, lead binding affinity, and the selectivity against other ions in aqueous solution.

Abstract Text

Metal ions perform essential functions in all facets of life. Analysis of metal ion concentration and function in live cells and tissue is a topic of considerable importance in virtually every field of biology. Such analysis is made challenging by several factors, among which the following three are prominent: 1) large metal ion concentration variations in cyto and in vivo; 2) dynamism in metal ion concentration; 3) detection selectivity amongst metal ions can be very difficult using various means of analysis. Small molecule fluorescence-based sensors have been developed for many physiologically relevant metal ions, including Ca²⁺, Zn²⁺, Pb²⁺, Na⁺, and K⁺. Key to successful molecule and analysis design is achieving physiologically appropriate metal ion affinity, sufficient selectivity among potentially confounding metal ion species, live cell permeability of probes, and sufficient S/N ratios to accurately determine the metal ion concentration of interest in various experimental systems. Detection is commonly achieved via fluorescence spectroscopy in multiwell plates, fluorescence microscopy, and flow cytometry. The talk will provide several examples of fluorogenic sensors from the metal ion list above, deployed in various experimental systems ranging from high throughput screening to live tissue.

Abstract Text

Understanding the role of nutrients and metabolism in diseases such as cancers requires functional omics, of which network metabolomics is a bedrock approach. Metabolites are often referred to as "nuts and bolts" of metabolism; the analogy is appropriate, in that each metabolite is used in many places for disparate purposes. Thus, despite excellent analytical signal-to-noise ratio (s/n) of modern analytical techniques, the information s/n of each metabolite is less than unity due to their participation in multiple pathways. However, stable isotope labeling can distinguish pathways and functions among otherwise chemically identical metabolites. Using stable isotope resolved metabolomics (SIRM), we have demonstrated the capability to elucidate key pathway/network metabolic reprogramming in cancers, in effect achieving functional proteomics via vivo enzyme assays, and unambiguously assigning up/down regulation of pathways for signaling/transcriptomic work. For example, glucose vs glutamine sources of carbon in cancers has revealed key aspects of resource allocation, including the up regulation of anapleurosis via pyruvate carboxylase. In fact, we initially elucidated this pathway in lung cancers resected from ¹³C glucose infused human subjects. This demonstrates the unique ability of SIRM for untargeted discovery of specific metabolic pathways directly in humans for maximal relevance, following up with identical experiments in animal and cell models for unprecedented congruence of results. Of course many technical challenges remain some which will be described, however the greatest challenges are a new horizon revealed by SIRM, that of complex metabolic pools corresponding to previously unknown dynamic compartmentation. This is a crucial area poorly addressed by all of the omics, in part due to lack of phenotypic information, which SIRM can help to remedy.

Abstract Text

Advances in metabolomics, transcriptomics, proteomics and in vivo stable isotope based fluxomics have made it possible to interrogate metabolic pathways in unprecedented detail. The convergence of multi-omic approaches is especially attractive to scientists in the field of diabetes and metabolic disorders, as they attempt to identify metabolic control points for therapeutic intervention. We have developed a framework for the step wise interrogation of complex models of insulin resistance, using metabolomics and stable isotope based fluxomics as primary tools for examining the functionality of tissue specific changes in gene/protein expression, and protein post-translational modifications, seen in the evolution of the diabetic state. For example, our published work has shown fasted/fed changes in metabolic network lysine acetylation can be associated with substrate re-partitioning down metabolic pathways, affecting the development of the (pre-) diabetic state. Changes in mitochondrial fuel utilization and energetics may not only be affected by alterations in gene/protein expression and post-translational modifications, but also via lipidomic interactions with components of the OXPHOS chain. The understanding of the evolution of metabolic network dysfunction that results in a diabetic phenotype requires a systems approach dependent on metabolomics and fluxomics for integration of the spectrum of transcriptomic and proteomic responses seen.

Abstract Text

Any toxic event ultimately represents a disruption of homeostasis, which may be viewed either at the level of the epigenome, the transcriptome, or the metabolome. In almost all cases the metabolome is the earliest responder. The route by which homeostasis is disrupted will depend initially on the mechanism of action of the toxin and converge into one or more irrecoverable (fatal) disruptions. Between the initial and fatal disruptions are a number of possible states. In this study we examine the metabolomic response of yeast to three well characterized toxins, Ketoconazole, Terbinafin, and 5-fluorocytosine, as an initial attempt to see if the IROA protocol provides a reasonable approach to determining these states.

Abstract Text

Traditionally, isotope-tracer studies have been performed with targeted analyses examining a limited number of known downstream metabolic intermediates. Here we describe an alternative workflow that leverages recent advances in mass spectrometry-based metabolomic technologies to track the fates of isotope tracers in a global, unbiased manner. To accomplish this isotope-based metabolomic workflow, we have developed both software and a database optimized to identify isotopically enriched metabolites. We have applied these technologies to study labeled glucose in cancer cells. While it is well established that cancer cells uptake increased amounts of glucose, the fate of this glucose has not been well characterized. We provide a comprehensive list of intracellular metabolites enriched from glucose and quantitate the fraction of consumed glucose that ends up in proteins, peptides, sugars, and lipids.

Abstract Text

One of the most rapidly growing areas in analytical chemistry is metabolomics, much as it was for proteomics ten or fifteen years ago. One driver of that growth is the enormous investment of NIH common fund resources in metabolomics centers across the country. Global and targeted metabolomics are poised to have one of the biggest impacts on human health, and innovations in analytical chemistry will drive that impact.

One of the most important tools in metabolomics is stable isotope labeling, which is used in unraveling metabolic pathways, in measuring metabolomics flux, in calibration for quantitative targeted metabolomics, and most recently as a strategy for comparative global metabolomics studies.

This talk will focus on the utility of isotopic labeling in MALDI imaging mass spectrometry, particularly for metabolomic applications.

Abstract Text

As a platform for analytical separations, microfluidic devices offer a number of potential advantages over conventional methods. Microfluidic separations have been described that demonstrate major improvements in speed, sample consumption, automation, integration, separation power, and ease of use. However, the vast majority of these methods have been limited by a lack of mass spectrometry detection. We have pioneered the development of a sensitive, stable, and efficient microchip electrospray interface that enables the integration of MS detection with microfluidic separation methods. These devices yield electrospray ionization (ESI) performance as good as any nanoESI emitters without sacrificing the quality of microfluidic separations. Most of our work has utilized microchip capillary electrophoresis (CE) with integrated ESI. Compared to CE-MS performed using fused silica capillaries, microchip CE-ESI-MS can achieve greater separation efficiency in shorter analysis times because the integrated injection and ESI functional elements greatly reduce extra-column band broadening. Microchip CE-ESI-MS could therefore be used simply to improve CE-MS for challenging applications such as the characterization of intact biopharmaceuticals and protein/drug conjugates, where achieving optimal separation efficiency is crucial for the success of the analysis. Additionally, this technology could be applied to new analytical methods, which take advantage of the high separation speed and integration enabled by the microfluidic platform. A number of examples will be presented including the analysis of biopharmaceuticals and proteolytic peptides.

Abstract Text

Mass spectrometry (MS) is an efficient, sensitive, and highly specific detector for a wide range of compounds encountered in the analytical laboratory. Low-flow electrospray ionization, referred to as nano spray, has been the ionization method of choice to interface mass spectrometry to capillary separation techniques such as reverse phase LC, capillary electrophoresis, and related methods. Nanospray has enjoyed a great deal of success as the interface to both planar and capillary microfluidic systems.

LC and CE are inherently analog technologies. Considerable effort in method development and technical overhead (operator expertise) is required for success. High quality chemical separations take time, both to develop the method, as well as to achieve each individual separation per sample. Chemical separations in LC, for example, occur on the minutes to hours time scale. In contrast, MS is inherently digital. Ions are generated and analyzed at a rapid rate in discrete packets. MS is acquired on the microsecond to millisecond time scale. The resulting high economic cost of LC in LC-MS is limiting the adoption of MS in many applications.

Droplet based microfluidics is rapidly becoming a transformative technology for LC-MS. The segmentation of samples, standards, and mobile phase into 1- and 2-dimensional linear microfluidic arrays effectively digitizes LC. As a result the MS is no longer tied to the timescale of the separation. The mass spectrometer may now be used in entirely new ways.

Here we will present some of the fundamental advantages of nanospray for the coupling of high speed segmented droplet flow microfluidics. These unique characteristics preserve the integrity of the fluid flow, as well as the optimizing MS performance. A novel approach for in-line SPE using structured droplet arrays will be presented.

Abstract Text

Investigations of metabolite profiles from endothelial cells cultured for multiple days on a hybrid polydimethylsiloxane (PDMS)/glass chip will be discussed. To mimic the cardiovascular environment, aortic endothelial cells are cultured in a PDMS-based microfluidic platform with continuous flow imparting physiological shear stress (>15 dynes/cm²). Cells are viable and maintain physiological shape for longer than 7 days under these conditions. Novel cell lysing methods are employed to optimize reproducibility, reduce artifacts from sample preparation, and minimize manual sample preparation steps. Removal of enzymes and lipids from the metabolite lysate will be explored. Leveraging the porosity/low back pressures of monolith columns, flow based culture systems and sample preparation can be joined. Monolithic stationary phases will be used for metabolite preconcentration. Metabolites relevant to glucose metabolism and oxidative stress will be evaluated as a function of external glucose stimuli. Both MALDI and ESI-based mass spectrometry will be employed for metabolite identification.

Abstract Text

Mass spectrometry imaging techniques can currently obtain excellent spatial resolution for small molecules, but imaging of larger molecules is obtained at the expense of resolution. Novel approaches are needed to bring large biomolecule mass spectrometry analysis to the sub-micrometer size regime. Laser-based methods such as matrix-assisted laser desorption ionization (MALDI) using conventional laser focusing configurations are currently limited to a resolution of 10 to 100 μm by the ability to focus the laser using conventional optics. In this project, we are using an atomic force microscope (AFM) to image the sample and to focus the laser energy for sample ablation for analysis of the captured material by mass spectrometry. The system uses the AFM and tip enhanced laser ablation to transfer biomolecules from cell and tissue samples from the AFM stage to a microfluidic system for analysis by nanoelectrospray ionization or matrix-assisted laser desorption ionization mass spectrometry. The metal-coated tip acts as an antenna to focus the light in the optical near field to ablate a spot with a size of 100 nm to 1 μm . Initial studies indicate that amol quantities of peptides can be transferred and analyzed by mass spectrometry with high efficiency. We are investigating the use of separations and protein digestion directly on tissue samples and after sample transfer. Tip-enhanced laser ablation transfer provides a new method for high spatial resolution sampling, microfluidic processing, and mass spectrometry detection will enable the analysis minor biomolecule components of cells and tissue.

Abstract Text

Separations and mass spectrometry are critically important analytical techniques that are useful for a wide range of applications. But a limitation for both techniques is the requirement of laborious, multi-step sample preparation prior to analysis. This has led to great interest in the microfluidics community in the development of automated, integrated techniques to serve as a front-end complements to separation systems and mass spectrometers. Most of this work has relied on the conventional microfluidic device format of planar devices with enclosed microchannels, but a new format known as "digital microfluidics" has recently become a popular alternative. In digital microfluidics, droplets are manipulated electrostatically on open devices (with no channels) bearing an array of electrodes covered with a hydrophobic insulator. Digital microfluidics has significant advantages for sample preparation, including the capacity to handle both liquids and solids (with no risk of clogging), and the ability to address each droplet individually (allowing for absolute control over all reagents). In this talk, I will review a number of methods recently developed using digital microfluidics for processing samples upstream of mass spectrometry and separations, highlighting applications involving core needle biopsies, dried blood spot (DBS) samples, and solid phase microextraction (SPME) probes. I propose that these examples and others suggest that the combination of digital microfluidics with separations/mass spectrometry may be useful for a wide range of applications in laboratory science.

Abstract Text

After decades of development in laboratories and land operations, chemical analysis of submerged objects is starting to become a reality. While the analysis of water at variable depth has been demonstrated in the past using fluorescence spectroscopy and Raman spectroscopy, determination of the atomic composition of submerged objects is much a more complex task. Technology based on laser-induced breakdown spectroscopy (LIBS) has been recently developed for such sub-sea operations. This paper will discuss the operating parameters of a marine LIBS analyzer. Metals, alloys, rocks, marble, concrete, can be analyzed at a depth of up to 50 m. The system has been tested in several coastal surveys in Mediterranean waters.

Abstract Text

The use of chemical analysis and comparison of materials that are of interest to forensic scientists is possible by the progression from fundamental research and method development, validation in several forensic laboratories and the publication of international standards. While analytical standards such as ASTM do not currently exist for the application of LIBS in forensic analysis, evidence is mounting that analytical LIBS is fit-for-purpose for the elemental analysis of materials including glass, paint, soils, precious metals, diamonds, paper and ink on paper. Laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) has been called the “gold” standard for solid-sampling and high-sensitivity elemental characterization of materials providing sub-ppm detection limits while providing true quantitative analysis data that can be used in numerical/statistical hypothesis testing to determine “match” and also to populate databases that are useful to determine the probability of a match for a given elemental profile. More than 30 forensic laboratories around the world now routine employ the use of LA-ICP-MS for materials characterization but there is an opportunity for many more laboratories to adopt LIBS as an analytical alternative to the expensive and complex LA-ICP-MS methods. This presentation compares the analytical figures of merit of LIBS to LA-ICP-MS for the analysis of several matrices of importance to forensic scientists. A comparison of the type of information gathered from LIBS and how the data is interpreted is also presented. Recent advances in instrumentation and data analysis schemes now makes analytical LIBS a viable alternative to LA-ICP-MS and other elemental analysis methods within the forensic science laboratory.

Abstract Text

There is a well-known and urgent need in the fields of medicine, environmental health and safety, food-processing, and defense/security to develop new 21st Century technologies for the rapid and sensitive identification of bacterial pathogens. In only the last ten years, LIBS has become a potential candidate technology for this application. LIBS' significant advantages over current as well as other competing emerging technologies include speed (< 1 sec analysis), portability, robustness, lack of consumables, little to no need for sample preparation, no need for genetic amplification, no need for user expertise, and the ability to identify all bacterial pathogens without bias (including spore-forms and "viable but non-culturable" specimens).

In this talk I will present the latest achievements of our lab to more fully develop LIBS-based bacterial sensing. We have uniquely identified species from over five bacterial genera with high-sensitivity and specificity (chart 1). We have shown that bacterial identifications are unaffected by environment, nutrition media, or state of growth. We have shown that accurate diagnoses can be made on autoclaved or UV-irradiated specimens (chart 2). Efficient discrimination of bacteria at the strain level has been demonstrated. A rapid urinary tract infection diagnosis has been simulated with no sample preparation (chart 3). We have shown that efficient discrimination is possible in contaminated or "mixed" samples (chart 4) and a variety of autonomous multivariate analysis algorithms have been investigated.

I will then review the challenges facing us as we transition from laboratory demonstration experiments to more commercial biolab techniques and instrumentation. These challenges include: identifying a suitable substrate for mounting the bacteria, concentrating a number of cells for sufficient signal-to-noise from a clinical specimen, and introducing a limited number of cells reproducibly into the analytic spark.

Abstract Text

In this presentation, we review the various LIBS applications to combustion science including combustion products and flame diagnostics. The measurements of temperature, fuel concentration and equivalence ratio using LIBS in various flames have been investigated. Atomic emission from laser-induced plasma of various flame conditions was recorded. The intensity ratios of elemental lines of N, H and O present in the LIBS spectra were found correlated with the equivalence ratio. The technique has successfully tested with various flames (e.g. methane/air, biodiesel flames, kerosene/air mixture, internal combustion engines, etc.). LIBS is also capable of being used as an engine health monitor to detect trace amount of metals emerging from any part of a engine during a diagnostic test. By comparing LIBS spectra and standard atomic emission from a rocket engine simulator, it was found that the LIBS technique has several advantages over standard emission methods to serve as a rocket engine health monitor due to its ability to provide time and spatially resolved measurements and improved detection limits for the metallic species. The various experimental parameters that are important to combustion application will be addressed. Various data processing methods to improve measurement accuracy will be compared. The possible other combustion applications will also be discussed.

Abstract Text

Drug testing for sports doping control is a complex and very challenging task. Firstly, the List of Prohibited Substances, updated annually by World Anti-Doping Agency (WADA), includes numerous classes of banned compounds having different chemical and pharmacological properties. Secondly, monitoring of these substances by anti-doping testing laboratories needs to be fast and efficient to analyze a large number of samples. Special attention must be paid to the sample preparation steps prior to instrumental analysis. Thus the objective of current research was to develop an automated method for the simultaneous multi-residue analysis of doping substances from urine, plasma, blood and saliva using solid phase microextraction (SPME) followed by LC-MS(/MS) and GC-MS analysis.

In this talk we will present the first successfully developed and validated SPME protocol, which requires very little sample handling for simultaneous analysis of more than 100 prohibited doping substances from urine. The optimization of method will be demonstrated and the results of validation according to the Food and Drug Administration (FDA) and WADA criteria will be provided. Additionally, aiming to improve the coverage of most polar prohibited drugs, the use of hydrophilic-lipophilic balance (HLB) SPME coatings for direct extraction of such substances from human plasma will be shown. We will also discuss the potential of using saliva as an alternative to urine and blood testing. We will demonstrate the use of HLB thin films for the extraction of the compounds followed by solvent and thermal desorption and with subsequent LC-MS and GC-MS analysis, respectively. Full validation of the method including precision, accuracy and matrix effect will be presented.

Abstract Text

Enantiomeric separations have played a pivotal role in pharmaceutical science and drug development for over 25 years. While some consider the technology to be mature, new advances and developments have continued to the present time in both analytical and preparative separations. Furthermore the “chiral separations” are providing valuable information in many other fields. Recently these techniques were used to show that “natural” substances in unregulated nutritional supplements were likely synthetic stimulants. Many neurotransmitters are chiral and can be indicative of altered vs. normal brain chemistry. New techniques developed in our laboratory have produced ultra-fast enantiomeric separations, often in less than 20 seconds. A comparison of these new vs older separation approaches will be made and discussed in terms of doing “real time” analysis of the drugs and/or their effects on biological systems.

Abstract Text

Clandestine laboratories constantly produce new synthetic cannabinoids to circumvent legislative scheduling efforts, challenging and complicating toxicological analysis. New designer drugs identification is an important anti-doping issue; however, synthetic cannabinoids metabolism and appropriate urinary target analytes are frequently unknown. With more than a 100 new synthetic cannabinoids identified in the last 6 years, these novel psychoactive substances are the emerging face of drug abuse.

We determined the most important urinary metabolites of new synthetic cannabinoids for which no metabolism information was available, and developed and validated qualitative and quantitative LC-MS/MS assays. We first incubated the drugs with human liver microsomes to determine the drug's metabolic stability. New synthetic cannabinoids were incubated with human hepatocytes, followed by high-resolution mass spectrometry (HRMS) characterization of the synthetic cannabinoid metabolic profile. To date, this approach determined the metabolic profiles of XLR-11, AKB-48, RCS-4, RCS-8, STS-135, UR-144, AB-PINACA and 5F-AB PINACA. These data enabled laboratories to search for these metabolites to identify drug intake, tie adverse effects to specific synthetic cannabinoids, and educate the public on the danger of these new drugs. In addition, reference standard manufacturers could identify the most appropriate metabolites to synthesize and market.

Our latest HRMS urine method simultaneously identifies the most current 47 synthetic cannabinoid metabolites from 21 synthetic cannabinoid families. SWATH™ MS data were acquired in positive electrospray mode. Identification criteria included molecular ion mass error, isotopic profiles, retention time and library fit criteria. This non-targeted acquisition technique enables easy addition of new synthetic cannabinoid markers and the ability to return to the data later to search for newly identified novel psychoactive substances.

Abstract Text

On-site sample preparation is an analytical approach based on direct sampling from the system under investigation. It has the advantage of combining sampling and sample preparation in to a single step, thus generally is fast, minimizes the potential sources of error and eliminates the risks for analytes instability. For such analysis solid phase microextraction in thin film geometry (TF-SPME) can provide robust and convenient in vivo sampling offering in the same time faster analysis and higher extraction recovery (i.e. better sensitivity) due to large surface to volume ratio.

In this study, TF-SPME in coated blade and membrane formats were used for in vivo and ex vivo saliva analysis by comparing the LC and GC based coverage of analytes with a single type of extraction phase. Due to applicability for wide range of polarity of analytes as well as thermal and solvent stability during the desorption, hydrophilic lipophilic balanced particles (HLB) were chosen as extraction phase and used for fast (5 min) in vivo and ex vivo sampling. The results of metabolomic profiling of the saliva are indicating that even 5 min in vivo sampling using TF-SPME followed by GC and LC analyses provides complementary coverage of wide range of analytes with different physical and chemical properties. To demonstrate the applicability of the method for doping analyses, the method was validated successfully for simultaneous quantification of 49 prohibited substances with limit of quantification (LOQ) ranging between 0.004-0.98 ng/mL. Moreover, the method was also validated and successfully applied for determination of endogenous steroids in saliva where the concentrations of the analytes are substantially low. The developed assay offers fast and reliable multiresidue analysis of saliva as an attractive alternative to the standard analysis methods.

Abstract Text

We report here the first use of oligonucleotide-modified substrates as diagnostic tools for the direct identification of mutations in the influenza virus genome related to virulence. In these studies we target: 1) the N66S gene mutation within the PB1-F2 protein, and 2) neuraminidase (NA) stalk deletion mutants. The method employed 5'-thiol-modified ssDNA sequences as probes to capture RNA isolated from avian and reverse genetics influenza viruses containing low virulence or high virulence determinants. We used a label-free and amplification-free optical read-out method, i.e. Raman spectroscopy, to determine the efficacy of binding. The Raman spectra of both high virulence and low virulence DNA-RNA target complexes showed high similarity; therefore, multivariate analysis was used to identify target binding. Binary classification models were developed to distinguish complementary from non-complementary DNA-RNA target hybrids. The SVM-DA model that was developed using a radial basis function kernel resulted in calculated values of 95 – 100% sensitivity, specificity, and correct classification of the test samples with small root-mean-square errors of prediction.

These studies establish that optical-based Raman diagnostic methods are able to sensitively and accurately detect influenza virus RNA mutations linked to pathogenicity in emerging highly pathogenic avian and pandemic influenza viruses without amplification or labeling. The results are also the first demonstration of the use of real influenza viral RNA for direct identification of diagnostic indicators of influenza virulence. Future work will address the applicability and robustness of this platform for more relevant containing the target viral RNA in complex influenza isolates.

Abstract Text

Directly detecting low concentrations of small molecules relevant in genomics, metabolomics, proteomics, etc. is often limited by similar molecular structures and function of the target species as well as complex sample matrices. When nanoparticles are used to facilitate detection, an additional limitation of signal irreproducibility from changing surface functionality further complicates detection. Often, biological recognition elements in these sensors are composed of antibodies, functional groups, nucleic acids, etc. Because surface recognition layers can exhibit variability as a function of temperature, matrix, shelf life, and pH; surface chemistry and quality control measures that promote both nanomaterial stability and responsiveness are vital and motivate our investigations. In this presentation, the design of stable, bio-responsive plasmonic nanostructures for the detection of biologically-relevant metabolites in a high throughput, sensitive, and selective manner thereby combating current dynamic metabolite detection limitations. Localized surface plasmon resonance (LSPR) spectroscopy and surface enhanced Raman scattering (SERS) will be discussed for applications in the direct, qualitative and quantitative detection of small biologically relevant molecules. In the future, exploitation of these perm-selective surface chemistries on SERS substrates for the direct transport and high throughput and sensitive detection of trace metabolites in complex sample matrices is expected to provide new opportunities for metabolomic analyses.

Abstract Text

Surface-enhanced Raman spectroscopy (SERS) is particularly powerful for biosensing because it can obtain the fingerprint information of the system we are interested in under the aqueous and ambient conditions, but with a much higher sensitivity compared with normal Raman spectroscopy. To obtain SERS signal of biomolecules (including amino acids, proteins, metabolites, and etc.) with very good reproducibility and high sensitivity is extremely important for a wider application of SERS in biological systems and is also a great challenge for SERS.

To address the issue, we proposed two direct detection methods. One is to mix the target molecules with metal colloids of high concentration and the detection is performed during the drying process, and the maximum sensitivity can be achieved right before the complete drying of the colloidal solution. This technique is called metastable SERS technique, which allows the SERS detection of 20 common amino acids and some important peptides with a highly reproducible signal.

□

The second method is to modify the surface of SERS-active nanoparticles or solid SERS substrates with some halide ions. Proteins were found to interact with the modified substrate via electrostatic interaction. The SERS signal of protein is enhanced by at least 1000 time over the solution species, but showing almost identical feature to that of the solution signal of proteins. This method allows the quantitative analysis of proteins and mixture of proteins. We further successfully extended this method for the DNA detection.

Abstract Text

The ability to identify and quantify multiple chemical analytes in biological fluids is key to utilizing the diverse molecular composition for biomedical diagnostics. In particular the array of metabolites found in biological fluids can provide a larger picture about a person's health. The current state of the art is a separation followed by mass spectrometry, which can be challenged when identifying many relevant small molecules. Our laboratory has developed a high throughput surface enhanced Raman (SERS) sensor that provides complementary detection to mass spectrometry and improved limits of detection appropriate for molecules in biological fluids. Preliminary results indicate utility for both targeted metabolomics, but also the potential for metabolic profiling. In this presentation we will discuss the development of the flow detector, results from coupling the detector to chemical separations, and the application of this sensor to the detection and quantification of metabolites in biological fluids.

Abstract Text

Dried blood spot (DBS) sampling, as a microsampling technology, reemerged and has attracted great interest in the pharmaceutical industry as a viable alternative to plasma/serum sample collection for toxicokinetic (TK) and pharmacokinetic (PK) studies. One of the main challenges to a wide application of this technology is the sometimes negative impact on the assay performance by study sample hematocrit. One solution to address this issue is to implement accurate sample volume collection for each DBS sample and perform the sample analysis using the entire DBS sample. Depending on the type of study, implementing this accurate pipetting can be challenging. The ideal characteristics for dried matrix microsampling technology should include the ease of use (during sample collection and sample analysis), consistent and accurate sampling volume, etc. BMS, along with other industry peers, has been involved in the evaluation of a new microsampling technology called Volumetric Absorptive Microsampling (VAMS™). This presentation will discuss the preliminary evaluation results and potential advantages /further improvement need of using this technology.

Abstract Text

Extensive investigation of dried blood spot (DBS) microsampling over the last few years has stimulated a renewed interest in all forms of microsampling. In addition to the advantages of small sample volumes, dry microsampling formats may also offer significant logistical advantages for sample handling, storage and shipment. However, widespread adoption of DBS has been limited by concerns about regulatory acceptance and potential technical issues, notably the potential for hematocrit changes to affect method accuracy. These concerns have led to investigation of various wet microsampling techniques as well as the development of improved dry sampling devices.

None of the above concerns are truly significant in the context of supporting early drug discovery studies, where DBS can provide a simple and practical method for collection of very low volume blood samples. Such low sample volumes can provide unique opportunities for pharmacokinetic sampling in various pharmacological, pharmacokinetic and toxicological studies conducted in small animals, both reducing animal use and improving data quality. A number of examples will be presented where minimal volume DBS sampling has allowed PK samples to be collected in sensitive pharmacology or toxicology models, and for full PK profiles to be collected from individual animals in studies in mice.

More recently a novel dried blood sampling device has become available that reliably absorbs 10 microliter volumes of blood and does not appear to be affected by changes in hematocrit. Investigation of this device for use in mouse PK studies will be described including a detailed comparison with results obtained with (wet) whole blood sampling. In addition, validation of an ELISA method for a monoclonal antibody drug using this device will also be reported, where similar performance was demonstrated to previous validations conducted with serum samples and DBS cards.

Abstract Text

As a micro-sampling tools DBS (Dried Blood Spot) Cards are used because of their simplicity, the small volumes of blood collected, low cost, and ease of transport. In a normal work routine a small disk is punched out of the DBS card. The amount of blood in these sub punches varies because the hematocrit of a blood sample mediates its viscosity and, therefore, how far the blood spreads out on a card. This leads to a volumetric assay bias that is a function of sample hematocrit.

We will describe a device comprised of a porous hydrophilic "tip" that is designed to have a controlled internal porous volume of 10 μ L. When this tip is touched to any aqueous fluid it will rapidly wick the fluid into its internal volume through capillary action. We will describe a series of evaluations that show the use of this device as a volumetric blood collection tool that can be dried, and then extracted for analysis (like a DBS card), but that overcomes the volumetric assay bias due to hematocrit. We will present experiments illustrating the volumetric accuracy of the device (regardless of hematocrit), the wicking speed of the device as a function of temperature and hematocrit, and the rapid drying of the sample on the device for storage. Extraction methodologies and analysis of analytes from the tip are shown, along with example assays with hematocrit bias < \pm 15%, and studies of on-tip analyte stability over 14 days demonstrate less than \pm 20% overall assay bias.

Abstract Text

New technologies to diagnose malaria must have high sensitivity and specificity to enable the detection of premature parasitic forms namely ring and gametocytes in peripheral blood. Diagnostic techniques must also be portable and robust to be transportable to remote communities on motorcycles. During the course of its life the malaria parasite transgresses through several developmental stages including a sexual and an asexual reproductive pathway. The intraerythrocytic asexual phase of the life cycle commences when merozoites invade red blood cells (Figure 1). The merozoites grow and divide in the food vacuole and progress through three distinct morphological phases known as the ring, trophozoite and schizont stages. The schizonts burst releasing the merozoites and the intraerythrocytic cycle continues. Instead of replicating, some merozoites in the RBCs develop into sexual forms of the parasite, called male and female gametocytes, which like the ring forms circulate in the bloodstream. The detection of the rings and gametocytes at low parasitemia in peripheral blood is critical for early diagnosis and treatment. We demonstrate that ATR-FTIR spectroscopy in combination with a partial least squares regression models has the required sensitivity and ease of sample preparation to become a standard for malaria detection and most importantly quantification. The project is now set for a clinical trial in Thailand and the results of that trial will be presented at the meeting.

Abstract Text

Breast cancer is the most frequently diagnosed cancer and the leading cause of cancer death in women worldwide. The development of disruptive technologies for diagnosis and prevention has, thus, become of prime importance to mitigate and potentially eliminate the impact of metastatic breast cancer-related morbidity and mortality. To this end, we seek to develop Raman spectroscopic assays for sensitive assessment of change in tumor burden to allow early detection of recurrence and to aid in the evaluation of new therapies while the tumor burden is low with the hope of improving cancer outcomes. In this context, the need of addressing both the field enhancement and the extinction of nanoparticle suspensions, however, has been underappreciated despite its substantive impact on the sensing performance. Here, we perform the systematic experimental investigation of SERS enhancement and attenuation in suspensions of gold nanostars, which exhibit markedly different behaviors in relation to conventional nanoparticles. We elucidate a remarkable relationship between the SERS enhancement and the localized surface plasmon resonance band, and probe the effect of the gold nanostar concentration on the signal propagation.

Abstract Text

Kidney transplantation is the main treatment for end-stage renal disease, however close monitoring of post-transplant biopsies is required to monitor and identify subclinical complications. In this study, we focused on identifying biochemical markers associated with recurrent diabetic nephropathy using Fourier Transform Infrared (FT-IR) spectroscopic imaging. FT-IR imaging is an emerging approach to obtain label-free images of the biochemical composition of tissue biopsies. Initial studies focused on identifying archival FFPE tissue blocks of 8 patients with no evidence of diabetic nephropathy and 8 patients with advanced diabetic nephropathy. Serial sections were acquired and stained with PAS or placed on an IR compatible substrate. High definition IR images were acquired. A diagnosis was made of the degree of diabetic glomerulopathy based on the PAS stain. IR spectra were extracted from the different glomerular and tubular structures and compared to identify biomarkers associated with diabetic nephropathy progression. A second study identified three transplant patients with multiple surveillance biopsies who underwent very rapid recurrent diabetic nephropathy within two years and three normal patients with no evidence of diabetic nephropathy after two years. A number of biomarkers were identified that were shown to change in glomerular and tubular structures associated with increasing severity of nephropathy due to diabetes. Increased levels of glycation and of the symmetric phosphate band were consistently found to be increasing in the cohort of patients that had multiple surveillance biopsies and underwent rapid diabetic nephropathy recurrence suggesting that these features may be used to be predictive of early changes associated with diabetic nephropathy. FT-IR imaging is potentially powerful adjunct to current pathological methods allowing for the label-free and rapid identification of early markers of transplant complications.

Abstract Text

Achieving maximal, safe resection is the central goal of brain tumor surgery. One of the greatest barriers to optimal surgical outcomes in brain tumor surgery is the ability of surgeons to accurately differentiate normal from tumor-infiltrated brain. We have applied a nondestructive, label-free technique, stimulated Raman scattering (SRS) microscopy to detect tumor infiltration within the human brain. Here, we used SRS microscopy to image specimens from series of neurosurgical cases. The resulting data suggest that SRS microscopy is a highly accurate method for detecting tumor infiltration within the human brain that holds promise for improving the surgical care and study of human brain tumors.

Abstract Text

Surface enhanced Raman scattering (SERS) is an analytical technique with several advantages over competitive techniques in terms of improved sensitivity and multiplexing. We have made great progress in the development of SERRS as a quantitative analytical method, in particular for the detection of DNA. However, the lack of quantitative data relating to real examples has prevented more widespread adoption of the technique. Detection of specific DNA sequences is central to modern molecular biology and also to molecular diagnostics where identification of a particular disease is based on nucleic acid identification. Here we demonstrate the development of new molecular diagnostic assays based upon SERS which have been used successfully for the detection of bacterial pathogens associated with meningitis using modified SERS active probes. The probes have been designed to give a specific SERS response resulting in discernable differences in the SERS which can be correlated to a specific DNA hybridisation event. In this presentation the simultaneous detection and quantitation of 3 pathogens will be demonstrated.

Functionalized nanoparticles are a key component of the modern bionanotechnology area. We favour the use of functionalised nanoparticles as sensing materials for the detection of DNA at ultra low levels, proteins and more recently as substrates for imaging approaches. We achieve this by combining functionalised silver or gold nanoparticles with the spectroscopic technique of surface enhanced resonance Raman scattering (SERRS). This combination can result in extremely sensitive and selective biosensing with unprecedented multiplexing capabilities. This presentation covers the full range of design, the optical properties and finally the biological properties of functionalized nanoparticles in relation to their assembly and how that relates to the provision of new biological knowledge.

Abstract Text

Recently, a number of proof-of-concept studies have shown that molecular spectroscopic techniques such as infrared absorption and Raman are capable of distinguishing diseased from non-diseased cells and tissue based upon the inherent chemistry contained within the cells. The presentation will review recent advances in the development of Infrared absorption and Raman spectroscopic modalities for applications in clinical diagnostics. It, and the subsequent discussion, will be guided by the UK EPSRC Network, Clinical Infrared and Raman Spectroscopy for Medical Diagnosis (CLIRSPEC-<http://clirspec.org/>), whose aims are to move forward the clinical application of IR and Raman spectroscopy by identifying barriers to their implementation in the clinical environment and, through multidisciplinary sandpits, propose ways to overcome these barriers. Specific objectives include:

1. To develop our understanding of the interaction of light with clinical samples
2. To develop internationally recognised protocols for the preparation of cells, tissue and biofluids for clinical spectroscopy
3. To provide evidence of the power of spectroscopy for use in the clinical arena
4. To determine the requirements of instrumentation suitable for use in the clinic
5. To develop strategies for pre-processing and statistical analysis in clinical spectroscopy
6. To develop inter-group data sharing protocols and portal

The presentation will thus identify key considerations under each objective, laying the platform for the subsequent open discussion forum.

Abstract Text

Thin films of redox-active block copolymers can be used as mediators for electrochemical enzyme sensors and as platforms for redox-controlled molecular deposition. For these applications, it is important to understand how to control the electron propagation efficiency of nanoscale redox-active microdomains formed in these films. This presentation will report our systematic studies on electron propagation through ferrocene-containing microdomains with different nanoscale morphologies. Specifically, three polystyrene-poly(2-(acryloyloxy)ethyl ferrocenecarboxylate) diblock copolymers (PS-*b*-PAEFc) with different PAEFc volume fractions (0.17, 0.30, 0.47) were synthesized by two-step atomic transfer radical polymerization. Their thin films were prepared on gold substrates via spin-coating, and characterized using spectroscopic ellipsometry and atomic force microscopy. Their electrochemical properties including the percentages of reactive ferrocene moieties and electron propagation efficiency (apparent diffusion coefficients) were quantitatively assessed using cyclic voltammetry and chronocoulometry.

Abstract Text

An important semiconductor nanocluster (SCNC) property is the propensity to accept and donate electrons, making them ideal candidates for use in solid-state devices. In order to maximize charge generation and transport in these devices, ligand-coated SCNCs must be considered as single, charge-state definable, inorganic-organic hybrid molecules (hard inorganic core and soft organic surface), where fundamentally new electronic, photophysical, and electrochemical properties emerge at the SCNC-ligand interface. We have investigated the mechanism of electronic interaction between strongly quantum confined CdSe SCNCs (<2.0 nm diameter) and surface passivating ligands through combined optical and electrochemical techniques. Solution phase electrochemical measurement showed that the highest occupied molecular orbital (HOMO) peak position and columbic interaction energy of electron-hole pairs of ligand-coated SCNCs were strongly influenced by the chemical functionality of the surface passivating ligands. Quantification of HOMO position and interaction energy will provide insight into the mechanisms controlling the interfacial electronic interaction between SCNCs and surface ligands, which together improve the overall stability of hybrid molecules and control the generation and transfer of charge carriers.

Abstract Text

Our group develops electrochemical methods to study semiconductors in colloidal suspension. In one example, we study photocatalytic processes of colloidal semiconducting nanoparticles. We have demonstrated the detection of individual anatase nanoparticles interacting with an electrode by photoelectrochemical currents. These interactions carry information about the photochemical process at the single nanoparticle level of the electron transfer reactions for the photooxidation of methanol, proposed as a model system. We first demonstrated the detection of titanium dioxide nanoparticles where the step-wise increase in current was assigned to the particle by particle contribution of the photocurrent (J. Am. Chem. Soc., 2013, 135, pp. 10894–10897). The step by step detection corresponds to the so-called sticking interactions where the irreversible attaches to the electrode surface but we have also been able to observe the transient interactions of the NPs with a microelectrode. The effect of NP aggregation as studied by dynamic light scattering will be discussed in this seminar. Also the effect of using different electrode materials on the photocurrent will be covered. Our more recent advances include detecting nanoparticles that have been modified with a dye with used for the dye-sensitized solar cells. We have also been able to detect the NP interactions of different materials, such as CdSe bare and covered with a layer of ZnS.

Another example covers studies of size-dependent electrochemical properties of ZnO nanoparticles. The NPs are reduced using a Hg microelectrode to reduce the Zn ions in the ZnO lattice to a Zn(Hg) amalgam. We demonstrate the size dependence of the reduction potential of ZnO nanoparticles.

Abstract Text

In this talk, I will present our research on single-nanoparticle electrochemistry. A carbon fiber ultramicroelectrode (UME) is used to study electrochemical and electrocatalytic activity of single gold/platinum nanoparticles. In this work, we use fast-scan cyclic voltammetry at ~ 500 V/s to measure transient voltammetric response of single nanoparticles undergoing free diffusion and collision with the probe UME. Kinetic information has been obtained from individual particles by analyzing their voltammetric response. This research demonstrates a new method to obtain chemically resolved information about transient particle–electrode interactions which is otherwise difficult to obtain with previous constant-potential techniques. Voltammetric responses can be obtained at single colliding NPs with millisecond time resolution prior to and after particle collision and immobilization. Such information can be particularly valuable for future mechanistic studies for electrocatalytic NPs such as particle–electrode interaction, particle activation and deactivation, and heterogeneous electron-transfer kinetics.

Abstract Text

There has been an enormous effort to study the electrochemistry of metal nanostructures to gain a better fundamental understanding of nanoelectrodes, study single particle electrochemical reactivity, and exploit nanostructures for electrocatalysis and electrochemical sensing. Our group has recently studied the electrochemical oxidation of metal nanoparticles as a function of size due to its relevance to nanoparticle stability, which is a critical issue for most applications. In these studies, we measured the oxidation potential of an array of Au and Ag nanoparticles attached chemically to glass/ITO electrodes, where the particle attachment occurred by diffusion to the electrode surface. For nanoparticles in the 1-4 nm diameter range, this leads to multiple oxidation peaks correlating to different size populations in disperse samples. In this presentation, we describe the size controlled assembly of nanoparticles on electrodes by electromigration. The size and amount of nanoparticles attached to the electrode surface strongly depends on the magnitude of the electrode potential during assembly and the direction of the voltage (negative or positive). Under certain conditions, we selectively assembled a large coverage of 1-2 nm diameter Au nanoparticles on the electrode with no evidence of aggregation. It is possible to selectively attach small nanoparticles in the presence of larger particles by controlling the voltage during assembly. The controlled assembly of small nanoparticles at large coverage on the electrode may find use in nanoparticle separation and purification and for electrocatalysis and sensing applications.

Abstract Text

The utility of biological nanopores for the development of sensors has become a growing area of interest in analytical chemistry. Their emerging use in chemical analysis is a result of their reproducible control over nanoscale pore sizes with atomic level of precision and amenability to resistive-pulse type measurements. A single binding event causes a change in the flow of millions of ions across the membrane per second that is readily measured as a change in current with excellent signal-to-noise ratio. To date, ion channel-based biosensors have been limited to well-behaved proteins utilizing channels that remain in the open, conducting state, with little-to-no chemical specificity. In this talk, we explore the use of naturally occurring channels with inherent chemical specificity to build sensors. Specifically we utilize heat shock cognate 70 (Hsc70) to quantify the presence of adenosine triphosphate (ATP). Because Hsc70 forms ATP-dependent multiple conductance states we introduce the measurement of 'charge flux' across the lipid bilayer membrane to quantify ATP. We believe that monitoring protein-induced charge flux across a bilayer membrane represents a universal method for quantitatively monitoring ion-channel activity. Furthermore, we have transitioned measurements of Hsc70 to the glass nanopore membrane to create robust sensors with long-term stability.

Abstract Text

Over the past decades, ultramicroelectrodes and nanoelectrodes have found wide applications in bioimaging and biomedical analysis. However, they have not been used in the fabrication of folding- and dynamics-based electrochemical biosensors. This presentation will highlight our recent advancement in employing gold-modified recessed platinum (Pt) nanoelectrodes in the fabrication of both stem-loop (SLP) and linear probe (LP) electrochemical DNA (E-DNA) sensors. We have successfully fabricated Pt nanoelectrodes with a radius less than 10 nm using an optimized laser pulling technique. Prior to sensor fabrication, the nanoelectrode is electrochemically etched to create a recessed nanopore, followed by electrodeposition of gold into the nanopore using either cyclic voltammetry or constant potential amperometry. Both techniques enable controlled deposition of gold into the nanopore, resulting in a nanostructured gold electrode with a well-defined surface area. In addition, we have systematically optimized the experimental condition for DNA probe immobilization and target interrogation. Both SLP and LP E-DNA sensors respond well to the full complementary target DNA. The extent of signal reduction is similar to that observed with sensors fabricated on macroscopic gold disk electrodes. While the application of these electrodes for real time biosensing in living cells requires further investigation, our results clearly show that these gold-modified nanoelectrodes can be used as substrates for this class of electrochemical biosensors.

Abstract Text

Well-controlled array of nanopore structure with all components of battery is described. This nanopore battery structure provides a test-bed for examining the ion transport limits in nanostructured storage and may bring a new opportunity for an ultimate miniaturization in energy storage. We report a nanobattery comprised of nanotubular electrodes and electrolyte confined within an anodic aluminum oxide (AAO) nanopore as an “all-in-one” nanopore device. The nanoelectrodes include Ru nanotube current collectors with V₂O₅ storage material on top of the Ru to form a symmetric full storage cell, with anode and cathode separated by an electrolyte region. The V₂O₅ is prelithiated at one end to serve as anode while pristine V₂O₅ at the other end serves as cathode, so that the battery can be asymmetrically cycling between 0.2V and 1.8V. Capacity retention of this full cell at high power (relative to 1C values) is 95% at 5C and 46% at 150C. At 5C rate (12 min charge-discharge cycle), 81.3% capacity remains after 1000 cycles. The all-in-one nanopore battery poses an extreme case of highly confined organic electrolyte environments in ultrasmall batteries and provides a valuable data source for fundamental modeling to understand and quantify a science of “nanoionics” – a mesoscale phenomenon resulting from dense packing of ion storage nanostructures. In addition, upon extensive interest in creating more complex fully interconnected 3D porous film as a materials scaffold, understanding and manipulating the structure of AAO is a critical step for developing new techniques for the rational fabrication of 1D and 3D nanomaterials. A good understanding of the factors which impact structural control and the ability to combine multiple modification techniques in a single structure may open pathways to new structures with a wide variety of applications.

Abstract Text

AFM-IR, the combination of atomic force microscopy and infrared spectroscopy, has provided a dramatic improvement in the ability to chemically characterize materials at the nanoscale. The AFM provides extremely high spatial resolution, but historically has been without broadly applicable techniques for chemical analysis. Infrared spectroscopy, on the other hand, has excelled at chemical analysis, but has spatial resolution limited to the scale of many micrometers. The combination of AFM and infrared spectroscopy provides nanometer scale spatial resolution and robust chemical analysis in a single platform. The AFM-IR technique has recently been improved to enable chemical imaging and spectroscopy on a much more diverse range of samples, including thick and opaque samples. Additionally, the AFM-IR sensitivity has been dramatically improved to enable spectroscopic measurements on extremely thin films, down to single polymer lamellae, lipid membranes and even self assembled monolayers. This presentation will explore expanding applications of AFM-IR in the materials and life sciences including polymers, composites, thin films, semiconductors, biological membranes, cells, and biominerals.

Abstract Text

Neaspec's near-field optical microscopy systems (NeaSNOM) allow to overcome the diffraction limit of light enabling optical measurements at a spatial resolution of 10nm.

Scattering-type Scanning Near-field Optical Microscopy (s-SNOM) [1] employs an externally-illuminated sharp metallic AFM tip to create a nanoscale hot-spot at its apex. The optical tip-sample near-field interaction is determined by the local dielectric properties (refractive index) of the sample and detection of the elastically tip-scattered light yields nanoscale resolved near-field images simultaneous to topography.

Development of a dedicated Fourier-transform detection module for analyzing light scattered from the tip which is illuminated by a broadband laser source enabled IR spectroscopy of complex polymer nanostructures (nano-FTIR) [2]. Identification of individual contaminants has been demonstrated. Other applications show characterization of embedded structural phases in biominerals [3] or organic semiconductors. The patented modular system design allows for tailored system configurations where the ultimate spectral coverage can be achieved by using synchrotron-based broadband IR light sources [4]. Use of material-selective frequencies for near-field measurements enable to fully characterize local morphology of organic semiconductors [5] or to analyse individual protein complexes at the nanoscale [6].

Abstract Text

By combining scattering-scanning near-field optical microscopy (s-SNOM) with mid-infrared synchrotron radiation, synchrotron infrared nano-spectroscopy (SINS) enables molecular and phonon vibrational spectroscopic imaging, with rapid spectral acquisition, spanning the full mid-infrared (500-5000 cm^{-1}) region with nanoscale spatial resolution. This powerful combination provides access to a qualitatively new form of nano-chemometric analysis with the investigation of nanoscale, mesoscale, and surface phenomena that were previously impossible to study with IR techniques. We have installed a SINS end-station at Beamline 5.4 at the Advanced Light Source (ALS) at Lawrence Berkeley National Laboratory, making the s-SNOM technique widely available to non-experts, such that it can be broadly applied to biological, surface chemistry, materials, or environmental science problems. We demonstrate the performance of synchrotron infrared nano-spectroscopy (SINS) on semiconductor, biomineral and protein nanostructures, providing vibrational chemical imaging with sub-zeptomole sensitivity.

Abstract Text

Near-field superlenses [1] have the ability to break the diffraction limit due to the resonance of surface plasmon (or phonon) polaritons (SPPs) and enable applications like optical lithography and near-field imaging. Combining the superlens with scattering-type-near-field optical microscopy (s-SNOM) [2] enabled subsurface imaging of metallic nanostructures [3]. Up to now, the practical application of the superlens has been limited by its narrow bandwidth and complicated fabrication. We show our latest results on two new superlensing concepts using natural layered 2D-materials that overcome these limitations: Graphene and hexagonal boron nitride (hBN): Graphene, a one-atom-thick planar sheet supporting surface plasmons at frequencies in the infrared (IR) and terahertz (THz) spectral range [4,5]. In contrast to conventional superlenses, the nonresonant operation of our so-called "Graphene-Lens" (GL) [6] provides the advantages of a broad intrinsic bandwidth, a low sensitivity to losses and the possibility for continuously frequency-tunable imaging while maintaining a good subwavelength resolution of better than $\lambda/10$. We will show first experimental evidence for graphene superlensing [7]. Finally, we will present our latest subwavelength imaging results using thin layers of hBN, a material that supports surface phonon polaritons [8] and exhibits exciting new subwavelength imaging properties due to hyperbolic dispersion.

Abstract Text

Mid-infrared absorption spectroscopy in the “molecular fingerprint” region is a powerful technique for chemical analysis. The mid-infrared photoexpansion nanospectroscopy was developed recently to measure absorption fingerprint spectra of samples on nanoscale [1]. In this technique, light absorption is detected by measuring associated sample thermal expansion with an atomic force microscope (AFM). Initially, this approach required high-power laser pulses to induce sample heating by 10-50 degrees and sample thickness of at least ~100 nm to produce detectable signal. We have recently demonstrated that the sensitivity of this technique may be improved dramatically to enable nanoscale spectroscopy of samples as thin as molecular monolayers [2]. This was achieved by adjusting the repetition frequency of low-power light pulses from tunable semiconductor quantum cascade lasers to match the mechanical vibrational frequency of the AFM cantilever and by employing tip-enhancement of the optical field below a sharp gold-coated AFM tip. We will discuss the latest development in sensitivity of this technique and present the first results of photoexpansion nanospectroscopy of samples in aqueous environment that requires mitigation of liquid damping of cantilever vibration and absorption of infrared light by water.

This project was supported by the Welch Foundation grant F-1705 and STTR program from the DOE.

Abstract Text

The combination of atomic force microscopy (AFM) and infrared spectroscopy (IR) is a powerful tool that provides chemical, conformational and molecular orientation information at a spatial resolution of 50-100 nm. Using an AFM-IR (Anasys) instrument we have explored the correlation between structure, processing and chain orientation/crystallinity and tested the hypothesis that improved chain orientation in electrospun nanofibers can increase modulus and tenacity even while crystallinity is disrupted by appropriate addition of longer side-chain comonomer compositions. Polymer nanofibers and films have been produced with a wide range of crystallinity and molecular orientation. They have been characterized using polarized AFM-IR spectroscopy and imaging in order to assess the role of processing on orientation and morphology. This talk will highlight the use of AFM-IR to characterize molecular orientation and crystallinity changes as a function of side-chain comonomer concentration and illustrate the importance of obtaining rapid spatial spectroscopic images in inhomogeneous materials.

Abstract Text

Using infrared (IR) near-field nano-imaging (s-SNOM) and nano-spectroscopy (nano-FTIR), we report direct visualization of spontaneous structural and electronic phase transition and phase separation in vanadium dioxide (VO₂). We show that s-SNOM and nano-FTIR are extremely powerful tools to study various types of phase transition materials such as VO₂ single crystals and highly oriented VO₂ films with epitaxial strain. The local strain induced by the substrate not only triggers spontaneous phase separation with facet dependent mesoscopic patterning in VO₂ films but also leads to intermediate electronic and lattice states that are intrinsically different from the bulk single crystals'. This is clearly demonstrated by sampling the IR spectroscopic responses of electrons and phonons in VO₂ with ~20nm resolution. I will also discuss the future applications of s-SNOM and nano-FTIR to many classes of transition metal oxides with low temperature phase inhomogeneities and magnetic orderings at microscopic scale.

Abstract Text

Critically ill patients in the intensive care units (ICU) commonly experience complications such as sepsis, delirium, acute lung injury (ALI) and acute kidney injury (AKI). These complex syndromes are all associated with systemic infections and lead to increased mortality. Currently these disorders are diagnosed through observation of clinical symptoms that are a result of the illness, meaning that treatments are administered reactively rather than proactively. Common to all of the aforementioned disorders is systematic inflammation, therefore biomarkers of emergent inflammation, namely pro- and anti-inflammatory cytokines, might offer a pre-symptomatic glimpse into latent syndrome. Cytokines help regulate inflammation through an intricate network of complementary and contradictory interactions that activate and deactivate different cohorts of immune cells. The complexity of these interactions necessitate a multiplexed approach to monitoring cytokine expression levels, and therefore panel-based diagnostic methods are needed to fully implement inflammatory-based diagnostics in a clinical setting. In response to this challenge, we have developed a powerful biomolecular analysis platform based on arrays of chip-integrated silicon photonic biosensors. Using this technology we have constructed a detection panel to simultaneously monitor fourteen serum-based inflammatory biomarkers and are correlating dynamic expression levels with the clinical outcome of patients being treated in the intensive care unit (ICU) at a local hospital. We expect that the biomarker trajectories of individual patients will reveal prognostic patterns suggesting the onset of complex clinical disorders.

Abstract Text

Solid contact ion-selective electrodes (ISEs) are multilayer structures, which have an intermediate layer between the ion-selective membrane and the electron conductor. The intermediate layer is used to improve reproducibility and stability of these electrodes compared to the coated wire electrode in which the ion selective membrane is in direct contact with the electron conducting substrate electrode. The influence of the intermediate layer composition and/or the electron conductor on the first equilibration time so far has not been studied systematically. The equilibration time is especially important for single use sensors and sensors implemented in point-of-care devices.

In this work we report equilibration times for solid contact ISEs prepared with (Poly(3,4-ethylenedioxythiophene) Polystyrene sulfonate – PEDOT(PSS)) conduction polymer as intermediate layer. The equilibration time is defined as the time interval from the first solution contact of the electrode and the time when the potential drift drops below a threshold value (0.3 mV/min). We have found that the second and third equilibration times are shorter for electrodes, which were kept dry between experiments. In addition, we found significant differences between the equilibration times of solid contact ISEs built on platinum, gold and glassy carbon substrates. The equilibration times were longer using Pt substrate. To trace the source of the unexpected differences in the equilibration times the structure of PEDOT(PSS) on Au and Pt surfaces were studied by X-ray photoelectron spectroscopy, and scanning electron microscope and the potential – time traces of PEDOT(PSS) coated Au and Pt electrodes were recorded.

Abstract Text

Nonspecific binding onto surfaces is an issue that often prevents the successful adoption of some advanced diagnostic technologies. We report a versatile biopolymer-based, antifouling hydrophilic coating material for enhanced diagnostic applications. A chemical modification strategy of hyaluronic acid (HA) with the thermoresponsive polymer poly(di(ethylene glycol) methyl ether methacrylate) (PMEO2MA), a polymer with a lower critical solution temperature of 26 °C in water, yielded an active coating onto a broad range of biomaterials without relying on the chemical functionalization of the surface. The polymer PMEO2MA was grafted onto HA to allow reversible formation of biopolymer coatings. Antibody conjugation of the obtained hydrophilic surface then yielded selectively bioactive, nonfouling surfaces (HA-PMEO2MA/HA-Ab). We demonstrate that the obtained surface significantly reduces non-specific binding to the surface and enhances detection levels of targeted markers. Detection sensitivity of inflammation marker TNF α in serum protein-competitive samples was established using enzyme-linked immunosorbent assay (ELISA) and compared against biolayer interferometry (BLI) detection method to gain kinetic insights. The results showed superior performance of the HA-coated surfaces as compared to the non-coated ELISA plates in protein-competitive samples with error percentages of 5% and 15% respectively. While ELISA is the gold standard in protein detection, HA coatings enhanced detection by better preventing nonspecific binding to the matrix, as well as the simplicity of the coating process, and, as a result, lends itself as a viable option for more versatile and complex platforms.

Abstract Text

A facile and robust method using redox active nanoparticles of cerium oxide to quantify enzyme activity in a single step procedure is reported in this presentation. The method takes advantage of redox changes of nanoceria surface after interaction with products of the enzyme catalyzed reaction, resulting in charge transfer complexes with very strong absorption characteristics. The developed assay is easy-to-use, robust and cost effective and does not require labeled reagents, secondary enzymes or soluble dyes. The assay can eliminate multistep procedures and minimize problems associated with the poor stability of substrates and enzyme labels of conventional enzyme assays. The assay has been adapted to both colorimetric paper and electrochemical sensing platforms and has demonstrated functionality for selected enzyme detection in human serum. This sensing concept can find wide applications as a general approach for improving sensitivity and simplifying detection schemes of colorimetric bioassays, e.g. enzyme, gene, immune and aptamer assays and related affinity sensing methods.

Abstract Text

Since 2001 “early, goal directed therapy” is the accepted protocol for treatment of shock. The protocol essence is careful monitoring of metabolic parameters (venous carbon dioxide (CO₂) and hematocrit) and adapting treatment to their changes. Emanuel Rivers demonstrated mortality decrease from 47% to 31% by following this protocol.¹

A previously unexplored metabolic parameter, urine CO₂, may also indicate prognosis and confer benefit to monitoring. Researchers have shown large differences in urine CO₂ between healthy controls (mean urine pCO₂ of 43mmHg) and hemodynamically unstable patients (mean urine pCO₂ of 79mmHg).² This discrepancy is likely from decreased splanchnic blood flow occurring in shock, where blood CO₂ builds-up and diffuses into urinary bladder.

To investigate utility of urine CO₂ as a prognostic tool for shock we have built a wall-jet type flow through manifold, which allowed continuous monitoring of pCO₂ levels in urine samples, collected from a Foley catheter, with intermittent calibrations. As a pCO₂ probe a commercial Severinghaus CO₂ sensor with a silicon gas permeable membrane was used (Orion Research). Standard solutions were prepared by saturating buffer solutions with medical grade CO₂ gas mixtures as well with an Instrumentation Laboratory tonometer.

In preliminary experiments we showed measurement set up and commercial CO₂ sensor adequate for monitoring CO₂ levels in quality control and human urine samples and developed a protocol for collecting urine samples from the Foley catheter with no CO₂ loss. Next we will test the difference in CO₂ content between patients in septic shock and healthy controls. This study is the first step of knowing the prognostic benefit of monitoring urine CO₂ in septic shock.

Abstract Text

A comprehensive analysis of human metabolites provides significant information on the status of the metabolism with regard to diseases, medication, nutrition or even success of a therapy. However, the proven laboratory analytical methods require in general invasive sampling, transportation to the lab for analysis and finally transfer of the results to the physician in the clinic. As a consequence of this time consuming procedure, in many cases the initiation of a specific therapy is delayed with negative effects for the patient- e.g. higher lethality - and higher cost for the health system. Therefore, there is need for rapid on-site analytical tools for the detection of relevant metabolites in many fields in the health system. Using ion mobility spectrometry with rapid gas-chromatographic pre-separation and non-invasive sampling of e.g. human breath or volatiles from sweat it could be demonstrated, that on-line anesthesia control is possible as well as diagnosis and therapy control in nephrology. This is possible using compound and pattern data bases and a suitable data evaluation and interpretation software. Furthermore, the identification of relevant human pathogen bacteria and fungi is possible after less than 24 hours which could be used for applying a specific antibiotics therapy in good time.

Abstract Text

Comprehensive understanding of a single cell in response to its biological environment and stimuli is the foundation of many biomedical research fields, including drug development, nanotoxicity study, biomarker discovery, cancer diagnosis and treatment, and many other areas. One of the most important parameters is the intracellular pH changes during its exposure to the external stimuli. However, there currently is no such a probe available to perform measurement of intracellular pH without interrupt cellular activities. In this study, a novel tapered fiber-optic and reflection based pH sensor was designed and fabricated for both extra- and intra- cellular pH measurement, providing real-time pH data in mediating a variety of cell responses to external stimuli. The new pH sensor is easy to operate, responds fast, and has high resolution and sensitivity. Real-time sensing capability can be acquired with a response time of 20 ± 5 seconds. A detection resolution of 0.02 - 0.05 pH unit was achieved with good repeatability and reproducibility. The detailed results will be presented at the conference. This project was supported by National Institute of Health (1R21GM104696-01).

Abstract Text

Optical fibers and capillary waveguides have been widely used in laboratory environments for biosensor applications; however, these biosensors have operational and design issues caused by several problems, including fragility, integration, and alignment of light and signals from optical fibers or capillaries, that prevent effective point-of-care usage. To address the challenges associated with optical fibers and capillary biosensors, we report an evanescent wave-based microfluidic capillary fiber-optic biosensor (MCFOB). As shown in the Figure below, the sensor combines capillary biosensors with microfluidic technology by embedding capillaries in a PDMS microfluidic device. Both capillaries and the microfluidic device serve a dual role within the device that enables integration and strengthen capillaries. The capillaries function as an optical element and a reagent vessel, while the microfluidic device serves as a cladding and multichannel for multiplexing. Since the geometry of capillaries has a defined volume, driving the reagent and sample is much easier and does not require complex tools such as pipettes. The alignment issues were addressed by using a CCD camera microscope and designing the capillary array in the plane. This makes detection and alignment from one capillary to another efficient. C-reactive protein (CRP), one of the biomarkers associated with inflammation and other diseases such as traumatic brain injury (TBI), was used to demonstrate the functionality of the MCFOB. A three-channel MCFOB was employed to detect CRP with a limit of detection of 7.6 ng/ml while the normal level of CRP in blood serum is around 640 ng/ml.

Abstract Text

Many different electrochemical and electrophysiological techniques are available to study neurochemical systems which can elicit information regarding cellular activity, transmitter release, or receptor identity. Compared to their isolated use, incorporation of multiple techniques within one system, termed multi-modal, permits a broader characterization of the neurochemical network under investigation. For example in contrast to studies utilizing a single mode, multi-modal data can show simultaneous pre- and post-synaptic behavior which provides stronger evidence and enhances relationships between observed phenomena. In this approach we demonstrate multi-modal characterization in brain slices by first incorporating simultaneous intra- and extracellular electrophysiological recordings. Action potentials were evoked from medium spiny neurons (MSNs) in the rat dorsal striatum by intracellular current injections through a patch pipette. Cell spiking measured by the patch pipette was compared to single units recorded on a carbon-fiber microelectrode at various distances from the cell body to give a spatial profile for the extracellular electrophysiological signals. Secondly, iontophoresis was used to deliver dopamine to a cell in order to determine the cell type (D1 vs. D2) by the electrophysiological response, demonstrating how the combined techniques are useful for determining cell or receptor identity. Lastly, electrophysiological and electrochemical information were obtained simultaneously during electrically stimulated dopamine release. Oxidation of dopamine was performed on a carbon fiber to determine the release concentration from striatal dopamine terminals while the electrophysiology of MSNs innervated by the terminals was recorded.

Abstract Text

Huntington's disease (HD) is a fatal, genetic, autosomal dominant neurodegenerative disorder. Although HD's primary symptoms include motor deficits, patients with HD are also at increased for depression, heightened anxiety and aggression, as well as other mood disorders. Since serotonin has been implicated in mood disorders, including depression, it is important to study serotonin release in HD. Fast-scan cyclic voltammetry (FSCV) is an electrochemical technique with high spatial and temporal resolution that, when used with carbon-fiber microelectrodes in brain slices, can be used to elucidate information about neurotransmitter release. Here, we employ FSCV in order to measure serotonin release in HD. Electrically stimulated serotonin release was measured in brain slices from R6/1 and R6/2 model HD mice. We find that, in both models, release is significantly impaired. Moreover, using pharmacological manipulations, we quantified reserve pool serotonin in the dorsal raphe nucleus. Findings from these experiments will also be discussed.

Abstract Text

Salicylates (SA), such as Acetylsalicylic acid which is also known as aspirin, and its active metabolite, salicylic acid, are widely used to treat moderate pain, inflammation and fever. However, consumption in large doses of SA can have serious side effects, including internal bleeding and dizziness. The mechanism of the causes of these side effects by SA are still not clear. Despite various reported analytical methods for identification and qualification of SA, its characteristic features in the body have not been fully studied. In this study, we present the electrochemical characteristics of SA in the brain of anesthetized rats using fast-scan cyclic voltammetry (FSCV). FSCV coupled with carbon fiber microelectrode possesses high temporal and spatial resolutions which allows us to monitor sub-second change of the SA concentration in small brain regions. Here we demonstrate the stability and sensitivity of this method in the brain. With the optimized conditions, the minimum detected concentration was 50 nM and a linearity range was from 200 nM to 20 μ M. The response sensitivity was largely unchanged. We demonstrate for the first time that the FSCV coupled with a carbon-fiber microelectrode yields a sensitive, reproducible and stable response for the salicylates during in vivo electrochemical measurements.

Abstract Text

Hydrogen peroxide, whose role in the complex environment of the brain is not well understood, has been implicated in the slow destruction of dopaminergic neurons in Parkinson's disease (PD). This neurodegenerative disease affects more than a million people in America, creating a critical need to identify the mechanisms through which hydrogen peroxide interacts with dopaminergic neurons. Real-time in vivo detection of this analyte has recently been described using fast-scan cyclic voltammetry at carbon-fiber electrodes. However, selectively identifying hydrogen peroxide from interferences such as adenosine and pH shifts remains a challenge. Additionally, some chemical agents used to pharmacologically verify the presence of hydrogen peroxide production in the brain, such as mercaptosuccinic acid, also have a similar oxidation peak as that of the target analyte, further convoluting the characterization of hydrogen peroxide dynamics in the brain. We have addressed these problems by fabricating a hydrogen peroxide-selective electrode. 1,3-phenylenediamine (mPD) was electrodeposited onto the surface of a carbon-fiber electrode to render it sensitive to hydrogen peroxide fluctuations and pH shifts, but not other analytes. Since pH changes generate a well-characterized and distinct voltammogram, they can easily be removed from the signal using principal component regression, to reveal a straight-forward quantifiable electrochemical signal due solely to the oxidation of hydrogen peroxide. This technology was fully characterized on glass-insulated electrodes for acute implantation, as well as electrodes designed for chronic implantation. The work presented herein will facilitate the selective detection of hydrogen peroxide, opening the door for further elucidation of the neurodegenerative role it plays in PD, as well as other neuropathies involving oxidative stress.

Abstract Text

Fast-scan cyclic voltammetry (FSCV) is a useful tool for the sub-second detection of catecholamines in vivo. When monitoring dopamine neurotransmission in freely-moving animals, both high sensitivity and high temporal resolution are desirable. The traditional waveform used, which scans between -0.4 V and 1.0 V, has high temporal resolution, but only moderate sensitivity. Modifying the anodic limit of the voltammetric sweep can increase sensitivity towards dopamine. Dopamine adsorbs to the surface of carbon-fiber microelectrodes under physiological conditions. At more positive potentials, overoxidation of the carbon-fiber surface produces negatively charged carbonyl groups that promote adsorption of dopamine and other physiological cations. However, adsorption and desorption kinetics slow the time response of the voltammetric measurement, resulting in diminished temporal resolution, leading to a commonly observed tradeoff between sensitivity and temporal resolution.

In order to pair sub-second dopamine changes with behavioral information, it is crucial to understand the benefits and limitations of the voltammetric waveform employed. It is our aim to investigate the effect of several waveforms on the dopamine signal while a rat is pressing a lever for intracranial stimulation. Data collected with anodic limits of 1.0, 1.3, and 1.4 V reveal contrasting dopamine signals during this behavior. Additionally, pharmacology will be used to further investigate the underlying regulatory processes behind dopamine dynamics during ongoing intracranial self-stimulation.

Abstract Text

Brain microdialysis allows the collection of a variety of substances and can be paired with numerous detection methods, thus the versatility of this technique has led to its widespread use. While microdialysis is an extremely important technique, it is limited by the immune response occurring around the probe. The severity of the response changes with time and impacts the concentrations of evoked dopamine measured with the probe. This results in a discrepancy in the concentrations sampled from the probe compared to the concentrations in the surrounding tissue. Voltammetry next to the probe has illustrated this problem by showing a decreasing gradient of evoked dopamine the closer the electrode is placed to the probe. In an acute study, dexamethasone, an anti-inflammatory drug, reduced the immune response and protected evoked dopamine directly next to the probe. The goal is further investigate the relationship between the concentrations detected with voltammetry in the striatum to those sampled with the microdialysis probe. To directly compare to the responses next to the probe, voltammetry was used at the outlet of the microdialysis probe in a 4 and 24 hour study with and without dexamethasone. After 4 hours the outlet concentration was not significantly affected by dexamethasone. However, after 24 hours dexamethasone preserved the evoked response while the concentration significantly decreased without the anti-inflammatory drug. The positive effects observed after 24 hours with dexamethasone prompted further investigation into longer terms studies.

Abstract Text

Clinical results of monitoring brain injury patients have characterised rapid metabolic changes, notably spreading depolarisations (SDs) in the injured human brain [1]. During SD events, glucose levels decrease and lactate levels increase and event repetition can drive the local glucose levels down, possibly to a level where the tissue is no longer viable [2].

We have designed a bedside monitoring system to analyse the dialysate from a microdialysis probe implanted in the “at-risk” brain tissue. This uses a microdialysis probe connected to an online microfluidic analysis platform. Combined needle electrodes, designed to fit into an analysis chamber on a microfluidic chip [3] are fabricated into amperometric sensors by first applying a protective mPD film formed by electropolymerisation. An enzyme layer is added by dip coating the electrode in a mixture of BSA, glycerol, PEG-DE and specific enzyme and drying at 55°C for 2 hours [4]. Sensors for glucose, lactate and pyruvate will be discussed. A common problem is calibration and an automatic system will be described, eliminating the need for a specialist to constantly be nearby the equipment. The system has been tested and is now located at the hospital awaiting patient access.

Abstract Text

Aversive and pleasurable stimuli have been shown to drive dopamine (DA) signaling in the nucleus accumbens (NAc). Increased DA signaling in the nucleus accumbens (NAc) has been demonstrated following pain offset, suggesting that this region is important for pain relief. To date, changes in NAc DA efflux have not been extensively investigated using voltammetric methods in freely moving animals or demonstrated over extended periods of time. Pain is expected to affect both tonic (steady-state concentration in the extracellular space) and phasic (transient changes induced by burst firing) activity of dopaminergic neurons. Recently, we have developed fast-scan controlled-adsorption voltammetry (FSCAV) and coupled this technique to fast-scan cyclic-voltammetry (FSCV) to enable multitemporal analysis of dopamine signaling with a single sensor. This single sensor strategy and the stability of PEDOT:Nafion coated electrodes was validated with measurements of tonic and phasic dopamine signaling over a 4 week period at 1, 7, 14, 21 and 28 days after probe implantation in Sprague-Dawley rats. Electrode placement was then verified post-hoc with histology. Lastly, using FSCAV the degree of tissue damage over the 4 week period was quantified using a previously validated implicit finite difference model. Detection of NAc DA in freely moving animals over extended time periods may allow for investigation of pain without complications of anesthetic agents.

Abstract Text

Monolayer protected gold nanoparticles (NPs) have recently been proposed as possible components of improved photovoltaics. The passivating layer can create an electrical double layer on the NP surface, allowing NPs to serve as quantized double-layer (QDL) capacitors and store charge for such devices. In order to effectively implement nanoparticles in this field, it is important to understand the electron transfer properties of a variety of protecting ligands.

In this research, we determine the forward heterogeneous electron-transfer rate constant (k_{f}) of wired organic-soluble and water-soluble monolayer protected gold NPs using the scanning electrochemical microscope (SECM). Using SECM approach curves, we were able to determine the electron transfer rates of nanoparticles protected with a variety of ligands. By altering the monolayer composition through place exchange as well as changing the ligand charge by adjusting solution pH, we demonstrate effective means of modulating electron transfer rates.

Our results show that the electron transfer rate is largely dependent on the protecting monolayer composition and the charge presented by the ligand shell. By adding a relatively small amount of highly conductive molecular wires, we can dramatically increase the electron transfer rate. By changing the ligand charge on tiopronin protected gold NPs through the adjustment of solution pH, we show that the electron transfer rate is inversely proportional to pH and decreases dramatically as the ligands move from an uncharged species to a negatively charged one. This demonstrates charges on ligands inhibit the tunneling of the electron through the protecting monolayer and lowers the electron transfer rate.

Abstract Text

Characterization of small colloidal nanoparticles (NPs) i.e. NPs less than 10 nm in diameter is an analytical challenge. We present ZnO quantum dots (QDs) as a case study for the electrochemical detection of small nanoparticles. Quantum confinement imparts different properties to ZnO from the bulk such as exceptional optical, electronic and magnetic properties. Currently this material has been used as a promising candidate in different technical fields that include applications of the QD colloids. ZnO QDs were synthesized according to the sol-gel method and were characterized by UV-Vis and fluorescence prior to the experiments (Chem. Commun. 2011, 47(43), 11921-3); the spectroscopic measurements were used to follow the stability of the materials. Different concentrations of ZnO quantum dots in CH₃CN were reduced at -2.40 V vs. Ag/AgCl at an electrochemically prepared Hg ultramicroelectrode on Pt. ZnO reduction is carried after collision with Hg microelectrode with the particle resident time at the Hg surface influencing the shape of the current transients. We present the detection of the QDs by the reduction of Zn²⁺ in ZnO. Current spikes and steps are observed likely due to different contributions from single nanoparticles and agglomerates at the Hg microelectrode. The number of moles of reduced Zn²⁺ was calculated from the stripping peak around -1.5 V vs. Ag/AgCl, which represents the oxidation of Zn²⁺ in Zn(Hg). The calibration curve plotted as a function of the reduced amount of Zn²⁺ vs. concentration of ZnO quantum dots is used to study the limit of detection of the technique.

Abstract Text

The metal galvanic exchange reaction has been utilized in recent years to synthesize pure metal and alloy nanomaterials with structures not easily obtainable by other methods. Examples include the synthesis of hollow nanotubes, nanoframes, nanorattles, and nanocages. These materials usually exhibit unique optical, electronic, or catalytic properties. While this reaction has been widely studied on various shaped metal nanostructures, there is little known about the effect of nanoparticle size on the galvanic exchange reaction. Our group recently showed that the oxidation potential for Au nanoparticles decreases by about 200 mV from bulk size to 4 nm in diameter and by another 600 mV for Au nanoparticles in the 1-2 nm diameter range. Since galvanic exchange involves the oxidation of one of the metals involved, it is reasonable that the reaction will be highly dependent on size, especially for very small sizes, where the negative oxidation potential shift is dramatic. In this presentation, we describe the galvanic exchange of Au nanoparticles attached to electrode surfaces with different concentrations of PtCl_4^{2-} complex as a function of the Au nanoparticle size from 4 nm to 90 nm, while keeping the surface area of Au constant. We used voltammetry, scanning electron microscopy, and CO stripping analysis to quantify the amount of Pt on the resulting AuPt alloy nanoparticles in order to determine the amount of exchange. The exchange reaction is highly size-dependent, showing a much larger amount of exchange occurring on Au nanoparticles smaller than 10 nm. The difference in reactivity is due to the negative shift in the oxidation potential of Au nanoparticles as size decreases. We discuss this unique reactivity for small metal nanoparticles and possible applications in catalysis and sensing.

Abstract Text

The in situ characterization of the main photogenerated chemical intermediates, holes and hydroxyl radical, on operating semiconductor electrodes in aqueous media through their basic surface descriptors such as coverage, mobility, and spatial distribution, including the effect of surface perturbations, remains largely unexplored.

Here, we studied the water splitting and water oxidation reactions at n-doped strontium titanate electrodes. In our approach, carbon probes with radii few [micro]m to tens of nm were used in the context of scanning electrochemical microscopy feedback measurements to activate redox mediators capable of titrating reacting species on the operating semiconductors during UV illumination and external bias. Positive feedback curves were obtained in general during illumination, and this allowed to extract the overall rate of oxidation by both holes and hydroxyl radicals. Using the recently-introduced Surface Interrogation mode of SECM [1] for studying adsorbed intermediates, and in combination with simulation methods, we were able to decouple the reactivity of hydroxyl radicals and obtained their coverage and reaction kinetics. This result permits to weight the contribution of both surface species on photo-assisted oxidations. Furthermore, electrochemical imaging allowed to detect differences in the local surface reactivity on well-controlled crystal defects. Experimentally discerning the differences in the dynamics of holes and hydroxyl radicals on native and defective structures will open new avenues in the rational design, modification and efficient utilization of photoactive materials for environmental, energy and synthetic applications.

Abstract Text

Composite corrosion coatings that increase hardness and slow the rate of corrosion at a reduced cost have been heavily studied due to the persistent problems occurring with corrosion. Electrodeposition has become an advantageous technique in manufacturing coatings because of reduced cost, convenience, and the capability of working at low temperatures. In the off-shore oil field industry, high corrosion resistance and hardness are needed to extend the lifetime of coatings due to exposure to high stress and salt environments. In marine environments, copper alloys are used to defend against biofouling of materials by inhibiting microbial induced corrosion (MIC). Copper ions are capable of eradicating viruses, algae, fungi, bacteria, and other microbes. A major copper alloy currently studied is Cu-Ni (90/10), which shows good protection in low flow to stagnant conditions. With the addition of montmorillonite into the Cu-Ni matrix, an increase in strength, adhesion, wear and fracture toughness of the coating occurs, which leads to an increase in corrosion resistance and longevity of the coating. These coatings were evaluated for composition and morphology using many different types of instrumental techniques including x-ray diffraction, atomic absorption spectroscopy, scanning electron microscopy, energy dispersion spectroscopy, atomic force microscopy, and nanoindentation. Also, electrochemical techniques including electrochemical impedance spectroscopy and Tafel analysis were used to evaluate the corrosion protection of the films. The overall corrosion resistance and hardness was improved with the films, which holds promise for the off-shore drilling environment in the oil and gas industry.

Abstract Text

The present work has been carried out with the aim of quantitatively investigate the mass transport parameters of electrochemically facile systems such as hydrogen evolution reaction (HER), potassium ferri/ferrocyanide, and ruthenium hexaammine(III/II) in high concentrations.

HER, as one of the most prominent reactions in renewable-energy technology occurs in highly concentrated media at a real hydrogen power station. At this high concentration, migration contributes to mass transport which in turn affects the overall rate of proton reduction and hydrogen generation. To the best of our knowledge, these effects have not been discussed at high concentration ($> 0.1\text{M}$) in the literature, in part because of limitations of conventional techniques.

Here, two electrochemical techniques, cyclic voltammetry and chronoamperometry, are used to measure the apparent rate constant and the diffusion coefficient of the electroactive species, in the presence and absence of supporting electrolyte and high analyte concentration on micrometer-sized and nanometer-sized electrodes experimentally and by simulation.

In the absence of a supporting electrolyte, changes in diffusion coefficients of electroactive species and steady state currents reveal the obvious effect of migrational component coupled with electron transfer due to the build-up of an electrical field within the electrode's depletion layer.

More interestingly, chronoamperometric evaluation of D for highly concentrated ruthenium hexaammine(III/II) (Fig.1) and HER, as two reference systems can allow the accurate determination of electrode surface area in nanometer scale by providing larger diffusion-limited currents that do not require a highly sensitive potentiostat. Thus, electrode area characterization, a common challenge in nanoelectrode technology would be facilitated.

Abstract Text

Supporting electrolyte is commonly used in electrochemical experiments to minimize the contribution of electromigration transport of the redox-active species being studied. At low ionic strength, ion migration can contribute significantly to mass transport, promoting or impeding the movement of ions to the electrode surface. In addition, ion enrichment has been widely observed in charged nanopores and nanofluidic channels at low ionic strength to maintain electroneutrality. By taking advantage of the effects of both ion migration and ion accumulation, large current enhancements are achieved during cyclic voltammetry of Ru(NH₃)₆³⁺ at a recessed ring-disk nanoelectrode array without supporting electrolyte. Limiting current as a function of the concentration of Ru(NH₃)₆³⁺, exhibiting three distinct regimes, revealed strong dependence of ion accumulation and transport on ionic strength. Voltammetric response at low analyte concentrations is especially interesting, since ions accumulating in the nanopores results in dramatically increased limiting current compared to measurement in the presence of supporting electrolyte. As large as 100-fold current enhancements due to ion enrichment and migration effects adding to the ~20-fold enhancement arising from redox cycling produces a total current amplification of ~2000-fold compared to that obtained on a single microelectrode of the same total area.

Abstract Text

A magnetophoretic enrichment method was designed for improving signal response time and detection limits in the chronoamperometric observation of discrete nanoparticle/electrode interactions by electrocatalytic amplification. The strategy relied on Pt-decorated iron oxide nanoparticles which exhibit both superparamagnetism and electrocatalytic activity for the oxidation of hydrazine. A wet chemical synthetic approach succeeded in the controlled growth of Pt on the surface of FeO/Fe₃O₄ core/shell nanocubes, resulting in highly uniform Pt-decorated iron oxide hybrid nanoparticles with good dispersibility in water. The unique mechanism of hybrid nanoparticle formation was investigated by electron microscopy and spectroscopic analysis of isolated nanoparticle intermediates and final products. Individual hybrid nanoparticle collision events were detected in the presence of hydrazine electrochemical indicator using a gold microband electrode integrated into a microfluidic channel. The experimental nanoparticle/electrode collision rate correlates much more closely with simple theoretical approximation in comparison to previous related systems, due in large to the accuracy of the nanoparticle tracking analysis method used to quantify nanoparticle concentrations and diffusion coefficients. Further modification of the microfluidic device was made by applying a tightly focused magnetic field to the detection volume in order to attract the magnetic nanoprobe to the microband working electrode, thereby substantially increasing the relative frequency of chronoamperometric signals corresponding to nanoparticle adsorption events. With proper biomodification of nanoparticle and electrode surfaces, the presented magnetically enriched single-nanoparticle detection platform has the potential to develop into a practical lab-on-a-chip device for nucleic acid and protein sensing at ultratrace concentrations.

Abstract Text

Burn inhalation injury is difficult to diagnose, lacks effective treatment, and significantly increases patient mortality. The characterization of volatile organic compounds (VOC) in burn patients with smoke exposure may assist in future diagnosis and treatment of burn inhalation injury, and in turn, decrease related mortality. The purpose of this study was to characterize the VOC concentration levels of burn patients and compare these levels to estimates for certain U.S. subpopulations (e.g., cigarette smokers and nonsmokers). Blood samples were quantified by passive headspace sampling using solid phase micro-extraction (SPME) followed by GC-MS with select ion monitoring (SIM). Internal standard was added during sample preparation to compensate for analyte specific matrix effects, competition effects at the SPME fiber, and diffusion loss biases. The analysis of volatiles at low levels is easily influenced by contamination, so study design and sample collection must take into account the prevalence of VOCs in common lab materials. Because the compounds in question are volatile, care must also be taken to protect against sample loss. To prevent contamination bias or loss of VOCs, samples must be stored in pre-cleaned, airtight, blood collection tubes from sample collection to analysis. Our method possesses the sensitivity and specificity to distinguish among VOC exposure sources, including smoke from cigarettes and burning buildings. For example, mean blood benzene levels are significantly different (p-values <0.05) for nonsmokers (29 ppb), smokers (211 ppb) and smoke inhalation victims (910 ppb). This presentation will cover the importance of VOC biomonitoring, the analytical method described above, and a discussion of the results used to differentiate exposure sources.

Abstract Title **Fence Line Monitoring: The Most Cost Effective Green Solution: Single Tube Sampling and Analysis of Volatile and Semi-Volatile Organics in Air**

Primary Author Lee Marotta
PerkinElmer Instruments

Date: Monday, March 09, 2015 - Morning

Time: 08:50 AM

Room: 267

Co-Author(s) Roberta Provost

Abstract Text

There is an increasing need to measure both volatile and semi-volatile components in air samples as impact to human health concerns continue to be an issue. Until recently, the analysis of both volatile and semi-volatile components required two analytical methods. This presentation will demonstrate the ability to test both volatile and semi-volatile components in air using one analytical method.

Through rigorous investigation, a new sampling tube and method have been developed to monitor 1,3-Butadiene, Benzene, Toluene, Ethyl Benzene, Xylenes (BTEX) and the 16 EPA regulated polynuclear aromatic hydrocarbons (PAHs) in one air sample. It is advantageous to perform this in one analysis instead of two. Only one sample will need to be collected in the field instead of two which reduces sampling costs significantly. Using one method, EPA Method TO-17, instead of two methods EPA TO-13 and TO-15 enhances laboratory productivity, profitability, and safety. In addition, since the analysis can be accomplished with one method, less solvent and electricity is used, making it a "greener" analysis.

EPA Method TO-13 requires 24 hours of soxhlet extraction using 100-300mL of methylene chloride and a concentration step before the sample gets to the instrument for analysis. TO-17 requires no sample preparation when the samples get to the lab. The tubes are placed on the autosampler. After starting the thermal desorber, the instrument automates the process of desorbing the analytes from the tube, and injecting the sample into the analytical column for analysis and GC/MS results. This is a fast analysis driven by chromatography and not tube desorption.

This presentation will include additional benefits of TO-17 over TO-13 and TO-15. A brief overview of the thermal desorption process will be reviewed. The analytical results will be discussed including data from site samples.

Abstract Text

Atmospheric pressure GC (APGC), first developed in the 1970s, has recently made a comeback as an alternative to high resolution EI-GC/MS and EI-GC/MS/MS. For many of the POPs on the Stockholm Convention, only the molecular ion is formed under APGC ionization conditions. By avoiding fragmentation, the sensitivity in MRM or SIR mode is enhanced. In this work, APGC with a high sensitivity tandem quadrupole mass spectrometer was used in MRM mode under "dry" N_2 conditions. Standards for dibenzo-p-dioxins and furans were obtained from Wellington Labs. Data were acquired with two transitions for each of the native compounds and their ^{13}C analogues. The results demonstrated that the sensitivity achieved using APGC-MS/MS is comparable with high resolution GC/MS. Injection of a 1/10 dilution of calibration standard CSL of concentration range 10-100 fg/ μ l resulted in S/N from 10 to 65. A calibration curve was generated by analyzing 1/10 CSL up to CS4 standard. Coefficients of determination (r^2) for all compounds over the calibration range were all > 0.998. To test the sensitivity of the system, the lowest calibration point was diluted 1/10. The S/N for the first or second MRM ranged from 10 (10 fg TCDD/TCDF) to over 50 (other congeners 50-100 fg). Repeatability for n=10 injections of the CSL standard were all less than 10% RSD. The relative standard deviations ranged from 2.5 to 9.6%. In addition, ion ratio deviations were all less than 20% across the calibration range. These results meet the specification often set for high resolution GC/MS systems.

Abstract Text

Halogenated dioxins and furans have long been persistent organic pollutants of environmental concern produced as byproducts from a variety of sources. It has become important to be able to detect a range of dioxins and furans at trace levels in a diverse range of matrices. In addition to increased sensitivity, accuracy and repeatability are also important for dioxin analysis of environmental samples. Historically, the preferred method of analysis has utilized GC-HRMS systems employing double-focusing, or "sector" based instruments that monitor specific mass-to-charge fragments for each target compound. In this study, an alternate method utilizing atmospheric pressure ionization gas chromatography (APGC) coupled to a triple quadrupole mass spectrometer (TQS) is described to allow identification of a more comprehensive list of compounds in a single run, as well as its use as a discovery tool.

Through an extensive comparison of samples analyzed using both methodologies, APGC-TQS analysis has demonstrated to be a comparable technique to sector-based HRMS analyses for trace level identification of dioxins and furans in environmental samples. Another benefit of this instrumentation is the ability to report a limit of detection on the single femtogram level. The method developed can simultaneously monitor for tetra- through octa- chlorinated dioxin and furan congeners, including the seventeen toxic congeners, in a single run. Furthermore, methods have been developed for identification of a variety of polybromo- and mixed bromo/chloro- dioxins and furans. Application of these methods will be demonstrated on a variety of sample matrices including sediment, fire debris, and human serum.

Abstract Text

Polyaromatic hydrocarbons (PAHs) are compounds containing two or more aromatic rings and are known for their potential carcinogenic and mutagenic properties. They are typically formed during incomplete combustion of organic matter, as industrial byproducts, and in food processing. As such, they are compounds of interest in environmental food and beverage, and toxicological analysis. PAHs have become a target for many governments and regulatory agencies. US EPA method 610 is the benchmark method for PAHs, using nonpolar silicon based stationary phases operated at high temperatures. Separations on these phases are prone to coelution, specifically for the isomers of anthracene, chrysene, benzo(k)fluoranthene, and dibenzo (a,h)anthracene.

Ionic Liquids (ILs) are a new class of GC stationary phases that provide unique polar and highly polar selectivity with higher thermal stability compared to traditional GC phases with similar selectivity. Our previous work demonstrated that phosphonium ILs possess superior selectivity for PAHs than imidazolium IL-based phases. In particular, SLB-IL 59 has baseline resolution of isomeric pairs that are of interest including anthracene/phenanthrene, cyclopenta(c,d) pyrene, chrysene/triphenylene, and the benzofluoranthenes. Building upon these results, our goal has been to study the chemistry of other phosphonium IL analogues, attempting to improve thermal stability and decrease analysis time. Our secondary goal has been to study and optimize the GC and column parameters to create a robust method for PAH analysis.

Abstract Text

Concern about environmental impact and the need to remain current with evolving regulation has driven many refineries and chemical manufacturers to adopt increasingly rigorous methods for measuring the composition of the gas mixtures headed to their flare stacks. Most recently, in the United States the EPA's implementation of 40 CFR 60 subpart Ja has mandated the measurement of hydrogen sulfide, total sulfur, and hydrocarbon content in many refinery flares. Similar regulations have been enacted, or are in process in other countries and parallel industries.

Flare streams consist of a mixture of off gas from several plant processes, meaning that they are subject to wide variation in terms of components present and their relative concentrations. While gas chromatography has been employed in monitoring flare emissions for some time, process mass spectrometry is less common. The ability of a mass spectrometer to measure hydrogen sulfide, total sulfur, and hydrocarbon content (heating value) within the changing mixture of the flare stream provides the plant with a single-analyzer solution capable of measuring from the ppm level up to 100% without saturating the detector. Additionally, the linearity of analysis offers the potential for system validation using safe-to-handle standards. A quadrupole mass spectrometer was used to monitor a variety of flare gas mixtures. Release conditions were simulating and the concentration of H₂S was monitored from ppm levels up to 100% to demonstrate accuracy, and linearity.

Abstract Text

Fluorescence generation and quenching are two common approaches to RNA/DNA biosensing. Often fluorescence generation (signal-on) is considered to be more sensitive than quenching (signal-off) based mechanisms. However, sensitivity is not the only metric when considering optimal biosensor performance. To the best of our knowledge, no work has been done directly comparing the analytical figures of merit for a biosensor that can both generate and quench fluorescence. We have established such a comparison using a fluorescent miRNA biosensor recently developed in our group. The overall mechanism starts with the reporter molecule in a fluorescence-quenched hairpin configuration. Addition of a partially complementary probe opens the hairpin, resulting in the generation of fluorescent signal. Presence of the target analyte (miRNA) will displace the reporter as the analyte binds the probe. The reporter then folds back into the quenching hairpin. We will present a detailed comparison of the sensitivity, specificity, limits of detection, false signals, and signal to noise for a signal-off reporter-probe vs. a signal-on molecular beacon biosensor. Upon comparison of signal-on to signal-off, we found an order of magnitude lower LOD for signal-on mechanisms. However, the signal-off mechanism of the reporter-probe biosensor demonstrates higher selectivity than the signal-on molecular beacon. Given the signal-off biosensor achieves picomolar limits of detection with similar signal to noise as signal-on approaches, we conclude that for short nucleic acid sensing, signal-on does not offer any substantial advantages over signal-off approaches. Ongoing work is focused on using the reporter to image miRNA in cells and tissue.

Abstract Text

A sensor for H₂O₂ was developed by enclosing the semiconductor nanocrystals (NCs) inside the hydrogel nanoparticles together with the metal-responsive dyes. Oxidation of the NCs by H₂O₂ causes NC dissolution, and the dissolved cations would trigger fluorescence from the fluorogenic dyes, making the nanogel particles emitting strong fluorescence. The reaction mechanism was investigated. The linear range was found to be from 0.1 μ M up to 8 mM, with the detection limit of 0.08 μ M. The sensor has good selectivity for H₂O₂ over other oxidative species. Its application in testing release of H₂O₂ from cancer cells has been explored.

Abstract Text

The quenching property of graphene oxide (GO) was widely used for the fluorescence sensing and imaging. However, the quenching distance of GO to dyes were only investigated with the assistant of DNA strands, which might cause false distance measurements because of their flexibility on the surface of GO. Therefore, a rigid distance spacer, silica shell, between GO and dyes was used in this work. Organic dye was doped in the silica nanoparticles first, followed by the modification of another layer of silica shell with different thickness. Due to the electrostatic interaction between GO and positive charged silica nanoparticles, GO wrapped the silica nanoparticles when they are mixed together. Therefore, the distance between GO and organic dyes was adjusted by the thickness of the silica shell. The results showed that the quenching efficiency was higher than 50 % when the distance was smaller than 7.1 nm. This quenching ability investigation of GO to dyes with distance-dependent manner would provide important information for the design of the fluorescent functional composite using GO in the future.

Abstract Text

Silica spheres have been used as a carrier for small molecules in the past few decades because of their intrinsic features, including the relative ease of surface modification, which has permitted application in biological/biomedical areas. Many types of fluorophores (e.g., dyes and metal-based quantum dots) have been incorporated into the silica skeleton/surface to prepare luminescent particles. One major problem with dyes is their leakage from the silica particles, hampering the long-term stability of the imaging system; this is also the case with metal-based quantum dots. The chemical stability and photostability also need to be improved. Fluorescent carbon nanodots (C-dots) have been gaining increasing interest as a new type of fluorescent material. Their excellent biocompatibility, chemical inertness, and photostability make them ideal alternative for traditional organic dyes or metal-based quantum dots. In this study, sub-micron fluorescent silica particles were synthesized by a modified Stöber method. Fluorescent C-dots made from bottom-up synthesis were used as fluorescent precursor. Experimental parameters such as water concentration, base catalyst concentration, and silane concentration were studied to control the final particle size. Scanning electron microscopy (SEM), transmission electron microscopy (TEM), and diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) were used for particle characterization. Their fluorescent properties were also investigated. In this presentation we will discuss the synthetic procedure, unique fluorescent properties, and potential applications of these fluorescent C-dots/silica particles.

Abstract Text

The reaction of o-phthalaldehyde (OPA), a thiol compound, and a primary amine at alkaline pH to form the fluorescent isoindole derivative is one of the most important analytical approaches for the determination of amino acids and selected pharmaceuticals. The most common thiols used are the liquids mercaptoethanol and mercaptopropionic acid, both of which have offensive odors. We have considered alternative nonvolatile solid thiol compounds such as mercaptosalicylate, mercaptosuccinate, and captopril. Using lysine as the test amine, the aromatic sulfhydryl compound does not seem to react to form a fluorescent derivative and the succinate compound shows only a modest linear response. However, upon reaction of HPLC grade captopril with OPA and lysine, a strong stable fluorescent signal can be measured which appears to be comparable to that when mercaptopropionate is used. We plan to compare the reactivity of a monoamine (glycine), a diamine (lysine), and a hexamine (neomycin) with OPA and captopril. Linearity of response and detection limits will be compared. In addition, an indirect fluorescent method involving captopril has been developed to determine nitrite. The first reaction occurs between nitrite and captopril at acidic pH to generate nitrosocaptopril. This small volume solution is added to the borate buffered OPA and amine solution, and the resulting mixture will produce a fluorescent signal if captopril remains from the first reaction. Some experimental parameters, such as pH, temperature, reactant ratio and salt concentration have been studied indicating the method is sensitive and precise.

Abstract Text

A Group of uniform materials based on organic salts (GUMBOS), i.e. organic salts with M.P between 25-250 oC was recently introduced by Warner [1]. It exhibit similar outstanding properties as ionic liquids except these materials are solids rather than liquids and, are being used for wide scope of applications [1]. In the present work, novel carbazole-based GUMBOS are synthesized and characterized. By changing the substituted group at carbazole, GUMBOS with tunable emission spectra are obtained. Detailed photodynamics study of these materials indicate that emission emanates from multiple excited states. In order to understand these complex emission process, lifetime measurements, excitation emission matrix and transient absorption spectroscopy are performed and the results obtained from these measurements are consistent and in well agreement. Furthermore, carbazole-based GUMBOS are highly photostable, displayed improved thermal stability, and exhibited high quantum yields. The unique photodynamic characteristics of these GUMBOS suggest the potential use of these materials in optoelectronics such as organic light emitting diodes (OLEDs) and as laser dyes.

Abstract Text

Semiconductor quantum dots (QDs) have received much acclaim for their bright, spectrally narrow, and tunable emission. A sometimes unappreciated advantage of QDs is their surface area, which provides new opportunities for bioanalysis. This presentation will describe some of our recent and ongoing efforts to develop fluorescent probes that exploit both the optical properties of QDs and their interface. These efforts include the design and characterization of so-called concentric Förster resonance energy transfer (cFRET) probes that utilize energy transfer networks to achieve multiplexed detection at discrete nanoparticle probes. For example, a configuration that combines peptide and aptamer probes with three cFRET pathways between a central QD and two fluorescent dyes is able to detect and distinguish between the concentration and hydrolytic activity of thrombin, a model protease. This capability is important because both concentration and activity are important in the biological function and regulation of proteases. Preliminary results on the combination of a QD with three fluorescent dyes, comprising six possible cFRET pathways toward triply multiplexed detection of protease activity, will also be presented. In addition to permitting the assembly of multiplexed FRET networks, the physicochemical properties of the QD interface--its ligand coating and peptide density in particular--can affect proteolytic activity with ramifications for the sensitivity and selectivity of activity-based assays. Finally, new results related to the design and function of self-contained QD-probes for the FRET-based detection of target nucleic acid sequences will be presented. Overall, this collection of research shows that the greatest value can be obtained from QDs when they are used as more than a substitute for fluorescent dyes, and one takes full advantage of the QD interface as a platform for bioanalysis.

Abstract Text

There is much more to validating your laboratory instrument and/or information systems than just running the vendor supplied Installation Qualification (IQ) and Operational Qualification (OQ) testing packages. In order to avoid costly bottlenecks in your validation effort, it is critical that you perform an accurate GAMP5 risk based assessment, undertake adequate validation planning, develop your deliverables (URS, FRS, Config Spec, etc...), and establish your validation process roadmap. Your effort can also become constrained if you are unable to secure the right resources to execute the validation activities.

Doing things right, the first time, is always our goal when beginning a project. However, over 60 percent of implementation projects fail to reach a go-live status, stay within budget, or meet the deadline; and validation is often the cause of the constraint. There are many factors that can cause such roadblocks, but there are also ways to avoid these detours. In the presentation, the author will share “Lessons Learned” when validating laboratory instruments and information systems so you may increase your chances of a successful implementation.

Abstract Text

In collaboration with the Royal Society of Chemistry, a project to develop the Chemical Analysis Metadata Platform (ChAMP) has been initiated to identify analytical science metadata that characterize chemical analysis methodologies.

In this work, we propose that the development of standards for organization, representation, and annotation of analytical science information, be based around the definition of metadata in ChAMP. This project involves development of specifications for metadata collection, a taxonomy (organizational structure), ontologies to link the metadata semantically, design rules, and use cases.

This presentation will report the current state of ChAMP, show examples of application, and a discussion future developments.

Abstract Text

User acceptance is probably the most critical factor in a successful implementation of any laboratory informatics solution (e.g. LIMS, ELN, CDS). Unfortunately, many times the end user is overlooked and underutilized in the planning and implementation of these solutions. Though end users are often tasked with participating in the requirements gathering portion of the project, this crucial resource is often left out of the development and implementation process until final training just prior to roll-out.

In this presentation, strategies to best utilize existing resources in all phases of a laboratory informatics solution will be covered. Case studies will be introduced to provide strategies used for success. Specific project tasks will be outlined and processes to implement identified. Common pitfalls and avoidable errors will also be exposed. In addition, the presentation will look at the actual return on investment for both effective and non-effective scenarios. Beyond just efficiency in the laboratory, discussion will identify how wise use of existing resources will directly translate into meeting customer and regulatory requirements, audit readiness, personal development of employees, and the overall health of the organization.

Abstract Text

R&D organizations IT groups are under pressure to evolve laboratory informatics environments and, not just support but also, to increase their organizational value. Therefore strategic themes for simplification have aimed at reduction and replacement of disparate software technologies such as CDS, ELN, LES, LIMS, SDMS, and data warehouses, with goals of consolidation, unification, and integration. This is leading to the emergence of hybrid informatics platforms for unified laboratory intelligence that can homogenize structured and unstructured data, while supporting the codification of knowledge to drive automated and intelligent workflows.

Having appropriate knowledge for effective decision-making in each R&D domain requires accessible analytical information. This drives the development of informatics architecture and components from desktop applications and virtualized environments, to enterprise databasing, thin/web/mobile clients and range of cloud-based deployment and access approaches.

This presentation will offer a view on emerging informatics strategies, integration and platforms with an emphasis on the applicability of technologies in the Unified Laboratory Intelligence (ULI) category for chemistry R&D subdisciplines that feature a substantial variety and volume of analytical data in their workflows.

Abstract Text

President Obama signed the Leahy-Smith America Invents Act (AIA) into law in September of 2011. This affected many sections of the existing U.S. patent statutes, the most talked about being the shift from a first-to-invent patent system to a first-to-file system. The first-to-file patent system went into effect in March of 2013.

In the “old days” our patent system granted the patent to an invention based on who could prove they came up with the idea first. This is the “first-to-invent” patent world. To prove who was first you needed “business records” which are court admissible records that are dated, signed, witnessed records that you could prove have not been changed or tampered with. Business records could be electronic and an Electronic Laboratory Notebook (ELN) was the perfect system to capture and store them. ELNs provided date/time stamping, electronic signatures, and audit trails. Intellectual property preserved! ELN justified and paid for!

Now our patent laws have changed. Now, the first person to file the patent or disclosure is the one granted the patent. This is the “first-to-file” patent world. So the need for business records goes away! Uh oh! Do you still need ELNs? The quick answer to this question is yes!

This presentation will summarize the changing information landscape that ELNs address as well as the technical, business, and legal reasons why ELNs are still needed in the organization.

Abstract Text

Instrumentino is an open-source modular graphical user interface framework for controlling Arduino based experimental instruments. It expands the control capability of Arduino by allowing instruments builders to easily create a custom user interface program running on an attached personal computer. It enables the definition of operation sequences and their automated running without user intervention. Acquired experimental data and a usage log are automatically saved on the computer for further processing. The use of the programming language Python also allows easy extension. Complex devices, which are difficult to control using an Arduino, may be integrated as well by incorporating third party application programming interfaces into the Instrumentino framework.

In this presentation, the Instrumentino [1] infrastructure will be explained and the benefits of its usage will be discussed. A series of example systems in the field of analytical chemistry, already using Instrumentino, will be presented as well.

The main goal is to expose the Instrumentino framework to fellow researchers and promote future collaborations.

Abstract Text

Lab managers and scientists struggle every day with efficiently managing large and small laboratories containing instruments from multiple vendors. Making the right decisions concerning how laboratory assets are deployed, utilized and managed throughout their lifecycle allows labs to make the proper choices and implement changes that will increase productivity, gain efficiencies and drive overall business improvement. However, collecting and compiling the data required to drive those decisions can be challenging.

This presentation explores the impact of mobile applications and visualizing instrument performance using new techniques with the objective of creating a more interactive and informative lab environment. These powerful reporting tools to provide you with a visual and interactive way to review laboratory asset data as well as exposing instrument "hot spots" where attention needs to be invested. Additional possibilities include visualization of system performance over time to more precisely see when service is required. Gaining higher efficiencies in the lab results in higher levels of uptime and instrument availability as well as better overall laboratory operation and saved costs.

Abstract Text

Phosphorylated carbohydrates play an important role in energy utilization. Specifically, the phosphorylated disaccharide trehalose-6-phosphate (T6P) is essential for, among other functions, carbon regulation in plants. Resolving and quantifying phosphorylated sugars, however, can be difficult due to the interaction of the phosphate group with stainless steel components of the HPLC system, resulting in a tailing effect that can impair the sensitivity of the method. Additionally, many HILIC methods use high concentrations of mobile phase modifiers and pH > 11 to separate T6P from other phosphorylated disaccharides (sucrose-6-phosphate, S6P), pushing the limits of column pH recommendations. Herein, we report the benefits of incorporating the reverse-phase "tail-sweeping" reagent, methylphosphonic acid (Han et al. 2013, Anal. Chem.), in the aqueous mobile phase along with minimal amounts of triethylamine (TEA) in the organic mobile phase to maintain alkaline conditions necessary for HILIC resolution of T6P and S6P. Addition of methylphosphonic acid significantly reduced peak tailing, producing a 30% increase in peak height while maintaining baseline resolution of T6P and S6P. Sensitivity was further improved by minimizing the amount of TEA without adversely affecting the separation in both standards and unspiked plant extracts. The proposed method also resolves and thereby enables simultaneous quantification of the phosphorylated monosaccharides of glucose and fructose such as G6P, G1P, F6P, and F1P. The method was then applied to flooding tolerant and intolerant rice varieties to determine the effect of submergence stress on T6P and other phosphorylated sugars to further elucidate plant stress response.

Abstract Text

Pteridines are a diverse family of endogenous metabolites that may serve as useful diagnostic biomarkers for disease. While many preparative and analytical techniques have been described for limited pteridine analysis in biological fluids, comprehensive pteridine profiling and intracellular pteridine detection to support biomarker qualification efforts have continued to face analytical challenges. In this study, a simple, rapid, specific, and sensitive high performance liquid chromatography – quadrupole time-of-flight – mass spectrometry (HPLC-QTOF-MS) method was developed to simultaneously quantify seven intracellular pteridines and semi-quantitatively monitor 17 additional intracellular pteridines. In addition, pteridines were extracted from the cell lysate using a newly developed and optimized pteridine extraction method. The resulting method was validated through evaluation of spiked recoveries (84.5% - 109.4%), reproducibility (2.1% – 5.4% RSD), method detection limits (0.1 – 3.0 µg/L) and limits of quantitation (0.1 – 1 µg/L), and application in two cell lines including healthy embryonic kidney HEK-293A cells and non-small cell lung cancer A549 cells. This new platform enables comprehensive pteridine analyses to generate novel pteridine profiles for various pathological conditions. The detailed HPLC-QTOF-MS method, extraction protocol, and results will be presented at the conference.

This study was supported by the US National Science Foundation and the National Science Foundation of China.

Abstract Text

The study presents a novel protocol for accurate quantification of reduced (GSH), oxidized (GSSG) and total (tGSH) glutathione in biological samples using molecular speciated isotope dilution mass spectrometry (EPA Method 6800), which involves isotopic ratios and not calibration curves. For GSH and GSSG measurement, the sample was spiked with isotopically enriched analogues of the analytes, along with N-ethylmaleimide (NEM), and treated with acetonitrile to solubilize the species via protein separation. After centrifugation, the supernatant was analyzed by hydrophilic interaction liquid chromatography–tandem mass spectrometry (LC-MS/MS), and the GSH and GSSG were quantified with simultaneous tracking and correction for auto-oxidation of GSH. For tGSH measurement, the sample was spiked with isotopically enriched GSH and treated with dithiothreitol to convert the disulfide-bonded glutathione to GSH. After removing the protein, the supernatant was analyzed by LC-MS/MS and the analyte was quantified by single-spiking isotope dilution mass spectrometry (IDMS). Red blood cell (RBC), whole blood and saliva samples collected from healthy subjects were analyzed. The protocol was validated using spike recovery tests and by analyzing synthetic standard solutions. The concentrations of tGSH in the RBC and whole blood samples were two orders of magnitude higher than those found in saliva. The fractions of GSSG were 0.2–2.2% (RBC and blood) and 15–47% (saliva) of the free glutathione (GSH + 2xGSSG) in the corresponding samples. Up to 3% GSH was auto-oxidized to GSSH during sample workup; the highest oxidations (>1%) were in the saliva samples.

Abstract Text

Febuxostat is a novel non-purine selective inhibitor of xanthine oxidase (XO), which is used for the treatment of gout. In the present study, a rapid and sensitive liquid chromatography-tandem mass spectrometry (LC–MS/MS) method for simultaneous determination of febuxostat and its three active metabolites, hydroxylated febuxostat 67M-1 and 67M-2, carboxylic acid 67M-4 in human plasma has been developed and validated for the first time. After addition of internal standard (IS) losartan, plasma samples were pre-treated by one-step protein precipitation with methanol. Febuxostat, three metabolites and the IS were separated on a ZORBAX SB- C18 column (50mm×4.6mm, 5µm) using gradient elution with a mobile phase consisting of acetonitrile, water and formic acid. Detection was performed on a triple quadrupole tandem mass spectrometer by selective reaction monitoring (SRM) mode to monitor the precursor-to-product ion transitions of m/z 317 → 261 for febuxostat, m/z 333 → 261 for 67M-1 and 67M-2, m/z 347 → 261 for 67M-4 and m/z 423 → 207 for I.S. respectively using a positive electrospray ionization (ESI) interface. The total run time was about 12 min per sample. The method was validated over the concentration range of 10–20,000 ng/mL for febuxostat, 1.0–270 ng/mL for 67M-1 and 67M-2 and 0.8–250 ng/mL for 67M-4 respectively. The extraction recoveries of all the analytes at three concentration levels were consistent. The intra-day and inter-day precisions of the investigated components exhibited an RSD within 14.7%, and the relative errors ranged from 4.3% to 5.1%. The proposed method has been successfully applied to a clinical pharmacokinetic study of febuxostat in Chinese volunteers after oral administration of a single dose of febuxostat at 40, 80 and 120 mg.

Abstract Text

A high-throughput method using solid-phase microextraction coupled to liquid chromatography-tandem mass spectrometry (SPME-LC-MS/MS) for concomitant determination of tranexamic acid and rocuronium in human plasma was developed and validated. Because of instability of rocuronium in collected plasma samples the standard analytical approaches employ acidification of the sample, what affects the binding equilibrium of the drug and consequently no information on the free/bound concentration can be obtained. Contrary to these protocols, the proposed method requires minimum sample handling and no ion pairing and derivatization procedure. A weak cation exchanger coating was chosen for the first time as the best extracting phase for selected drugs, guaranteed a good recovery, minimum carry-over and selective extraction. SPME procedure met all Food and Drug Administration acceptance criteria for bioanalytical assays at three concentration levels, for both selected drugs. Post-extraction addition experiments showed that matrix effects were less than $\pm 3\%$. Therefore, a weak cation exchange thin-film solid phase microextraction (WCX TF-SPME) approach presented here offers simple cleanup procedure and full quantitation of the drugs in plasma as one the most challenging matrices with regards to its complexity. In addition, 96-well plate format of WCX TF-SPME system provides many advantages like high throughput analysis for up to 96 samples in 30 min (19 s/sample), a need of a small amount of plasma sample (0.8 mL), and simple sample preparation protocol, which shows a promise for possible on-site application in hospital e.g. to support of clinical pharmacokinetics studies.

Abstract Text

Currently available biomarkers such as anionic sugars lack sensitivity for early detection of health related diseases, in particular certain cancers. To address this challenge, paired ion electrospray ionization (PIESI) was employed for ultra-sensitive detection of anionic sugars (i.e., sugar phosphates, carboxylic sugars and sialic acids). The PIESI-MS approach provides enhanced sensitivity for these anionic sugars, and overcomes the drawbacks of the less sensitive negative ion mode ESI-MS by detecting the anionic sugars in the positive ion mode at higher m/z where the background noise is less. Using PIESI-MS, the absolute LODs for these tested biomarkers were one to two orders of magnitude better compared to negative ion mode detection. Up to three orders of magnitude improvement were obtained compared to other reported HPLC-MS based methods performed in the negative ion mode. Structurally similar anionic sugars such as isobaric sugar phosphates were chromatographically separated and detected by HPLC coupled with PIESI-MS. The developed HPLC-PIESI-MS method may provide a powerful approach for the sensitive detection of disease biomarkers and is useful for diagnosis.

Abstract Text

Collection of dried blood spots is a minimally invasive technique to sample blood on cards of filter paper for biochemical or genetic analysis. This technology offers the advantage of being much less invasive than conventional venous blood sampling, and requires only limited infrastructure for sampling and logistics. In practice, a sampling can be achieved anywhere and without specialist training. Such methodology is of particular interest for application in web-based studies, in which the participants are remote at home. The Food4Me study is a large multi-center, web-based personalized nutrition intervention, which aims to compare the effectiveness of three levels of personalized nutrition (based on dietary, phenotypic and genotypic data) on behavioral changes (diet and physical activity) and health outcomes (blood metabolites and obesity-related anthropometrics), www.food4me.org. In total, 4123 dried blood spot samples from participants recruited by seven clinical centers in different European countries have been analyzed for 25-hydroxy vitamin D3 (25-OH-D3). Three time points, baseline, 3m, 6m, have been analyzed from each participant who finished the study. Analysis was performed by LC-MS/MS with APPI. Blood with known, endogenous 25-OH-D3 content was used for calibration. The current method was developed specifically for the FOOD4Me study, and was validated following EMA guidelines. The results gave valuable information on the acceptance and possible issues associated with unsupervised sampling by the participants at home, especially with regard to sample quality. For each center a status distribution for men and women was compiled. The data was further investigated regarding variations between time points of the same subject, possibly reflecting influence of seasons, sun exposure and/or food/supplement intake data.

Abstract Text

Adenosine 5'-triphosphate (ATP), adenosine 5'-diphosphate (ADP) and adenosine 5'-monophosphate (AMP) play critical roles in cellular metabolism as well as energy transfer and storage. When cells are exposed to different types of bioactive materials, the normal cellular functions can be affected and the concentrations of ATP, ADP and AMP may be significantly changed. Therefore, the measurement of these molecules is of importance to evaluate the cellular energy changes upon exposure to biomaterials. In this study, a simple and sensitive ultra-fast ion-exchange chromatography coupled with tandem mass spectrometry (UFIC-MS/MS) method was developed to determine ATP, ADP and AMP in biological samples. Three biomolecules can be fully separated and detected by MS/MS to the low $\mu\text{g/L}$ level. This method has been applied to analyze the ATP, ADP, and AMP levels in cell culture media released from human fibroblast cell line CCL-110 upon exposure to bioactive glass nanofibers, which are used in soft tissue engineering. The detail experimental designs, results, and discussions will be presented at the conference. This research was supported by the Center for biomedical Science and Engineering (CBSE) and department of chemistry in Missouri University of Science and Technology.

Abstract Text

The detection of pharmaceuticals and personal care products (PPCPs) and pesticides in surface waters is critical for their combined environmental and health effects. Some of these compounds are classified as carcinogenic, endocrine disrupting, and they may act synergistically to cause these effects. Solid phase extraction (SPE) using disks or cartridges is a commonly used method for extracting these environmental contaminants, but the efficiency of these two methods has not been thoroughly compared to determine which is the optimum choice for these compounds and their metabolites. Additionally, liquid-liquid extraction is used far less frequently in the extraction of PPCPs and pesticides from surface water and hasn't been rigorously compared to SPE methods. In this study, we comprised a list of 12 commonly found PPCPs and 33 pesticides and compared these three extraction methods using liquid chromatography-time of flight mass spectrometry (LC-TOF-MS) and gas chromatography-mass spectrometry (GC-MS) as our detection systems. Our results showed that SPE disks gave a significantly higher recovery than the cartridges for both groups of compounds, while liquid-liquid extractions had higher precision and recoveries than SPE disks for most of the compounds and their metabolites that were tested. We conclude that, although SPE disks have the advantage of higher throughput, liquid-liquid extraction is an excellent choice when preparing samples containing trace PPCPs and pesticides, and should be used for their combined analysis in surface and wastewater samples.

Abstract Text

Chlorination is the most commonly practiced method for water disinfection. An increasing number of water utilities are turning to the use of bulk hypochlorite solutions due to homeland security concerns. It is well known that chlorination produces disinfection by-products (DBPs) such as trihalomethanes (THMs) and haloacetic acids (HAAs). These DBPs are carcinogenic and the United States Environmental Protection Agency has established maximum contaminate levels for Total THMs and Total HAA5 to be 0.080 mg/L and 0.060 mg/L, respectively. The majority of studies have focused on the formation of DBPs in the distribution system while much less is known about their presence in bulk hypochlorite solutions.

Recently, significant concentrations of three regulated HAAs were detected in thirty bulk hypochlorite solutions from twenty-four water utilities. These measurements were made by post column reaction-ion chromatography where the HAAs are separated by anion-exchange chromatography followed by a post-column reaction to produce a fluorescent product. The HAA concentrations in bulk hypochlorite solutions could contribute to HAA concentrations in the distribution system through dilution.

An alternative method employing liquid chromatography-tandem mass spectrometry (LC-MS/MS) will be presented for the detection of HAAs in bulk hypochlorite solution. The optimization of method parameters, MDL, accuracy, and precision of the method will be discussed. Finally, analysis of real world bulk hypochlorite solutions will be presented

Abstract Text

The objective of this research is to develop a target based extraction method that is capable of detecting a variety of chemotherapeutic agents at a level that is appropriate for the analysis of drinking, surface, and wastewater. Identification and quantification of chemotherapeutics throughout water purification processes have not been reported in the United States. There currently is not an established method for targeting a variety of chemotherapeutic drugs in the initial and final stages of the wastewater treatment process. Although these pharmaceuticals share a common physiological effect, their structures and chemistries vary dramatically. Developing an extraction method that will retain trace amounts of these diverse compounds proves challenging and places significant demands on both the sample preparation steps and instrumental analysis.

The identification of samples will be conducted using an UHPLC-triple quadrupole mass spectrometer to yield the necessary overall sensitivity to detect trace level contaminants. A method for the analysis using a UHPLC-triple quadrupole mass spectrometer was optimized and provides sufficient separation of a variety of chemotherapy standards. The stationary phase column chemistries that provide the most efficient separation of a mixture of chemotherapeutic agents were determined using UHPLC-PDA. The final step is to optimize a method for extraction of a variety of chemotherapeutic agents from surface, drinking, and wastewater. This involves investigating solid phase extraction phases in order to maximize percent recovery of the targeted compounds. Due to the compounds trace levels a large-volume SPE-based sample preparation technique that is compatible with UHPLC analyses will be developed.

Abstract Text

Iron (Fe) and manganese (Mn) have been associated with discoloration of drinking water in the Northwest UK. In the cases of discoloration, iron network pipework has been replaced with plastic. This should have reduced the number of discoloration events if iron was the sole cause of the problem. Unfortunately, this has not reduced the number of failures. Both Fe and Mn have also been associated with toxicity at high levels particularly with reference to neurotoxicity, which has been discussed by Elsner and Spangler (1).

The aim of this study was to analyse iron and manganese species in drinking water. Water samples were collected in the Northwest region of the UK to assess discoloration issues. The samples were analysed using Thermo X series ICP-MS with a Thermo 4000 series HPLC being used for speciation and sample introduction.

This worked considered the use of ion chromatography separation of Fe(II), Fe(III) and Mn(II). In reverse phase mode, Thermo Accucore columns were employed with an EDTA and TBAH (tetrabutyl ammonium hydroxide) mobile phase. This gave rapid analysis times for Mn(II) i.e. less than 5 minutes. Cationic exchange material (Dionex CS5) in conjunction with a PDCA (pyridine dicarboxylic acid) was investigated to separate Fe(II) and Fe(III). Data will be presented of the separation and will show how the speciation obtained can be used to identify the source of discoloration in the drinking water samples.

A spiked recovery study was carried out and values between 95-105% were obtained. The results indicated that discoloration may not be due to iron but to manganese within the samples and also the water treatment process. The implication is that discoloration maybe minimized without the need for costly pipe replacement work.

Abstract Text

A myriad of pharmaceuticals have been detected as contaminants in surface and wastewaters all around the globe, which can be linked to adverse health effects of local residents in those areas. According to the Center for Disease Control, eastern North Carolina has the highest accounts of stroke, heart disease, diabetes, and other diseases than any other region in the state. In this study, multiple water samples were obtained along various points of the Tar River and various stages of water treatment plants in eastern North Carolina to determine the types and levels of pharmaceuticals and personal care products (PPCPs) in surface waters and their potential link to the high incidences of disease in this area. Samples were prepared by solid phase extraction (SPE) or liquid-liquid extraction and analyzed for parent pharmaceutical compounds and their metabolites by liquid chromatography-time of flight mass spectrometry (LC-TOF-MS) and gas chromatography-mass spectrometry (GC-MS). Many parent PPCPs and their metabolites were detected in municipally treated water as well as in the Tar River including: carbamazepine, iminostilbene, oxcarbazepine, epiandrosterone, loratidine, gabapentin, Estradiol, triclosan, and others. From these findings, we conclude that PPCPs are currently water contaminants in eastern North Carolina, and may play a role in the frequency of differing disease states while also having a potential environmental impact on aquatic biota in this region.

Funding for this project was provided by an internal grant from the ECU Division of Research and Graduate Studies.

Abstract Text

During the development of proteins or monoclonal antibodies as therapeutics, it is critical to monitor the deamidation of asparagine residues as part of the stability study. LC-MS tryptic peptide mapping has become the method of choice for the analysis of deamidated degradation products, typically requiring 1.5 hours or even longer to achieve sufficient chromatographic separation between the native and the deamidated species. Subsequent relative quantitation by LC/MS peak area integration based on accurate mass XIC has been considered the gold standard, widely accepted, and routinely used in both industry and academia.

In this presentation, we will demonstrate an important pitfall and a systematic error in accurate mass XIC quantitation, due to a confluence of factors including aggressive settings on mass tolerance window, the mass spectral overlap between the A+1 isotope of the native peptide and the monoisotope peak (A) of the deamidated peptide, and the MS centroiding process. A novel and unique peaks shape calibration and analysis approach based on full profile mode data without centroiding will be presented as a fast and accurate alternative to LC peak area quantitation, allowing for highly accurate mixture analysis and the relative quantitation of deamidated and native peptides. Through comprehensive investigation on 9 different peptides with actual experimental data acquired with Orbitrap MS, we conclude that quantitation by mass spectral accuracy is at least as accurate as that from conventional LC peak area integration when there is true baseline separation. Equally accurate results can be obtained even with limited LC separation or no separation at all, i.e., through direct infusion. Interestingly, this approach also allows for the quantitative analysis of other degradation products such as multiply deamidated peptides or tryptophan oxidation products, all simultaneously in an one step full mass spectral calibration and analysis process.

Abstract Text

It was desired to administer crushed tablets in various solutions and food matrices. To demonstrate stability under the conditions of use, appropriate analytical methodology is required to quantify the potency and potential degradants for each proposed sample matrix. This presentation will describe the challenges encountered during method development concerning sample matrix interference for key degradants, sample extraction robustness, and the mitigation strategy. Specifically, the formation of an early-eluting API degradant could occur in the presence of two matrices and significant matrix interference is observed with detection and quantification of the degradant using conventional techniques. . Additionally, the interference varied as a result of the composition of the two food vehicles, apple juice and applesauce. Data presented demonstrate that analysis by LC/MS ensures accurate quantification of the potential degradant in all desired vehicles: water, 5% Dextrose in water, apple juice and applesauce. Additionally, sample preparation techniques were required to mimic clinical administration techniques. Data indicates that a single tablet crush and rinse preparation satisfies the clinical requirement while demonstrating that recovery and quantification risks are minimized.

Abstract Text

Robust, reliable chromatographic methods must be based on complete separation of all sample components. For reversed-phase methods, it has become common practice to screen organic solvents, column chemistries, and gradient slope as the first steps in developing a separation method. It is, however, also recognized that adjustment of mobile phase pH can also provide important and useful changes in selectivity where the analytes are ionizable. This manipulation has often been underutilized in method development because the preparation of buffered mobile phases is time consuming and labor-intensive. Most often, only widely separated pH conditions are tested to maximize retention. For groups of related compounds, however, small changes in pH can be more effective because the analytes behave as though partially charged. We have developed techniques and software to facilitate the preparation of buffered mobile phases from concentrated stocks using the solvent proportioning capabilities of the UPLC pump. To extend the utility of this approach, a buffer system has been developed that covers the pH range from 2-12 with good linearity and capacity. To facilitate peak identification and tracking, the buffers are volatile and transparent. Electrospray MS detection can, therefore, be combined with UV spectral detection using a photodiode array detector. We have shown the use of this buffer system for developing separations of pharmaceutical formulations as well as a variety of industrial chemicals. The fully automated preparation of mobile phases with different pH properties helps to ensure the optimum selectivity for separation of analytes in reversed-phase liquid chromatography.

Abstract Text

In recent years, it has become obvious that analytical chromatographic methodology is greatly improved when the stationary phase uses core-shell media as compared to fully porous media. The core-shell media will provide higher efficiency, improved sensitivity, and increased resolution when compared to what could be achieved with the same stationary phase on the same size fully porous media. Core-shell stationary phases are available in 5 μ m particle size for prep chromatography and all of the positive chromatographic properties observed at the analytical scale translate to the prep scale. However, the goals for prep methodologies are different than for analytical methods. The prep chromatographer is looking to collect material and optimize the triangle of purity, yield and throughput for that particular project. The properties achieved by core-shell material will help significantly with the purity and yield aspect but throughput is very dependent upon loading before the purity and yield are impacted.

The conventional thinking about loading is that it is driven by the surface area of the stationary phase media. Since core-shell media is not porous in the center of each particle, it has less surface area than an equivalent sized particle that is fully porous. The work presented here evaluates how significant this difference in surface area is with respect to loading for prep chromatography. Loading studies on both core-shell and fully porous media for several pharmaceutically related compounds will be presented.

Abstract Text

Transfer of established HPLC methods across both HPLC and UHPLC chromatographic instrumentation from different vendors requires careful consideration of chromatographic principles as well as an understanding of each instrument's operating parameters. For example, the instrument's attributes, including temperature control and fluidic pathway, can all impact the fidelity of the separation and, thereby, the overall success of method transfers. Instrument parameters, such as operating pressures and flow rates, as well as method conditions, can also limit the transferability of methods to/from instruments. To overcome these challenges, all of the factors must be considered and accounted for when transferring an HPLC method from instrument to instrument and across different vendors.

We will present a series of studies illustrating methods transfer of HPLC methods across multiple instruments and instrument vendors. Chromatographic properties such as gradient delay, sample considerations (sample solubility and diluent) and temperature will be assessed and factored into the method transfer studies. These studies will also evaluate the impact of instrument attributes including temperature control, system volume, injector design and pump characteristics. Transferability of the method will be assessed through system suitability criteria (retention time, relative retention time, area, etc.). Consideration is made to conduct method transfer in accordance with USP-NF Chapter 621 guidelines for allowable adjustments to compendial methods. The studies will culminate in guidelines for successful methods transfer of HPLC methods across both UPLC and HPLC instrumentation.

Abstract Text

New stationary phases consisting of high performance R,S-hydroxypropyl ether derivatized β -cyclodextrin (HP-RSP CD) and native cyclofructan-6 (CF-6) bonded to silica superficially porous particles (SPP) were developed and analyzed in hydrophilic interaction chromatography (HILIC) mode. These new SPP stationary phases (2.7 μ m diameter) were evaluated and compared to HP-RSP CD and CF-6 bonded to fully porous particles (FPP) of 5 μ m and 3 μ m diameters. The HP-RSP CD and CF-6 SPP phases showed faster and more efficient chromatography compared to both 5 μ m and 3 μ m in diameter FPP phases. The analysis of SPP phases yielded a reduction of analysis time by 50 to 70% with a higher value of N/min over the entire range of flow rates analyzed compared to the FPP phases. Van Deemter plots of the SPP phases showed a higher optimum flow rate compared to the FPP phases. In summary, HP-RSP CD and CF-6 SPP HILIC phases showed clear advantages compared to the FPP counterparts in terms of high throughput and efficient separation of compounds.

Abstract Text

Analytical chromatographic methodologies can use a wide range of eluent modifiers to optimize their chromatography. Prep Chromatography processes are more limited in the use of eluent modifiers. The only requirements for modifiers in analytical HPLC are compatibility with the detector, not precipitating the analyte and not causing degradation within the timescale of the chromatographic run. The requirements for modifiers used in Prep Chromatography must meet the same requirements but also must not impair the isolation of the final material. There can't be any undesired salt formation, degradation during isolation, or hindering of the desired crystallization.

Trifluoroacetic acid (TFA) is a commonly used modifier for chromatography. TFA is used to improve the peak shape or change the column selectivity for the analytes of interest. One of the best attributes TFA has for use in Prep Chromatography is that it is volatile. Typically it can be removed by drying in an oven, under vacuum or with a rotovap. However, sometimes TFA will form a salt with the isolated compound and cannot be removed with the usual techniques. Another issue encountered with TFA, is that some compounds degrade in its presence and this degradation is often accelerated during the concentration / isolation process. The work presented here will describe methodology we have developed to remove TFA from collected Prep Chromatography fractions by using solid phase extraction. This technique has been applied at several different scales from mg to multigram with fraction volumes as large as several liters.

Abstract Text

The advantages of the analysis and purification of basic compounds by RP-LC in high-pH mobile phases have been clearly established in the past ten years since the introduction of alkaline resistant hybrid-type fully-porous sorbents. These proven benefits include extended retention for polar basic analytes, improved peak shapes, different selectivity as well as increased loading capacity. The advancements in core-shell particle technology of recent years also bring to reality the benefits of unparalleled resolving power for the demanding chromatographic applications. These particles enable the development of analytical methods with shorter run times and higher sensitivity. The purpose of this study is to demonstrate the benefits of a new stationary phase that is optimized for the challenging analysis and purification of basic compounds by combining the hybrid organo-silica grafting and core-shell technologies.

Abstract Text

Superficially porous alkyl phases such as Poroshell EC- C18 are widely used for reversed-phase HPLC. Superficially Porous HPLC columns such as Poroshell 120 show comparable efficiency to sub 2 micron particles with about half the back pressure. Columns packed with these materials can be used in older HPLC instruments or in new higher pressure instruments for high resolution in longer column formats. However, analysts occasionally encounter difficult separations for which selectivity, ruggedness or reproducibility is not easily obtained with a C18 column. These separations might require the use of bonded phases or conditions that may yield a different selectivity. In these cases a method that is orthogonal, or offering differing relative retention to the first method, is desirable.

The use of pH is particularly powerful way to affect selectivity, especially with compounds of pharmaceutical interest. As these compounds are ionizable, pH can affect the retention time dramatically. With the introduction of newer more pH stable superficially porous particle columns such Poroshell HPH-C18, a wider variety of buffers is available for use by the analyst without sacrificing lifetime at high pH compared to silica based columns. In addition to pH, choices of bonding and end capping chemistry can vary selectivity. Retention factors are measured for neutral, acidic and basic compounds on a variety of superficially porous columns. Several chromatographic conditions are varied including buffer/pH modifier, organic modifier (MeOH or ACN), and column chemistry (C18, Polar Embedded, Phenyl-Hexyl, PFP, end-capped vs. non – end capped). These conditions are examined to determine selectivity differences and similarities across a range of commonly used LC/MS compatible, preparative and LC only compatible conditions. The most orthogonal separation conditions are identified.

Abstract Text

Aggregate analysis via gel filtration chromatography (GFC) is a primary quality indicating method for any protein, and a required lot release test for most protein therapeutics. As protein aggregates are typically the principal cause of drug neutralizing antibodies, determination of the level of aggregation in a sample is important in determining the safety of a drug. In an ideal setting GFC can deliver a highly accurate value of covalent and non-covalent protein aggregates in solution. Unfortunately, secondary interactions between the stationary phase in a GFC column and aggregated proteins in solution can adversely affect their quantitation leading to inaccurate results. Recent innovations in column chemistries by several leaders in the field have overcome some of these issues; however different operating conditions are often required to achieve accurate results. In addition, some new products feature smaller particle media which have allowed for rapid GFC separation that require further HPLC method development and different analytical challenges. In this study several new GFC column technologies were evaluated including some sub-2 μ columns recently introduced into the market. Secondary interactions were assessed over various salt, pH, and temperature conditions for the mobile phase. In several cases changing the ionic strength of the mobile phase could significantly increase the recovery of protein aggregate. In addition, repeat injections of proteins can "prime" a column by saturating sites of interaction leading to higher recovery of proteins. Results from these experiments attempts to present a methodology for making GFC methods that properly report the level of protein aggregation in therapeutic drug samples in a robust and reproducible manner.

Abstract Text

Reversed phase high performance liquid chromatography (RP-HPLC), hydrophilic interaction liquid chromatography (HILIC) and ion exchange chromatography (IEC) technique were investigated for the simultaneous determination of heparin and its impurities including oversulfated chondroitin sulfate (OSCS) and dermatan sulfate (DS) in heparin products. Different types of HPLC columns, e.g. ODS, HILIC amide and strong anion exchange (SAX) columns were studied. Composition of mobile phases including types and pH of buffer and type and amounts of organic modifiers (methanol and acetonitrile) were varied. The examined RP-HPLC and HILIC conditions did not retained heparin and its impurities, resulting in overlapping peaks at the solvent front. SAX-HPLC (gradient elution of sodium chloride and Tris phosphate buffer pH 3.0) showed some retention of the analytes. Thus, IEC seemed to be the most suitable technique among the three selected techniques for the analysis of heparin and its impurities. Lowering mobile phase pH and addition of acetonitrile enhanced the separation ($R_s = 1.46$). The separation of heparin, DS and OSCS (R_s above 2.0) was achieved on a SAX column with a gradient elution of 10-70% of 2.5 M sodium chloride and 20 mM Tris phosphate buffer pH 2.1 at a flow rate of 0.6 ml/min and UV detection was at 215 nm. The method was fully validated according to the ICH recommendations and applied to analysis of raw materials and heparin products in Thailand. The method will be valuable to the Thai Food and Drug Administration (FDA) and hospitals for selection of heparin products.

Abstract Text

The uses of nanoparticle based analytical technologies are dramatically increasing in the fields of analytical chemistry, nanotechnology, clinical diagnosis and the food industry. In this presentation, we describe development and characterization of portable nanoparticle based-assays, similar to a small sensor patch, for rapid and sensitive detection of target analytes and the use of these particles as colorimetric probes in bioanalysis. These assays are based on the immobilization of metal oxide nanoparticles onto filter paper, which change color after interaction with the target analyte by means of redox and surface chemistry reactions. Paper based sensors have advantages in terms of low-cost and portability, allowing development of point-of-care (PoC) diagnostic devices. Integration of metal oxide nanoparticles onto a paper platform enables realization of a sensor that does not require external reagents, as all the sensing components are fixed onto the paper platform. The proposed mechanism can find wide application as a general approach for simplifying detection schemes of colorimetric bioassays, e.g. enzyme, gene, immune and aptamer assays and related affinity sensing methods. Several examples of such applications will be presented.

Abstract Text

Current bioanalytical sensing and imaging applications utilizing nanomaterials require distinct properties such as high brightness, chemical inertness and colloidal stability in physiological media. As many established nanoparticle systems either lack at least one of these properties or have several disadvantages (for example, complicated synthesis, tedious surface engineering), researchers continue to seek alternative materials. Recently, carbon dots (Cdots), have emerged as promising candidates for new applications, as they combine all of the desired properties mentioned above.

The reported Cdots, prepared via hydrothermal treatment of starch and tryptophan, are closely related to graphene quantum dots in terms of luminescence properties with the advantages of lower cytotoxicity and excellent colloidal stability. The optical properties, as well as possible toxic effects were characterized in detail. These water-dispersible particles with a diameter of 1.6 ± 0.8 nm exhibit unique luminescence properties which enable multicolor imaging of mammalian cells. Extreme photostability as well as high quantum yields of up to 26% render them as attractive probes in confocal laser scanning microscopy (CLSM). A concentration dependent wavelength shift in the fluorescence of the Cdots from blue ($\lambda_{\text{max}} \sim 450$ nm) in low concentrations to green ($\lambda_{\text{max}} \sim 525$ nm) in higher concentrations is observed. This effect may be attributed to reabsorption effects of short wavelength light or distinct luminescent species with different self-quenching properties. As such, this behavior could be the basis for several (bio)analytical applications utilizing this effect which is unique to Cdots. Via CLSM imaging, it is shown that normal rat kidney cells incubated with Cdots of different concentrations exhibit varying colors depending on the local Cdot concentration and the laser excitation wavelength.

Abstract Text

Nanotechnology became most reliable system for environmental and for biomedical applications within the last decade. This advancement shifted the focus on small carriers to increase the efficiency of the drugs and as a catalyst. Among these, gold nanoparticles (GNPs) found to have profound biomedical and catalytic applications. Our main research focuses on designing gold nanoparticles (GNPs) capped with range of molecules for various biomedical such as enhanced antibacterial, antidiabetic, anticancer activity and catalytic application. We have been successful in synthesizing GNPs using carbohydrates, antibiotics, anti-diabetic and anticancer drugs. The GNPs are characterized by various analytical techniques such as TEM, SEM, FTIR, UV-Vis, TGA, ICP-OES, MALDI-MS and DLS. Antibiotic GNPs are evaluated for their antibacterial activity against Gram-positive and Gram-negative bacterial strains using broth dilution and colorimetric assays. Anti-diabetic GNPs are evaluated using alpha-glucosidase and alpha-amylase assay. Anticancer GNPs are evaluated in various cancer cell line including HeLa cells. Results showed enhanced antibacterial, anti-diabetic and anticancer activity in comparison to the pure drug by itself. We also synthesized carbohydrates capped GNPs for their use as an effective catalyst for industrial applications. We are currently evaluating the effect of size of GNPs on the antibacterial and catalytic properties which will be followed by in-vivo studies and wide array of catalytic testing. Results of these studies not only provide us a novel synthesis method but also yield an efficient drug carriers as well as catalytic agents. This research was support by KY NSF EPSCoR Grant 0814199, WKU research foundation.

Abstract Text

Silver nanoparticles (Ag NPs) have posed a wide range of potential applications including serving as therapeutic agents and ultrasensitive optical imaging probes. As Ag NPs have also been used in consumer products, potential release of Ag NPs to aquatic environments could lead to adverse health impacts on human. In this study, we have synthesized and characterized purified and stable silver nanoparticles and then studied their effects on embryonic development using zebrafish embryos as [i] in vivo [/i] model organisms. To determine their specific effects on various developmental stages and their related mechanisms, we incubated the embryos with Ag NPs for two hours, and characterized their effects upon embryonic development over time using a wide variety of bioanalytical tools. We also used dark-field plasmonic optical microscopy and spectroscopy to quantitatively characterize single NPs embedded in the tissues of development zebrafish. We found that the effects of NPs on embryonic development highly depended upon embryonic developmental stage, incubation time, the size and dose of NPs.

Abstract Text

Gold nanorod (GNR) is at the center of attention in biological applications spanning from biosensing to drug delivery. To be successful, conjugation of biomolecules with GNRs is the crucial basis. Current functionalization methods are often problematic, involving multi-step nanoparticle modification to replace surfactant bilayer, delicate nanoparticle protection during surfactant exchange, and material loss due to inevitable aggregation. Instead of intensive surface modification of GNRs, we demonstrated a facile method to functionalize gold nanorod surfaces via covalent Au-S bonds by thiolating receptors. The resulting GNR-bioconjugates showed superior stability and biofunctionality. To demonstrate the practical use, we developed a label-free nano-biochip with optical transduction based on surface plasmon resonance shift of GNRs. The antibody thiolation facilitated a straightforward biochip functionalization with anti-human IgG molecules, which can detect human IgG targets in a chip format with high sensitivity and specificity. Compared to electropolymeric coating to functionalize the GNR, our method exhibited a five-fold enhancement in the spectral sensitivity to refractive index change caused by the target binding. This is due to the significant shortening of the distance between binding events to the optical transducer surface (i.e. GNR sensor) as a result of CTAB replacement by the thiolated antibody moieties. Since gold nanorod is a material of great interest in current research, this work to simplify the biofunctionalization in a simple and efficient fashion is timely and universal for various applications.

Abstract Text

Structural biology underpins rational drug design, with crystallography serving as the most widely used method of high-resolution structure determination. The difficulties associated with obtaining large, well-diffracting crystals and X-ray damage have been the biggest limitations of traditional protein crystallography. Serial nanocrystallography overcomes those limitations by focusing on protein nanocrystals and has been shown to be useful in solving the structures of membrane proteins. As a result, the need for fast and selective characterization of protein nanocrystals has arisen.

Second harmonic generation correlation spectroscopy (SHG-CS) is demonstrated as a nondestructive and selective approach for screening different crystallization conditions and for assessing crystal quality prior to exposure to X-ray free-electron laser source. The presence of nanocrystals and the size distribution can be retrieved from the intensity fluctuation of the SHG signal through autocorrelation analysis as particles diffuse through the focus of the laser. Unlike dynamic light scattering, the intrinsic selectivity of the second order nonlinear optical process provides SHG-CS the ability to distinguish well-ordered structures like nanocrystals from conglomerated protein and amorphous aggregates. Custom built instrumentation and software with real time data analysis have been developed to perform SHG-CS measurements. Validation of SHG-CS was performed using BaTiO₃ nanoparticles ranging from 200nm to 500nm, and was shown to provide good agreement between the measured correlogram and the theoretical model. SHG-CS was extended to the detection and characterization of protein nanocrystals.

Abstract Text

Silver is used for many uses including purification of drinking water to coatings for medical and industrial applications to take advantage of its antibacterial and antimicrobial abilities. This precious metal while effective at sanitizing is toxic in higher concentrations to organisms in the environment. The use of silver in nanoparticle form is gaining popularity in consumer products and in turn are becoming a threat to the environment with more rigorous usage. These particles enter the waterways through the wash or more directly through the discard of silver coated items. The understanding of silver's interactions with higher plants used for phytoremediation purposes is lacking without further research especially on the cellular response within the plant in the presence of reactive oxygen species. These reactive species are essential to several biological process. However, the overproduction of these reactive oxygen species can cause major oxidative stress leading to cellular damage that may cause cell death or irreversible cellular damage.

This research looks into the production of reactive oxygen species within the leaves of Pistia stratiotes, a plant commonly used for phytoremediation, caused by the presence of silver nanoparticles and silver(I) with various environmental cations using fluorescence detection of oxidative stress.

Abstract Text

Sample preparation for global metabolomics of human plasma is currently predominated by methanol and methanol/ethanol precipitations which produce samples comprised mostly of medium to high abundance metabolites. Solid-phase extractions remain underused in untargeted metabolomics despite their potential to aid in the detection of low abundance metabolome. In this work liquid and solid-phase extraction methods were systematically compared for the extraction of human plasma by liquid chromatography-mass spectrometry (LC-MS). Complex chemical composition of plasma exceeds quantitative and identification capabilities of LC-MS analytical methods. To address this complexity issue, standard mix enriched with hydrophobic (lipids and fatty acids), neutral (sugars, steroids), cationic (amines), anionic (organic acids) and zwitterionic (amino acids) compounds covering range of logP from -6 to 7 was also extracted using all methods for full recovery studies. Samples were extracted in replicates (n=6) with ethanol-methanol, methanol, methyl-tert-butyl ether (MTBE), methanol-MTBE, divinylbenzene-pyrrolidone, octadecylsilane, divinylbenzene-strong-cation-anion exchange and acrylamide-based size exclusion methods. Samples were analysed on mixed-mode (octadecylsilane / weak anion / weak cation) and HILIC (unmodified silica) chromatographic columns coupled to Orbitrap Velos mass spectrometer. Methanol and its blends quantitatively recover high to medium polarity metabolites, while MTBE extracted non-polar compounds. Solid phase extractions demonstrated compound-specific selectivity and size exclusion extracted variable metabolites smaller than 1.5 kDa. Overall, the study allowed to compare selectivity, ionization suppression, repeatability and absolute recovery of extractions from standard mix and human plasma. The novelty of this work is in improved interpretation and applicability of solid-phase extraction methods in untargeted metabolomics of biological fluids.

Abstract Text

For more than two decades, CDC researchers have measured tens of thousands of samples for serum cotinine levels as part of the National Health and Nutrition Examination Survey (NHANES). Challenged with more than double the sample load, we developed and validated a rugged, automated sample-to-answer preparation method using Hamilton STARlet and PerkinElmer Staccato Systems robotics technologies. Analysis of serum cotinine is performed by isotope-dilution UPLC/APCI-MS/MS using a Shimadzu Nexera UPLC System coupled to an AB SCIEX Triple Quad™ 6500.

To our knowledge, we are the first to use a fully automated method in the analysis of serum cotinine in smokers and non-smokers. The automated method includes aliquoting via the Hamilton STARlet followed by on-column liquid-liquid extraction and evaporation of extracts on the Staccato System. The Staccato System integrates sample preparation automation via multi-layer platforms, which host multiple peripherals with flexibility to extend modularity and future modification. A powerful Mitsubishi RV-6SDL S15 6-axis robot integrates these peripherals for multi-task operations. The UPLC-MS/MS design integrates additional technologies, such as an autosampler with direct sampling from 96-well plates, and sub-minute separation is achieved. Moreover, software automation is achieved using Indigo Biosystems Ascent to handle the sample-to-answer workflow from sample batch building to data review and final reporting saving hours/days of labor in data analysis. This innovative, automated method has quadrupled sample throughput to 384 samples per day, reduced sample volume by 60% and solvent usage by more than 88%, and cut consumable costs dramatically with no change to our limit of detection. Overall, this sensitive, accurate, and precise method is the basis for future assessment of cotinine in other matrices, such as saliva and urine, as well as the assessment of other major nicotine metabolites, such as trans-3'-hydroxycotinine.

Abstract Text

New regulations for the analysis of trace metals in pharmaceutical ingredients have generated new challenges for the pre-analytical preparation on the wide range of samples that would undergo testing. For USP 232/233, the demand for a clear process is evident. To obtain high quality multi-element ICP-OES/MS data, several techniques have been used without a solution for all samples. Conventional closed-vessel microwave digestion has been recognized as the most effective technique for the digestion of the widest range of sample types in metals analysis. Unfortunately, pressure and temperature constraints using traditional techniques have complicated the picture: multiple steps, incomplete digestions and specific methods for troubling elements. Single reaction chamber (SRC) microwave technology is a new technique with the capability of digesting several different types of samples simultaneously at temperatures up to 300 degree Celsius and pressures to 199 bar. Utilizing this new microwave design with user feedback, an optimized primer on critical factors in preparation choices as well as a single method solution utilizing SRC technology and ICP-MS multi-element analysis will be presented.

Abstract Text

Solid phase microextraction (SPME) is explored as a sample preparation method for profiling volatile metabolites from biological samples (e.g. blood, urine) by GC and GCxGC. Conventional sample preparation methods for biological fluids can be somewhat complex and laborious, whereas sample preparation using SPME is minimized. With the application of SPME, only a fraction of the sample is selectively extracted and introduced to the instrument. However, this may be a small price to pay for the reduced sample preparation requirements. In this contribution, headspace SPME is examined for analysis of human metabolites in whole blood and urine to simplify the sample preparation procedure. Preliminary studies were conducted on whole bovine blood to minimize sample volume and sample preparation for acid- and base-neutral extractions while minimizing issues associated with clotting. Optimized parameters include sample volume, acid, salt, and dilution volume. Extraction times and temperatures were also optimized and fibre chemistry was also explored, as was the use of vacuum-assisted SPME.

Abstract Text

Purpose. The experimental objective was to develop a mechanical device that can generate lifelike pharmacokinetic profiles for any chemical compound (realistic animal alternative – RAT).

Methods. An in vitro model matching the biological characteristics of a rat was developed in order to generate pharmacokinetic (PK) profiles corresponding to the one compartment (1C) and two compartment (2C) models with various routes of administration. The majority of the experimental setups generated first order curves, with one setup used to simulate a zero order curve. The device was entirely mechanical, created with pumps and tubing. The change in compound concentration in the liquid was monitored online using spectrophotometry. At the end of each experiment various PK parameters were calculated along with the relative standard deviation (RSD) associated with each of the 3 trials per experimental setup.

Results. The device successfully generated ten types of realistic pharmacokinetic profiles, with all coefficients of correlation (r^2) between the desired models and experimental results higher than 0.99 (most r^2 were found to be 1).

Conclusions. These results suggest that this device is highly accurate and precise at generating realistic PK profiles, and can be used in research and teaching in analytical chemistry and pharmaceuticals.

Abstract Text

The neurotransmitter glutamate is the primary excitatory neurotransmitter in mammalian nervous systems. Determinations of glutamate in the nervous system are essential to understanding neurochemical control. Nonetheless, there is wide disagreement with a fundamental measurement; reported concentrations of glutamate found endogenously in the nervous system vary by greater than three orders of magnitude (nanoM to microM). Glutamate levels are studied in this work with low-flow push-pull perfusion applied to mouse hippocampal slices. Perfusate samples are labeled with a fluorophore and separated with capillary electrophoresis to quantitate amino acids including glutamate. Amino acid levels were monitored for 6 hr periods in order to follow any amino acid fluctuations due to tissue activity or bath superfusion of the tissue slice. Experiments determined effects of probe placement and tissue preparation on the observed glutamate. Basal level glutamate is determined from mutant mice (xCT) with a knocked-out cystine-glutamate transporter and the background strain mice. The transporter has been hypothesized to regulate the extracellular glutamate levels. Results demonstrate the capability of low-flow push-pull perfusion for sampling from relatively thin tissue slices and qualitative analysis of electropherograms shows good similarity to samples collected in vivo. There is a significant difference between the glutamate levels $4.90 (\pm 1.1)$ & $1.9 (\pm 0.5)$ μM for wild type and xCT ($p=0.0001$) mice, respectively. In contrast, no differences are seen in basal levels of glutamine, aspartate and glycine. Glutamate levels over time show that there are significant decreases of basal glutamate in wild type but not xCT slices over the course of 6 hours of sampling. These experiments show a sampling approach that is applied to a tissue slice preparation from which low nM basal glutamate levels are typically reported in contrast to the low microM levels observed here.

Abstract Text

The direct analysis of tissue samples by matrix-assisted laser desorption ionization imaging can be challenging both due to the requirements for addition of matrix to the tissue as well as limitations due to dynamic range and sample complexity. We are developing a laser ablation to selectively transfer biomolecules from a thin tissue sections using an infrared laser. After the biomolecules have been removed from the tissue and deposited on a separate target, they are analyzed using MALDI imaging. The current work is aimed at the detection of in-situ digested peptides in rat brain tissue sections. The tissue section is mounted on a microscope slide and trypsin digestion is performed after elimination of salts and lipids with serial washing steps. The receiving slide is a nitrocellulose coated indium tin oxide conductive slide. The two slides are mounted on a two-axis translation stage with an 80 μm gap between them. The slides are translated at a speed of 30 $\mu\text{m}/\text{s}$ so that the laser irradiates and transfers molecules from a selected area of the tissue. Tryptic peptides are transferred with an IR laser at 3 μm . After transfer, a matrix is sprayed onto the receiving slide and MALDI imaging is performed. With the sample transfer method, we are able to transfer the digested peptides from a tissue section to a target slide with high efficiency. Also, ion suppression due to tissue components is reduced. Ongoing research is being directed at optimizing the spatial resolution of the transfer and selective transfer of tissue biomolecules.

Abstract Text

We developed a two-dimensional (2-D) photonic crystal lectin sensing material that utilizes light diffraction from a 2-D photonic crystal attached to the surface of a mannose monomer containing hydrogel. Lectin-carbohydrate interactions create hydrogel crosslinks that shrink the hydrogel volume and decrease the 2-D array particle spacing. The lectin sensing hydrogel was prepared through copolymerizing a solution of acrylamide, acrylic acid, N, N'-methylenebisacrylamide, and allyl-modified mannose onto the 2-D array on a glass slide. This mannose containing 2-D photonic crystal sensor detects Concanavalin A (Con A) solution through shifts in the 2-D diffraction wavelength. Con A concentrations can be determined by either measuring the diffracted wavelength, or visually determined from the change in the sensor diffraction color. The concentrations are easily monitored by measuring the 2-D array Debye diffraction ring diameter with a green laser pointer. Our observed detection limit for Con A is 0.02 mg/mL (0.7 μ M). The 2-D photonic crystal sensor is selective for mannose-specific lectin sensing. The 2-D photonic crystal sensors are completely reversible and can monitor Con A solution concentration changes.

Abstract Text

Thiamine (vitamin B1) deficiency is a major cause for high mortality in fish of commercial and sport-fishing interest in the Great Lakes and the Baltic Sea. Its deficiency has been associated with poor immune system development and survival rate of fry, as well as reduced visual acuity, neurological symptoms, and muscle weakness in adult fish leading to their inability to migrate during spawning. Its deficiency is also known to cause neurological and cardiovascular problems in other species, including humans. This molecule has recently also been identified as an important nutrient in algal bloom proliferation. Current procedures for thiamine quantification rely on extensive sample preparation and formation of the fluorescent oxidation product, thiochrome, prior to chromatographic analysis. The cost and time required for these procedures limits data available for informed decisions critical to fish health by the fisheries industry and researchers alike. A high-throughput assay for thiamine quantification with specificity provided by biorecognition is thus needed and was the objective of this work. We have previously demonstrated that periplasmic binding proteins can exhibit exceptional specificity and can be used in analytical methods for small-molecule targets not amenable to antibody-based detection. Here, thiamine periplasmic binding protein (TBP) conjugated fluorescent dye-encapsulating liposomes, as an alternative to traditional enzymatic amplification, served to provide recognition and signal amplification in a competitive microtiter-plate assay for thiamine. Results and challenges to development of a total thiamine assay in fish eggs will be presented.

Abstract Text

Brevetoxins (BTXs) are very potent marine neurotoxins that increased in geographical distribution in the past decade causing the illness clinically described as neurological shellfish poisoning (NSP). The ethical problems as well as the technical difficulties associated with the currently employed analysis methods for marine toxins are encouraging the research for suitable alternatives to be applied in a regulatory monitoring regime. Here, we report an electrochemical biosensor platform for BTX-2 detection using aptamer as specific receptor. Using in vitro selection, high affinity DNA aptamers to BTX-2, were successfully selected for the first time from a large pool of random sequences. The binding of BTX-2 to aptamer pools/clones was monitored using fluorescence and electrochemical impedance spectroscopy (EIS). The aptamer BT10 exhibited the highest binding affinity, with a dissociation constant of 42 nM. The effect of the incubation time, pH and metal ions concentrations on the aptamer-toxin binding was studied. The aptamer BT10 was used to construct a label-free competitive impedimetric biosensor for brevetoxin detection showing good sensitivity. A high degree of cross reactivity of the selected aptamer to the two similar congeners, BTX-2 and BTX-3 was observed, whereas no cross reactivity to other marine toxins was obtained. Moreover, the aptasensor was applied for the detection of BTX-2 in spiked shellfish extracts showing a very high recovery percentage. We believe that the continual emergence of novel high-affinity aptamers will open the way to a variety of biosensing architectures, particularly for small-molecule toxin detection in complex samples.

The authors would like to thank NSERC for funding.

Abstract Text

Fluorocarbon solvents have low intermolecular forces and are both lipophobic and hydrophobic, causing low solubility for nonfluorous compounds. However, solutions of fluorocarbon carboxylic acid in fluorocarbon solvent have been shown to selectively extract organic bases through hydrogen bonding and ionic exchange. This research focuses on the interaction between perfluorodecanoic acid (PFDA) and pyridine in HFE-7500 (3-ethoxy-1,1,1,2,3,4,4,5,5,6,6,6-dodecafluoro-2-trifluoromethyl-hexane). This is a complicated titration composed of PFDA monomer and dimer, free pyridine, and three different complexes consisting of one, two, and three PFDA to one pyridine, making analysis difficult. Isothermal titration calorimetry was used to measure equilibrium constants and enthalpies.

This system contains eight unknowns: four equilibrium constants and four enthalpies. Reducing the number of unknowns will provide more accurate estimates of equilibrium constants and enthalpies. Thus, we have used MATLAB to determine conditions under which a smaller number of equilibria are relevant. Four sets of conditions, the most complex of which has four unknowns, provide good precision for all eight unknown parameters.

A comparison is being made between the equilibrium constants and enthalpies from ambient and dry experiments performed under a nitrogen atmosphere. Differences have been seen in: dimer enthalpies: -30.98 ± 0.15 kJ/mol (ambient) and -11.89 ± 0.81 kJ/mol (dry) and 1:1 complex enthalpies: -41.94 ± 0.15 kJ/mol (ambient) and -35.81 ± 0.59 kJ/mol (dry). Water content is measured with Karl Fischer titration.

Abstract Text

Binding interactions at the cell membrane interface are notoriously difficult to study. This talk will describe a novel integration of lipid bilayer nanodiscs, microring resonator sensor arrays, and a non-linear solution gradient generator that facilitates high throughput studies of the blood coagulation cascade. Calcium ions have long been known to regulate activation and binding of blood clotting factors; however, recent studies suggest an important role for magnesium as well. Using the aforementioned approach, we have probed the divalent cation dependence of Factor X binding to a model cell membrane interface. Importantly, the powerful combination of these technologies allowed for the rapid collection of information-rich, multi-dimensional binding profiles as a function of the divalent composition in the buffer. Equilibrium binding affinities were determined over a wide range of conditions showing that magnesium plays a key role in stabilizing Factor X lipid bilayer interactions, consistent with those found physiologically.

Abstract Text

Designing displacement-dependent nucleic acid biosensors with selectivity to a given analyte is dependent on conformational changes, thermodynamics, and kinetics of the displacement mechanism. We recently developed an innovative biosensor that uses a competitive displacement mechanism composed of a unique self-complementary reporter partially bound to a probe selective for a microRNA (miRNA) analyte. The analyte will displace the reporter from the reporter-probe complex to form a more thermodynamically stable probe-analyte complex and a free reporter. The free reporter, which contains dyes on the 5-prime and 3-prime ends of the sequence, folds into a hairpin structure forcing the dyes close to one another causing a dynamic signal change proportional to analyte concentration. The reporter-probe complexes must be robust to be selective for a given miRNA analyte and used in complex systems such as cells or tissues. Using a MATLAB program developed in-house, we are able to isolate potential reporter sequences that minimize off-target binding. We have designed various different reporters against miR29b-1-5p to evaluate which thermodynamic parameters are most important when developing reporter strands. Gibb's free energy and melting temperature of the hairpin, reporter-probe, and off-analyte binding are evaluated along with the number of reporter hairpins to identify those most likely to give a maximal signal change. To evaluate which parameters lead to optimal reporter strands, the extent of signal change and kinetics upon reporter-probe and probe-analyte binding were investigated. This research gives insight into what metrics are most important when designing reporter-probe biosensors for miRNAs.

Abstract Text

Sensing systems capable to assess very minute (0.2-0.5 units) changes of pH may benefit in molecular level understanding of physiological processes involved in cellular proliferation, apoptosis, ion transport, endocytosis, metabolism, and others. DNA quadruplex-based sensing systems have been established for detection of variety of targets from ions and small molecules to proteins. The sensors possess unique specificity and can be integrated with a variety of signal transduction platforms (e.g. optical, electrochemical, QCM, SPR, acoustic, and/or cantilever-based). We demonstrate on the example of DNA i-motif based pH sensors that both response range and response sensitivity of those systems can be tuned via deliberate manipulation of the quadruplex folding cooperativity. The tools of manipulation include the core quadruplex intrinsic structural features as well as rationally included allosteric elements. We achieved an unprecedented precision of transition point tuning (i.e. down to 0.1 pH units) and response sensitivity overcoming the Henderson-Hasselbalch limitation associated with conventional molecular sensors (i.e. width of transition between 10 and 90 % unfolding down to 0.2 pH units and tunable) for the particular systems tailored to respond in the physiologically meaningful pH range. Further, we showed that the sensing approach can be successfully integrated with fluorescent signal readout resulting in a biocompatible detection/imaging platform. The major advantage of the presented i-motif based system over conventional strategies employed for pH sensing is the capability to tune both the response range and/or response sensitivity with the high precision. Those qualities are expected to be instrumental in development of relevant bioanalytical monitoring tools.

Abstract Text

Stir bar sorptive extraction (SBSE) is a solid phase technique for extraction of hydrophobic analytes from aqueous matrices. SBSE has achieved widespread use among biological, agricultural, environmental laboratories and now in environmental human health by improving method runtime, sensitivity, recovery, and precision over existing methods of extraction, such as. Electromagnetic Assisted (EMA) extractions have been used for many decades in the form of microwave digestion and extractions to determine inorganic species, for example. This research was the first to investigate the use of electromagnetic adsorption to significantly reduce the time required for extraction equilibration. Using extraction equilibrium as an endpoint, this research compared sensitivity, extraction temperature, and extraction time of traditional SBSE and EMA-SBSE. Total extraction time was significantly reduced by approximately 90% and increased extraction recovery for the analytes using EMA. The mechanism governing the improved extraction time was investigated using laser-enhanced ionization to determine penetration depth of each analyte into the polymeric extraction phase at varying time intervals. This research has produced a novel extraction method that significantly reduced extraction time and can be paired with standard gas or liquid chromatography. Furthermore, the investigation of the increased extraction efficiency of EMA-SBSE has resulted in a greater understanding of the mechanism through which EMA interact with polymeric solid phase extraction materials.

Abstract Text

Quantitative and effective techniques for blood sampling and analysis are required to meet the growing needs of the medical and bioanalytical communities. Traditional blood draws are inherently used because of the amount of blood typically withdrawn from the patient and most of this blood is discarded. Dried matrix spot (DMS) greatly reduces the volume of collected blood in the sample, thus enabling more frequent and easier procurement with a finger stick instead of a venous blood draw. An additional benefit is the ability to transfer DMS across international borders. Development of the ability to quantitate DMS analytes using mass spectrometry is of importance to bioanalytical research and medicine. Traditional DMS workflows require tedious sample preparation and is more time consuming than direct analysis outlined in this study. Traditional DMS analysis techniques require punching out and extracting the analytes of interest off the card then perform liquid chromatography on the sample prior to mass spectrometric detection. The present study involves the technique of laser-enhanced ionization of the biomedically important peptide, glutathione (GSH). GSH and GSSG (oxidized glutathione) ratios are of particular importance because the ratio is a biomarker for the robustness of the immune and detoxification systems in the human body. This research was performed using an excimer laser enhanced ionization source coupled to a quadrupole time-of-flight (QTOF) mass spectrometer. Laser ionization via matrix-assisted laser desorption/ionization (MALDI) could prove to be a valuable quantitative alternative method for DMS analysis and medical measurements. By coupling MALDI with QTOF mass spectrometry in conjunction with Isotope and Speciated Isotope Dilution Mass Spectrometry quantification can be enabled.

Abstract Text

Electrospray ionization (ESI) has become a staple in the field of mass spectrometry (MS), but its requirement for high voltages makes it less than ideal for field analyses and coupling to miniature MS systems. In recent years, many novel alternative ionization techniques have surfaced, including, but not limited to, desorption electrospray ionization (DESI) (Takáts et al. Science 2004), Venturi easy ambient sonic spray ionization (V-EASI) (Santos et al. Analytical Chemistry 2011), and sonic spray ionization (SSI) (Hirabayashi, A.; Sakairi, M.; Koizumi, H. Anal. Chem. 1994). While these are all excellent ionization techniques, they each require high voltage or compressed gas. Here we present an easy to operate, cost effective ionization technique, spray pump ionization (SPI), that eliminates the need for voltage or gas flow, and demonstrate its utility for analysis of pharmaceutical, peptide, and protein ions.

Mass spectra for pharmaceutical and peptide samples were obtained using a linear trap quadrupole (LTQ)-Orbitrap mass spectrometer. For ESI and SSI, flow rates were set as follows: sample gas at 10 $\mu\text{L}/\text{min}$, sheath gas at 60 AU, and auxiliary gas at 6 AU. Sheath and auxiliary gasses were turned off for SPI experiments and spray voltage was set to 0 kV for both SPI and SSI.

Figure 1a shows the SPI mass spectrum of sildenafil. SPI generated similar spectra to SSI (Fig. 1b) and ESI (Fig.1c) in both positive- (Fig. 1, top) and negative-ion (Fig.1, bottom) modes. While SPI generates lower signal abundance than ESI, our preliminary results suggest that SPI is a softer ionization approach than ESI. Additional examples of the utility of SPI for peptides and proteins will be demonstrated.

Abstract Text

Matrix assisted laser desorption ionization mass spectrometry (MALDI-MS) is an extremely important method for analysis of biomolecules such as proteins and peptides, as well as synthetic polymers. However, MALDI has been very limited in the analysis of small molecules due to the interference of matrix clusters in the low mass regions of MALDI mass spectra. In this work, nanostructured surfaces (nanopillars) are used to effectively absorb laser energy for the vaporization, desorption and ionization of analyte molecules, leading to detection with high sensitivity, resolution and mass accuracy, without any interferences of cluster peaks. The nanopillars have dimensions matching the laser beam wavelength, and can therefore couple laser light very effectively into their local environment. This confinement effect results in electromagnetic field enhancement, high heating rates and prolonged interaction times all of which promote ionization. The excellent performance of these nanopillars is demonstrated using a range of relatively polar small organic molecules, with significant improvement over conventional MALDI in terms of performance and ease of use. These improvements make the use of laser desorption ionization mass spectrometry (LDS-MS) attractive for small molecule high throughput screening (HTS), metabolomics, and mass spectrometry imaging applications. Nanostructures such as these, with well-defined post diameter, periodicity and aspect ratio have been reported in the past, patterned using e-beam lithography, a very expensive and slow process. Here, deep UV projection lithography is employed to achieve the same quality of structures, using a process that is inexpensive and amenable to mass production of the devices.

Abstract Text

In this study, DART-TOFMS was used to quantitatively analyze the ergosterol content in wild-type and mutant strains of the fungus *Fusarium verticillioides* growing in and on cracked corn. This analysis, in turn, provided a method for the determination of mycelia mass growing in and on the corn. Samples of cracked corn infected with *F. verticillioides* were dissolved in a chloroform/methanol mixture with added internal standard. This mixture was used for quantitative DART-TOFMS analysis and the concentration of ergosterol present was determined using an internal-standard calibration curve. The ergosterol content of a sample could be directly correlated to mycelia mass present on the corn, and was quantified using a calibration curve created by measuring ergosterol concentrations in liquid cultures grown under similar conditions. Ergosterol quantification using a DART-100 ionization source was achieved using a custom mount that allowed repeatable analyte sampling in the ion beam. Cholesterol (369.34 Da) was used as the internal standard due to its similar molecular weight (379.33 Da) and structure to ergosterol. Cholesterol was also selected due to its absence in both plants and fungi, whereas ergosterol occurs only in fungal cell membranes. This approach detected ergosterol, and by extension the presence of fungi, on corn. Using appropriate calibration procedures, the mass of fungi growing on or in a plant can be determined. Preliminary data suggest ergosterol concentrations measured in this manner can be employed as a metric for mycelia mass which can be applied to perform mass normalizations for improved quantitative analyses on other solutes in a fungal system, such as sugar alcohols.

Abstract Text

Ion mobility (IM) spectrometry is gaining a lot of attention in analytical chemistry due to recent technical advances, which enable to conduct demanding experiments and develop new applications ranging from small molecules to biomacromolecules. Differential mobility spectrometry (DMS) is a variant of IM based on the use of two parallel conductive plates with applied asymmetric radio-frequency (RF) field, which is used in our work to investigate the separation of triacylglycerol (TG) regioisomers.

Traditionally, the separation of TG regioisomers has been achieved by silver-ion chromatography, which requires long gradients (i.e., hours). An alternative MS-based method uses ratios of fragment ions to determine the relative abundances of TG regioisomers in natural mixtures. Here, we present a new fast method for separating and quantifying ratios of TG regioisomers using DMS.

An AB SCIEX QTRAP® 6500 system with SelexION™ was used for these analyses of standard solutions and real biological samples using the direct infusion analysis. Silver ions were added to the solution to form adducts with TG molecules. Multiple reaction monitoring and MS/MS experiments of pure standards and their mixtures were conducted to confirm the identity of DMS-separated compounds.

We have successfully separated four regioisomeric pairs containing one (SOS/SSO, POP/OPP) or two (OSO/SOO, OPO/OOP) double bonds with the addition of silver ions; S means stearyl (C18:0), P is palmitoyl (C16:0) and O is oleoyl (C18:1 ω). The methodology was applied to a real sample of animal fat to test the applicability of the method for the identification and quantitation of regioisomers in natural samples.

We present a new approach to determine TG regioisomers using DMS. The DMS-based separation yields a marked reduction in the analysis time (i.e., seconds), compared to traditional alternatives. In addition, it offers the possibility of another dimension in the separation of lipids in LC/MS analyses.

Abstract Text

Novel Aspect

As a result, an optimized vacuum system with all necessary components: chambers, backing/turbomolecular pumps, gauges and peripheral devices is introduced.

Introduction

A vacuum is required in most analytical devices. The requirements of modern applications are constantly increasing. These requirements concern performance, quality, cost and size. Pfeiffer Vacuum assists in meeting these requirements with customized solutions.

Methods

The poster shows the development of an abstract technological vacuum requirement into an optimized extensive vacuum solution. This exhibits the technological possibilities and versatile approaches, which are developed in close collaboration with the customer. In the first step, a concrete vacuum diagram, using the example of a multi-chamber system, is developed from the requirements. Following this, further general requirements are specified. Using various calculation methods, components from our modular system are optimally selected and combined. This shows how different methods, such as the Monte Carlo method, the CFD method, the finite element method and analytical calculations are applied.

Preliminary Data

Not only the vacuum technology but also mechanical properties, service life and reliability are considered. An optimized vacuum system is produced from these results. This shows how the other components of the overall system are structured and synchronized.

From the overall analysis, important parameters, such as power input, cooling requirements, weight and size can be determined and adapted to the customer requirements.

Abstract Text

Nowadays, consumers keep away from taking foods that contain high salt (sodium chloride), due to adverse health effects of current dietary sodium intake. Thus, this study was carried out to investigate the influence of salt reduction on quality of brined white cheese.

The effect of varying salt concentrations of 1, 3, 5 and 7.5% on the quality of white brined cheese was examined by SPME-GC-MS, RP-HPLC, and urea-polyacrylamide gel electrophoresis (urea-PAGE). The cheese samples were stored at 4-6 °C and chromatographic analysis were performed at 7., 30., 60., and 90. days of ripening during the storage period. Proteolysis in the cheeses was monitored by HPLC and urea-PAGE analysis and the flavour compounds of the cheeses were determined by SPME-GC-MS. A method optimization process of the SPME procedure for white cheese was carried out by considering different fiber types, extraction temperatures, and sample mass.

The cheeses ripened in varying salt concentrations did not differ in hydrolysis of κ - and β -caseins. When the chromatograms obtained from HPLC were examined by principle component analyses (PCA), it was observed no significant difference in peptide profiles of the cheeses ripened in different salt concentrations. A specifically aimed SPME-GC-MS method was assessed in order to determine the volatile compounds of white brined cheeses. Consequently, CAR/PMDS fiber, extraction at 45 °C, and 10 g of sample were selected as the optimal experimental conditions. Twenty two volatile compounds were detected in the cheeses, consisting of 5 alcohols, 9 carboxylic acids, 2 esters, 5 ketones, and a terpene by SPME-GC-MS. This study has shown that the texture and flavour of the low salted cheeses has been conserved during ripening period because the low salt concentration of brine has not affected proteolysis in the cheeses. Therefore, the salt concentration can be reduced in white cheese production because of its contributions to health.

Abstract Text

The extravasation of the administrated nano-drug carriers played a crucial role in the outcomes of their distribution in the target and non-target organs as well as pharmaceutical efficacy and side effects. To evaluate the extravasation behaviors of the gold nanoparticles (AuNPs), currently the most popular drug delivery system, in a mouse tumor model, in this study we introduced the push-pull perfusion (PPP) as a means of continuously sampling the tumor extracellular AuNPs. To facilitate the quantification of the extravasated AuNPs by inductively coupled plasma mass spectrometry, a novel online open-tubular fractionation scheme was also developed to allow the interference-free determination of the sampled extracellular AuNPs from the coexisting biological matrix. After optimizing the flow-through volume and flow rate of this proposed fractionation scheme, (i) the system's temporal resolution was 7.5 h⁻¹, (ii) the stability presented by the coefficient of variation was below 10% (6-h continuous measurement), and (iii) the detection limits were in the range of 0.057-0.068 [micro]g L⁻¹ for the administrated AuNPs. Following by an intravenous dosage of AuNPs (0.3 mg kg⁻¹ body weight), the in vivo acquired profiles indicated that the pegylated AuNPs showed more tendency toward extravasating into tumor extracellular space. A higher accumulation of nanoparticles in the whole tumor tissues was also observed for pegylated AuNPs than that of non-pegylated ones. Overall, the experimental results confirmed that the pegylation would potentially promote the extravasation and accumulation of AuNPs for nano-drug delivery applications.

Abstract Text

More than half of the human proteome is regulated by the post-translational modification, O-linked N acetylglucosamine (O-GlcNAc), which is related to a number of human diseases such as diabetes, Alzheimer's disease, and cancer. The goal of this study is to develop a proteomic mass spectrometry (MS) approach to study sites of O-GlcNAc modifications on proteins produced in *E. coli*. MS experiments are performed on a nano-electrospray ion trap mass spectrometer with electron transfer dissociation (ETD) and collision induced dissociation (CID) to map the modification sites to specific serines and threonines. The system is also equipped with a nano-LC system. Preliminary work has been performed using chymotrypsin digestion using CID fragmentation tandem mass spectrometry. This work is being extended to ETD fragmentation. The O-GlcNAc modified Abelson tyrosine kinase 2 (ABL2) protein was produced by co-expression of O-GlcNAc transferase in *E. coli*. The ABL 2 protein was purified by Ni-affinity chromatography and gel filtration chromatography. Seven (S50, S51, T54, S60, S74, S94 and S99) out of twenty possible residues have been identified with the O-GlcNAc modification. Matrix-assisted laser desorption ionization (MALDI) tandem time of flight mass spectrometer has been used to maximize the sequence coverage up to 84%. The long term goal of this project is to use the *E. coli* system to generate O-GlcNAc-modified proteins for site mapping and structural analysis by mass spectrometry and nuclear magnetic resonance spectroscopy.

Abstract Text

This paper explores the use of thermally assisted derivatization techniques. In some cases, derivatization can simplify identification of polymers by providing larger, more descriptive fragments of the polymer when compared to conventional pyrolysis GC/MS. It can also improve chromatography on commonly used low polarity columns by transforming nonpolar molecules to polar ones. Techniques such as thermally assisted hydrolysis and methylation (THM) using tetramethyl ammonium hydroxide, and silylation using HDMS will be demonstrated. THM converts alcohols, amines and acids into methyl esters. Silylation with Hexamethyldisilazane (HDMS) performs the same function, only instead adding trimethyl silyl group to non-carbon atoms containing active hydrogens, and some carbonyl groups. Silylation reduces polarity, enhances volatility, and increases thermal stability, enabling the GC-MS analysis of compounds otherwise not volatile or too unstable. They often allow for better GC separation and the produce more diagnostic fragments in the MS. We will explore derivatization products of natural materials such as oils and waxes, lignin and polysaccharides (cellulose, sugar), and synthetic materials like polyesters, epoxies, polycarbonates and polyurethanes. Derivatization chromatograms will be compared with thermal desorption and pyrolysis chromatograms in which no derivatization was used.

Abstract Text

Direct probe analysis is a common option for rapid characterization of non-GC amenable liquids or solids having low vapor pressures. These materials include, but are not limited to, organometallics, drug substances, pharmaceutical powders, polymers, and natural substances. The ability to perform these analyses is essential for many core mass spectrometry labs. The objective of this study was to perform direct probe like analyses of substances utilizing high resolution time-of-flight mass spectrometry in electron ionization (EI) and chemical ionization (CI) modes for compound identification. A CDS 5200 series pyroprobe was coupled to Leco's Pegasus high resolution time of flight mass spectrometer (HRT) with an uncoated capillary connecting the inlet to the ion source. The benefit of using a pyroprobe to perform this analysis was the added versatility compared to direct probes. Liquids or solids could be introduced via a quartz tube or placed directly onto a ribbon filament and thermally desorbed or pyrolysed. Also, because the pyroprobe is interfaced directly with the GC inlet, it is possible to perform distillation cut type experiments or chromatographic separations if required. The effectiveness of this technique for analyzing sample types commonly submitted to core labs will be presented.

Abstract Text

Many laboratories are adopting GC triple quadrupole MS to access the widely accepted advantages brought by high selectivity detection of target analytes. However, while the advantages of MS/MS scan modes, particularly SRM, is well documented, some regulated methods such as EPA 8270 do not permit its use currently. Laboratories that are accredited for these "prescriptive" regulated methods are then compelled to continue with current technology such as GC single quadrupole MS. This prevents users become familiar with the latest technology and means triple quad technology is unavailable for unregulated sample analysis or special projects. This work describes how GC triple quadrupoles can be used in single quadrupole modes to satisfy current regulations as well as being able to very easily switch to powerful SRM methods when needed, especially in preparation of regulations being updated in future. Also included is some potential applications of mixed MS modes such as simultaneous FS/SRM.

Abstract Text

The islets of Langerhans are the endocrine portion of the pancreas help control blood sugar and metabolism through secreted hormones. Several diseases are associated with dysfunctional and unregulated secretion, most notably diabetes mellitus. Here we performed a proteomics analysis of the secretion of cultured intact murine islets under different conditions. These responses help to identify how islets respond to differing levels of glucose and lipids.

Abstract Text

Insufficient ion mobility (IM) resolving power of Ion Mobility-Mass Spectrometry (IM-MS) systems may hinder separation of isomeric species with similar collision cross sections (CCSs) and result in erroneous analyte characterization. Recently, we showed that unresolved IM profiles and collision-induced dissociation (CID) mass spectra could be deconvoluted using chemometric analysis of post-IM/CID MS data [1]. Here, we report collision-energy resolved IM deconvolution of a four component peptide isomer mixture with overlapping IM profiles.

IM-MS data were collected using a traveling wave IM time-of-flight (TOF) mass spectrometer operated in positive-ion mode electrospray ionization (ESI). A three or four component mixtures of peptide isomers will be isolated in the quadrupole mass filter (positioned prior to the IM cell). Subsequently, m/z -isolated species will be subjected to post-IM/CID as a function of collision energy (i.e., potential difference between the exit of IM cell and entrance of a stacked-ring ion guide assembly positioned between the IM cell and TOF). Our preliminary data show that collision energy corresponding to a 32 V potential difference provided appropriate post-IM/CID MS data for the successful deconvolution of the tertiary mixture. Successful deconvolution represents an energetic "sweet spot" for optimized chemometric analysis of the isomeric species. In this presentation, results from energy resolved deconvolution of various sample mixtures will be discussed.

Abstract Text

Carbohydrates are characterized by their complex structures and ubiquitous nature. They are involved in a wide range of crucial physiological and pathological cellular events. Screening mixtures of naturally occurring oligosaccharides for specific protein interactions using electrospray ionization mass spectrometry assay will be presented. The mass spectrometry assay boosts many virtues mainly its low sample consumption, speed, simplicity as minimum amount of sample preparation is required with no labeling or immobilization. In this study, the implementation of tandem mass spectrometry in identifying and quantifying oligosaccharides from natural sources as milk will be described. The assay allows the quantification of binding affinities for protein-carbohydrate interaction depending on the abundance ratio of bound to unbound protein directly extracted from mass spectra. The proposed method is extended to study human milk oligosaccharide isomers as lacto-N-tetraose, β -D-Gal-(1 \rightarrow 3)- β -D-GlcNAc-(1 \rightarrow 3)- β -D-Gal-(1 \rightarrow 4)- β -D-Glc; lacto-N-neo-tetraose, β -D-Gal-(1 \rightarrow 4)- β -D-GlcNAc-(1 \rightarrow 3)- β -D-Gal-(1 \rightarrow 4)- β -D-Glc also 2-fucosyllactose, β -L-Fuc-(1 \rightarrow 2)- β -D-Gal-(1 \rightarrow 4)- β -D-Glc and 3-fucosyllactose, β -D-Gal-(1 \rightarrow 4)-[β -L-Fuc-(1 \rightarrow 3)]- β -D-Glc. Using collision-induced dissociation (CID), the relative abundance of the isomeric ligands are determined from the abundances of fragment ions produced by CID. Furthermore, ion mobility separation is applied to measure the abundance of the isomers, where Gaussian functions were used to represent the arrival time distributions of each isomer. The reliability of the results extracted from the method is demonstrated using model systems. Different applications beside the mathematical framework for the presented method will be given.

Abstract Text

Ambient mass spectrometry (AMS) is a rapid analytical tool capable of providing comprehensive chemical analyses of reaction mixtures resolved on thin layer chromatography (TLC) plates. User-guided investigation of mass spectrometry imaging (MSI) data for mixture components with known m/z values is generally straightforward; however, spot detection for unknowns is rather tedious and has limited the applicability of mass spectrometric imaging for TLC plate analysis. For complex reaction mixtures, an understanding of all chemical products is necessary for the comprehensive investigation of reaction mechanisms. Therefore, we have developed DetectTLC, an automated approach that identifies m/z values exhibiting spot-like shapes in mass spectrometric images. Furthermore, advances in mass spectrometry instrumentation now allow for multi-modal analysis in which alternating scans are acquired in different modes of operation, i.e. alternating between a low-energy (parent ion) and high-energy (fragment ions) scans. Without precursor mass selection, correlating parent and fragment ions is impossible. DetectTLC is also capable of correlating spots observed in the two modes of operation without precursor mass selection based on the spatial distribution of m/z values. Employing desorption electrospray ionization mass spectrometry (DESI-MS) as the ambient sampling method in conjunction with DetectTLC, we were able to identify and characterize previously unknown products of an abiotic pyrazine nucleic acid synthesis products. This nucleic acid synthesis is of great interest to prebiotic chemists and the origin of life community but the DetectTLC software package is also expected to be extremely useful for any application that benefits from fast TLC separations or for reaction monitoring purposes.

Abstract Text

Characterization of the metabolome, the complete suite of metabolites expressed by embryonic cells, is key to understanding healthy embryo development. However, this requires new analytical technologies, particularly those that are highly sensitive, selective to diverse types of biomolecules, and compatible with extremely small sample volumes afforded by single cells. We report here a new approach based on mass spectrometry (MS) to enable profiling metabolites in single embryonic cells of the South African clawed frog (*Xenopus laevis*), the favorite model in cell and developmental biology. We use this information to uncover, for the first time, cell-type specific metabolic differences in the early developmental stage of the embryo.

Our technology combines microsampling and volume-limited capillary electrophoresis (CE) high-resolution tandem MS that we recently developed. CE-MS achieved a low limit of detection below 10 nM (60 amol) for acetylcholine among other compounds, sufficiently low to assess endogenous metabolite levels. Embryonic cells were identified and microdissected from 16-cell *Xenopus* embryos, their metabolomes were extracted, and 10 nL of the extracts were measured by CE-MS. Profiling revealed more than 80 different small molecules that were consistently expressed among the cells, 45 of which were confidently identified as metabolites. Multivariate and statistical analysis of the data revealed differential clustering between cells in the ventral, dorsal, and vegetal regions of the embryo. The finding that embryonic cells have characteristic metabolomes during early development is surprising, and demonstrates that single-cell MS raises a new opportunity to investigate biochemical processes that underlie embryonic development.

Abstract Text

Radio-frequency ionization (RFI) is a novel ionization method for mass spectrometry (MS) analysis of volatile organic compounds (VOCs) in positive- and negative-ion modes.¹ We recently reported on RFI/MS and chemometric analysis of VOC mixtures.² Despite the unprecedented sensitivity of RFI, mechanism of ion generation in RFI is not well understood. In this presentation, we will provide the first experimental evidence for generation of electrons in RFI. Moreover, we will demonstrate the utility electron capture ionization in RFI.

RFI source consists of a home-built RF power supply for generation of RF signals (~12 MHz, 400 V_{p-p}) and a set of dipole RFI electrodes. The dipole electrode are placed within the vacuum chamber of a 9.4 T Fourier transform-ion cyclotron resonance (FT-ICR) mass spectrometer and in proximity of an ICR cell. Headspace hexafluorobenzene (C₆F₆) will be introduced into FT-ICR vacuum chamber from a heated expansion reservoir (150 °C), transfer line (120 °C), and pulsed valve (120 °C).

Following a 2-s electron relaxation time after RF signal application and trapping RFI-generated electrons, C₆F₆ neutrals were introduced into the vacuum chamber. Resulting negative-ion mode FT-ICR mass spectra showed the presence of C₆F₆⁻ species. In recent studies and to further confirm that C₆F₆⁻ species were products of reaction between RF-generated electrons and C₆F₆, an electron-quenching event was introduced for varied time durations (0-13 ms). Results from negative-ion mode post-RF FT-ICR data that confirm the generation of electrons in RFI will be discussed.

Authors would like to acknowledge the financial support from Baylor University.

Abstract Text

Nanomaterials are being used extensively for industrial and medical uses. Gold or silver nanoparticles can be modified with organic monolayers often containing functional groups for covalent attachment to biomolecules or other organic molecules. The goal of our study was to identify various types of ligands attached to nanoparticles using ambient ionization mass spectrometry. A PerkinElmer DSA Time-of-flight mass spectrometer (TOF) was used for the analysis. The DSA source uses a "field free" corona discharge electron Reagent Ion Generator that ionizes analytes in ambient atmospheric conditions. The sample was layered on a steel mesh and then exposed to the source. The organic capped ligands are released from the nanoparticles due to thermolability of the covalent bonds however, the temperature of the source is not sufficient to volatilize the gold and silver particles themselves. Using accurate mass and isotope profile information provided by the TOF, along with powerful visualization software tools, we were able to confirm the presence of the different types of ligands attached to nanoparticles. Besides using the DSA-TOF as a screening tool for the organic ligands, we were also able to obtain semiquantitative information on the amount of ligand attached to the nanoparticles.

Abstract Text

This paper describes the theory of Single Particle-ICP-MS in analyzing Metal Based Nanoparticles using the NexION 350 Syngistix Nano Application Module. Single Particle (SP-ICP-MS) allow the differentiation/quantification between ionic and particulate signals, measures particles concentration (part/mL), ionic concentration ($\mu\text{g/mL}$), particle sizes, size distribution and explores agglomeration and dissolution kinetics.

SP-ICP-MS is a key analytical instrument in assessing the fate, behavior and distribution of engineered Nanoparticles (ENPs) in several types of matrices (environment, food, etc.), evaluating ENPs bioavailability and bioaccumulation in the biota, and improving bio-labeling capabilities and advancements in the medical field.

Abstract Text

Metabolomics, the study of small molecules involved in cellular processes, offers the potential for investigating disease pathogenesis and has proven useful in the development of therapeutic targets. Metabolites are a diverse group of compounds with a variety of functionalities including hydroxyl, amine, carboxyl, phosphoryl, and thiol groups. Electrospray ionization mass spectrometry (ESI-MS) is widely used to detect metabolites due to its high sensitivity and ability to generate structural information. However, the structural diversity of metabolites results in unequal ionization efficiency with ESI and consequently varying degrees of sensitivity. These limitations may prevent the detection of molecules present in low abundance in biological samples. Tagging approaches have been used to improve electrospray by allowing charge to be concentrated on the outside of the droplets and enabling more efficient evaporation of mobile phase. Furthermore, highly ionizable tags ensure equal ionization efficiency for all tagged analytes. The goal of this project is to use two cationic hydrophobic tags to label metabolites with hydroxyl, amine, carboxyl, phosphoryl, and thiol groups and improve sensitivity in ESI-MS. This work will make the simultaneous detection of a diverse group of metabolites possible, leading to a more complete picture of the metabolic system of interest.

Abstract Text

As the field of nanotechnology grows it becomes crucial to develop and validate methodologies to not only detect but to also characterize these particles. This remains a challenge due to their relatively small size and the complex matrices they may be found in. Single particle inductively coupled plasma mass spectrometry combines the traditional method of metal detection with the new approach of shorter dwell times to detect these nanoparticles (NPs). This technique scans and collects data at much shorter intervals, which allows for the detection of minimal variation in the number of ions striking the detector within a dwell time of milliseconds. This allows the short burst of increased signal contributed by a particle to be distinguished from the constant signal of ions. The intensity of this signal can be used to calculate the size of the contributing particle.

Here, single particle ICP-MS was shown to be a valid and robustness method for the detection, characterization and quantification of PVP-Ag NPs used in a study designed to investigate the effects of cell cultures exposed to this particle. NPs were suspended in solutions of a combination of media, serum and cells to for up to 48hrs to determine if dissociated occurred as well as total ion concentration.

Abstract Text

State-of-the-art Proton-Transfer-Reaction Time-of-Flight Mass Spectrometry (PTR-TOFMS) instruments perform with sensitivities of typically 100 - 200 cps/ppbv. Here we present a novel PTR-TOFMS setup that utilizes a Quadrupole ion guide (Qi) instead of a common lens system for a much more effective transport of ions into the mass spectrometer. With measurement data obtained by introducing certified gas standards into the PTR-QiTOF we demonstrate that its sensitivity is up to 4,700 cps/ppbv, i.e. about 25 times more than the best instruments so far. Such outstandingly high sensitivities are of particular importance in fields of application where time per analysis is limited, e.g. flux measurements in atmospheric chemistry and mouth- or nosespace analysis in food and flavor research. Notably, in these fields the chemical environment is usually very complex so that even the selectivity of a high-resolution mass spectrometer is not sufficient. Monoterpenes, for example, are important compounds in atmospheric chemistry as well as in food and flavor research and appear at m/z 137 (protonated monoterpene). Therefore, we coupled the novel PTR-QiTOF with a FastGC inlet system and analyzed manuka tea and spruce resin, respectively. In the figure below one can see that indeed in normal direct-injection mode all monoterpenes appear indistinguishably at m/z 137. However, after switching the inlet system to FastGC mode the monoterpenes get separated according to their retention times and are easily distinguishable. The FastGC run takes less than 60 s and can even be considerably reduced to quasi-real-time by applying a sophisticated GC pulsing method (patent pending).

Abstract Text

USEPA Method 8260 involves purging analytes out of a water matrix. During a split injection, the sample volatilizes in the inlet and is swept by the carrier gas through the liner onto the GC column with a portion of the sample being split off and sent out the split vent line. The amount of sample reaching the detector is dependent upon the split flow rate. Thus, the higher the split rate, the smaller amount of sample on the column. Furthermore, a higher split ratio minimizes column exposure to moisture. During purge and trap sampling moisture control is crucial to decreasing split flow and enhancing detection limits. This application will explore the effect split ratios have upon USEPA Method 8260 analytes.

Abstract Text

We have developed a novel mass spectrometric visualization method to generate pseudo cross-sectional skin images for fast and non-invasive transdermal drug delivery evaluations. Two-dimensional desorption electrospray ionization / mass spectrometry (2D-DESI MS) was utilized to obtain planer distribution information of drug penetrated into stratum corneum (SC).

We have visualized several drugs in SC successfully, but nonpolar compounds such as cholesterol and retinol were not ionized efficiently under typical DESI conditions because of their low proton affinity. To solve this problem, we have focused on reactive-DESI in which derivatization reagent is added to DESI spray solvent to increase their proton affinity.

In this study, we investigated potentials of reactive-DESI for mass spectrometry imaging (MSI) to expand the utility of DESI-MSI for compounds not efficiently. Retinol was chosen as a model compound, which was reacted in the gas phase with betaine aldehyde, a reagent of Reactive-DESI for -OH group(s). Potentials and limitations of reactive-DESI MSI will be discussed in the presentation.

Abstract Title **Bismuth as Internal Standard for Lead Determinations by ICP OES**

Primary Author Marcos A. Bechlin
São Paulo State University

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Edilene C. Ferreira, José A. Gomes Neto

Abstract Text

Elemental analysis by inductively coupled plasma optical emission spectrometry (ICP OES) can be influenced by variations in operating conditions and matrix effects. These interferences can be efficiently minimized by using the internal standard calibration (IS). Bismuth was recently proposed as general internal standard for Pb in atomic absorption spectrometric determinations [1]. Considering the possibility of expanding this proposal to other spectroscopy techniques, this work evaluated Bi as internal standard for Pb determinations by ICP OES. A Varian Vista AX ICP OES was used for simultaneous measurements of Bi and Pb at 223.061 nm (I) and 220.353 nm (II), respectively. The influence of variations of the nebulizer gas flow-rate (0.7 - 1.1 L min⁻¹), radio-frequency power (0.90 - 1.25 kW) and sample matrix (34 different samples) on the emission signals for Pb and Bi was evaluated, and similar variations were observed for both elements. Three certified reference materials were analyzed and results found for Pb using IS were in agreement with certified values at the 95% confidence level. The use of Bi improved the RSD from 0.8 - 9.0% (without IS) to 0.2 - 2.9% (IS). Recoveries of spiked samples improved from 56 - 91% (without IS) to 95 - 110% (with IS). These findings indicated the usefulness of Bi as internal standard for broad use in ICP OES for Pb determinations.

Abstract Text

The interaction of toxic metals with essential elements could lead to disruption in the homeostasis of essential metals. The study investigated the effect of low level exposure of inorganic mercury to essential elements (Zn, Fe, Se, Mg and Ca) of male and female rats. The rats were exposed to 0.5, 1.0 and 1.5 mg/kg of Hg concentrations for 12 weeks after which blood, liver, kidney, brain, spleen, heart and lungs were removed from the animals and these elements were determined by inductively coupled plasma-mass spectrometer (ICP-MS). The result showed that mercury accumulated in all the organs but more mercury uptakes were observed in the kidney than every other tissues, markedly in females (77.89 ± 7.7 and 23.78 ± 1.59 $\mu\text{gHg/g}$). The exposure resulted in decrease in Mg, Ca, Fe, and Zn in nearly all the tissues except for brain and liver where Fe increased significantly in both sexes compared to controls ($p < 0.05$). Se behaved differently in kidney and blood, in terms of its mutual competition with Hg. The increase in Hg dose resulted in gradual and significant increase in the concentration of Se in kidney and blood. There was also significant increase in Ca and Mg in lungs of both sexes. No variation was observed with zinc in brain and liver. Most notably, Hg correlated negatively with Ca and Mg. These findings indicate interaction between essential and toxic metals.

Abstract Text

Analytical chemistry is an important tool in the mining process. Quantitation of gold, silver or platinum group metals in ore grade material and mapping geochemical composition of rocks are essential to ensure the commercial viability and the environmental impact of mining processes. However, the analysis of geological samples can be very challenging because of their complex, heterogeneous mixtures of minerals. They are often formed from a multitude of small grains, each with a different composition.

Analytical technics such as ICP-MS, ICP-OES and AA provide viable solutions for inorganic analysis. However, they must be simple to use, offering flexibility, reliability, high productivity and accurate results with these challenging sample matrices.

This poster presents analytical results of mining samples by AA, ICP-OES and ICP-MS, focusing on simple sample preparation, method development. It also addresses the issues of accuracy, interference removal and stability. Results of real samples and Standard Reference Materials are shown with discussion.

Abstract Text

Mining activities involve mineral prospecting and exploration which can be quite expensive. A number of mineral prospecting methods which are commonly used include: excavation of soil for analysis, phyto-prospecting and hydrogeochemical prospecting. Ants and termites have been reported to burrow up to 55 metres to water tables. In the process, they bring up debris, which may contain traces of minerals in mineralized areas. Qualitative and quantitative analyses of anthills' and termite mound soil samples can be used as preliminary tests for prospects of finding a given mineral in a particular area. Termitaria sampling has been used in other parts of the World such as Australia, Ghana and India. This study sought to determine whether there are significant levels of iron and titanium in anthill soil samples as compared to top soil samples from Kwale, Kathwani and Kithiori, which are mineralised areas in Kenya. Flame atomic absorption spectroscopy was used to determine iron and titanium after carrying out acid digestion of soil samples. It was found in this study that the control samples had lower concentrations of iron for all the three sampling areas; 20.63+_{-0.29}mg/g compared to mean concentration of Fe in anthill samples of 25.30+_{-0.06} mg/g in Kwale. 90.53+_{-0.01}mg/g compared to 98.53+_{-0.29} mg/g at Kathwana and 82.63+_{-0.22} compared to 89.48+_{-0.01} mg/g at Kithiori. Titanium content in termitaria samples was higher than the control samples for all the three areas; 14.9+_{-0.24} mg/g compared to 14.72+_{-0.00}mg/g at Kwale, Kithiori 18.47+_{-0.03} mg/g compared to 15.93+_{-0.24} mg/g at Kithiori and 14.52+_{-0.03} mg/g compared to 13.13+_{-0.00} mg/g at Kathwana. These results demonstrate the potential for use of termitaria soil sampling in mineral prospecting. For conclusive results of iron and titanium mineralization, multimedia sampling is recommended.

Abstract Title **Investigation into the Presence of Mercury in Game Controllers**

Primary Author Bin Chen
P S Analytical

Date: Monday, March 09, 2015 - Morning

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Lee Hewes, Mark Scrimshaw, Peter B. Stockwell, Warren T. Corns

Abstract Text

The use of game controllers is prevalent with millions of units found worldwide, yet very little research has been conducted into the potential presence of hazardous materials. This study aims to assess the presence of hazardous materials and the potential environmental impact. A preliminary screening involved the dismantling of seven controllers from leading companies within the gaming industry into their individual components before using X-Ray Fluorescence (XRF) which detected mercury in one particular model. Five further controllers of the same model were purchased and the logos analysed using Scanning Electron Microscope (SEM) in order to provide a secondary qualitative measurement. Finally samples were analysed using Continuous Flow Vapour Generation Atomic Fluorescence Spectroscopy (CV-AFS). Initial results from XRF demonstrated the presence of mercury in the logo of a specific controller with further analysis of the sample using SEM confirming the initially findings. CV-AFS was conducted, which produced significant results. It demonstrated that mercury was present throughout the logo at concentrations at the parts per million levels. The high level of mercury discovered in the game controllers could pose a significant source of contamination which could have a potentially damaging impact on the environment through the disposal and degradation of materials in the controllers. This research will discuss and highlight game controllers as a novel source of major contaminants, such as mercury, within the environment. The use of continuous flow vapour generation atomic fluorescence spectroscopy to measure mercury in complex samples will also be discussed and presented.

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s)

Abstract Text

Sample introduction efficiency is very important for analytical atomic spectrometry, especially considering the method sensitivity. In comparison with the conventional nebulization technique, ultrasonic nebulization techniques greatly enhance the sample introduction efficiency from 5 to almost 100% resulting in almost two orders of magnitude improvement in sensitivity [1]. Recently, we have been working on ultrasonic micro-nebulization technique as a sample introduction tool for analytical microwave induced plasma optical emission spectrometry (MIP-OES) when performing of hydride forming (As, Bi, Ge, Sb, Se, Sn), cold vapor (Hg, Cd), transition (Au, Ag, Cu, Mn, Ni, Pb, Zn), noble (Pd, Pt, Rh) and non-hydride forming (Ba, Ca, Li, Mg, Sr) elements determination and speciation analysis. The ultrasonic nebulizer supplied a microliter sample to a quartz oscillator; the hydrides, metal volatile species and aerosols were rapidly transported via stream of Ar carrier to a MIP for simultaneous multi-element determination by OES. A univariate approach and simplex optimization procedure was used to achieve optimized conditions and derive analytical figures of merit (LODs, RSDs). The methodology was validated through determination of elements in several Certified Reference Materials and by the aqueous standard calibration technique. The proposed method was applied to the determination of elements in real samples.

Abstract Text

For the first time, a spatial-heterodyne spectrometer (SHS) is used for standoff laser-induced breakdown spectroscopy (LIBS) measurements. The SHS is a diffraction grating based interferometer with no moving parts. The SHS design offers advantages over dispersive spectrometers including 10-100 times larger acceptance angle and subsequently a much larger field of view, 100-10,000 times higher light throughput, high spectral resolution, and a relatively wide spectral range in a small package. In previous work our group described a spatial heterodyne Raman spectrometer (SHRS) for standoff Raman measurements at visible and UV wavelengths. A standoff spatial heterodyne LIBS spectrometer (SHLS) has not been described. In the case of standoff LIBS measurements the wide field of view of the SHLS design minimizes issues of laser pointing stability and alignment. Also, because spectral resolution is not a strong function of entrance aperture size, high spectral resolution can be achieved in a very small spectrometer using small diffraction gratings. In the described work 10 mm diffraction gratings were used to provide ~0.3 nm spectral resolution. Furthermore, the high light throughput of the system allows LIBS measurements to be made using no collection optics, other than the 10 mm gratings, at distances up to 20 meters. This corresponds to a collection solid angle of less than one microsteradian. In this paper standoff LIBS spectra of minerals and other materials will be shown, collected at distances up to 20 m, without collection optics. Measurements using a small telescope will also be described.

Abstract Text

In-situ chemical characterization of deep ocean water around hydrothermal vents requires the development of new classes of multielemental sensors. To this end, laser induced breakdown spectroscopy (LIBS) is being investigated to measure elements in seawater under realistic oceanic pressures, with a long-range goal of deploying a LIBS system on Alvin or other deep-ocean submersibles to measure the elemental composition of deep-ocean hydrothermal vent fluids. In previous work LIBS measurements of alkali and alkaline metals were shown at ppm levels at pressures up to 3×10^7 Pa (~2800 m water depth equivalent), and it was shown that matrix interactions between different elements were not a major issue. The use of O and H as internal standards was also shown to be promising to correct for emission intensity variations. In more recent work the effect of suspended particulates is being investigated. In one preliminary study using highly absorbing TiO₂ particles, the emission intensity for dissolved elements decreases in proportion to the optical density of the solution. Other studies are underway to determine the effect different types of suspended particles will have on the LIBS emission of dissolved elements in seawater. This paper will focus on studies aimed at improving the precision of LIBS measurements in high pressure water using O and H as internal standards, and on studies of the effect of suspended particle loadings for different types of particles on the LIBS emission intensity of dissolved elements.

Abstract Text

The applications of engineered nanoparticles (ENPs) are increasing and widespread. With this increase in applications comes an increase in the environmental exposure of ENPs. As such, it is imperative to understand what happens to them under environmental conditions and if they will persist through environmental treatments such as drinking water treatment processes. Because the expected environmental concentrations of ENPs are low, it is important to develop methods that can detect them at their natural levels in a complex environmental matrix. Single-particle ICP-MS (SP-ICP-MS) provides a new avenue for the detection of nanoparticles in environmental samples based on its super sensitivity and multi-element capacity. The objectives of this study are to develop sensitive, high-throughput SP-ICP-MS methodologies for detecting the presence of both dissolved and nanoparticulate metals present in water and to use these methodologies to study the occurrence and evaluate the fate of ENPs through varied drinking water treatment processes. SP-ICP-MS methods were developed using a NexION 300D ICP-MS system with unique SyngistixTM Nano Application software developed by PerkinElmer. Screening of ENPs in Missouri drinking water systems was conducted at different seasons. Drinking water treatment simulations were performed using surface (Missouri River) water spiked with ENPs. Water treatment was simulated with 6-gang stirrer by undergoing each major step of treatment – softening, coagulation, filtration, and disinfection. Samples were collected after each step and analyzed by SP-ICP-MS methods developed. The tested ENPs were mostly removed by lime softening and coagulation processes. This project was supported by PerkinElmer and Missouri Department of Natural Resources.

Abstract Text

Cadmium (Cd) contamination is closely monitored in water, food and health care products since it is one of the most toxic elements. Vapor generation is an alternative approach for measurement of trace amounts of Cd from complex samples by atomic and mass spectrometry, but it is not often preferred because of the low vapor generation efficiency and substantial interferences from transition metals of sample matrix. In this study, a new vapor generation method has been developed for measurement of low levels of Cd by ICP-MS. The effects and efficiencies of Al(III), Sc(III) and Y(III) were examined for generating volatile cadmium species in the presence of potassium cyanide (KCN). The sample solutions were mixed on-line with 0.16 M KCN and 0.04 to 0.08 M solutions of Al(III), Sc(III) or Y(III) and then reacted with sodium borohydride (NaBH_4). The effect of solution acidity was examined from 0 to 12% HCl. Cadmium vapor formed between 3 to 7% HCl range. Al(III) appeared more effective than Sc(III) and Y(III). Experimental evidence indicated that metal ions act as catalyst in generation of Cd vapor from reaction of acidic samples solutions with NaBH_4 . An improvement up to a factor of 10-12 was achieved. The interferences from transition metals ions were investigated on generation of Cd vapor. The method is validated by analysis seawater samples and various complex samples ranging from purely organic to inorganic by ICP-MS.

Abstract Text

Tea is one of the most popular beverages in the world. In recent years, the components in tea leaves have received great concern because they are related to health and disease. The leaves can supply many trace elements essential for human, which have positive effects on health. And different types of tea leaves contain different amount elements, so we can choose the appropriate tea as body needed. So determination of multi-elements in tea leaves is very important. The main objective of this work is to determine of multi-elements (Ca, Cu, Fe, K, Mg, Mn, Na, P, S, Zn) using ICP-AES, and the Selenium was measured by ICP-AES coupled with HVG-1 (Hydride Vapor Generator). The accuracy of this method was evaluated by measuring the tea standard reference material GBW10016, and the results matched the certified values well. The RSD for every element was less than 3.0%. This work also describes the performance and mechanism of the hydride generator, which can highly improve the sensitivity of Hg, Se, As and so on. This method is rapid and convenient, with high accuracy and good precision, which can be widely used for determination of major and trace elements in the tea leaves.

Abstract Title **Assessments of Human Hair Quality as a Function of Age, Based on Determination of Selected Metals: Preliminary Results**

Primary Author Mark T. Stauffer
University of Pittsburgh Greensburg

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Meena K. Gella, Shivam M. Patel

Abstract Text

This paper will focus on assessment of human hair quality with time, based on determination of concentrations of selected metals, e.g. Cr, Zn, Fe, and Cu, in human hair. As aging occurs, the quality of hair decreases. The hypothesis is that degradation of hair quality with time is partly due to concentrations of the aforementioned metals found in the hair. The prediction is that the concentrations of these metals will decrease with time.

At least 60 human hair samples were collected from a wide range of age groups. Each sample was prepared by microwave digestion using nitric acid, followed by dilution of the digests to 25 mL with deionized water. Concentrations of Cr, Zn, Fe, and Cu in the digests were determined by flame atomic absorption spectrometry (FAAS), using an air-acetylene flame.

Experimental procedures, preliminary results obtained, and future directions for this research will be presented and discussed.

Abstract Title **Leaching of Lead Through Soil In and Around a Recreational Shooting Range Built on a Reclaimed Strip Mine: Preliminary Results for Lead and Other Analytes**

Primary Author Mark T. Stauffer
University of Pittsburgh Greensburg

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Luke J. Metzler

Abstract Text

Leaching of lead through soil may be a problem in areas where lead content is high. This problem may be exacerbated by soil with a low pH, such as soil in and around reclaimed strip mines. The determination of lead is especially important, because it is well known that lead is toxic to humans and wildlife. In this specific case, the goal is to investigate whether or not soil acidity exacerbates or alleviates lead leaching. Determination of lead concentrations in, as well as the pH of, soil in and around a recreational shooting range built on a reclaimed strip mine will be performed. The soil at this site will be sampled and analyzed for lead in increments downhill from the range, as the grade slopes toward a manmade lake. In addition to the soil on the range itself, the lake water will also be tested for pH and analyzed for lead levels. Other determinations, such as dissolved oxygen, electrical conductivity, and water hardness will aid in characterization of the overall quality of the water as it relates to metal content in the ground. These determinations will allow for a thorough and guided assessment of the soil and water quality, as both are potentially affected by either the shooting range or the reclaimed mine, or a combination of the two.

Results from the aforementioned determinations, along with details of sample collection, preparation, and analytical methods used, and future directions for this research, will be presented and discussed.

Universidad del Valle

Date: Monday, March 09, 2015 - Morning

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Fernando E. Larmat, Walter Torres

Abstract Text

Molecularly imprinted polymers (MIP) have been used in an increasing number of applications to selective molecular recognition. With this technique is possible to create template-shaped cavities in polymer films during the polymerization process that are complementary in shape, size and chemical functionality to the analyte molecule used as template during the synthesis of polymers. Then the template molecule is removed from the polymer matrix, leaving behind a cavity complementary in shape and size to the template. The obtained cavity can work as a selective binding site for a specific template molecule.

In this work the MIP concept was used to develop enantio-selective electrochemical sensors for rapid, sequential and quantitative determination of L-tyrosine and L-tryptophan. The sensor consists of a gold electrode modified electrochemically with a thin film of polypyrrole in the presence of the amino acids and subsequent over-oxidation of the film. The result is the generation of an overoxidized polypyrrole film with molecular cavities for the highly selective detection of the aminoacids even in the presence of their respective enantiomers.

The results showed that the amperometric sensors have a lineal response ($R=0.99$) between 0.1-100 mM, with a limit of detection of 6.3 and 9.4 micromolar for L-tyrosine and L-tryptophan respectively. The amperometric response of the sensors was reproducible up to 36 hours when they were stored in a solution containing the corresponding aminoacid. A sensor for the simultaneous detection of the two aminoacids was also studied, the results showed a higher amperometric response for L-tyrosine and with a sensitivity of ca. 70% of the individual sensors.

Abstract Text

Hydrogen sulfide (H₂S) is a known toxic industrial pollutant, but also a third endogenous biochemical gaseous signaling compound (after NO and CO). Involvement of hydrogen sulfide (H₂S) has been regarded as an essential factor in various physiological processes such as vasodilation, antioxidation, and anti-apoptosis. Recently, it has been demonstrated that the concentration of H₂S in Alzheimer's disease and Down's syndrome patients' brains deviates from the normal physiological level, and could be used in diagnostics purposes. H₂S's presence at low (from nanomolar to micromolar) concentrations in biological media has made it a popular target for the development of fluorescent chemosensors. However, none of the described H₂S-responsive chemosensors were amplifying, whereas, due to the low concentration in physiological media, its detection would benefit from an intrinsic signal amplification provided by the "higher energy gap" mechanism. In this presentation, we will focus on a water-soluble fluorescent conjugated polymer as an H₂S sensor taking advantage of the "higher energy gap" paradigm that was recently developed in our group. Its operating principle is based on an analyte binding to the specially designed receptor chromophore creating a "higher energy gap" site acting as a "roadblock" to effectively limit an intramolecular exciton migration thereby providing an amplified turn-on fluorescent response. The details on preparation of this sensing conjugated polymer, as well as photophysical characterization and H₂S detection studies will be reported in this presentation.

The research was funded by the National Science Foundation (CAREER award CHE-0547895 and grant CHE-1362686).

Abstract Text

The non-enzymatic glycation of albumin has been extensively studied with D-glucose because of the relevance of the sugar to diabetes. Like D-glucose, D-galactose can non-enzymatically react with albumin in vivo in conditions such as galactosemia. The mechanistic similarity in the formation of non-enzymatically glycated and galactated albumin has been the subject of several studies and has generated interest in the characterization of the early and late galactation products of the protein. The objectives of this study were three-fold: 1) to study the advanced glycation endproducts (AGEs) of albumin with D-galactose, 2) to characterize the side chain D-galactose modification of albumin's AGEs, and 3) to evaluate the effects of galactation on the secondary structure of the protein. AGEs of galactated albumin were evaluated by fluorescence spectrometry at three sets of excitation and emission wavelengths. Excitation/emission wavelengths of 360 nm and 430 nm allowed the measurement of the total fluorescent AGEs. Excitation/emission wavelengths of 335 nm and 395 nm facilitated the measurement of the protein's pentosidine and argpyrimidine residues. At excitation and emission wavelengths of 485 nm and 530 nm the measurement of arginine modified AGEs of albumin was achieved. CD spectroscopic analysis of galactose modified albumin showed decreases in the α -helical content of the protein confirming changes in its secondary structure. These findings warrant further investigation as the management of patients with galactosemia has been proposed with galactated albumin.

Abstract Text

Since the detection of cancer needs significant accuracy, to get signal from a specific kind of cancer cell without leaking responds from other cells is very crucial. Most of the existing cancer detection methods are analyzing one kind of biomarker at one time, providing less information and efficacy than clinical requirement. Due to the low specificity and selectivity of single-biomarker detection, we designed an aptamer-based multiple-biomarker labeling method for cancer cells detection with enhanced accuracy and specificity. We use two aptamer-terminated oligonucleotides as probes to target two biomarkers respectively. Probe 1 is composed of aptamer sgc8, a T-linker and DNA sequence ab with Cy3 modified on the 3' end. Probe 2 is composed of aptamer TCO1, a T-linker, strand a' (the complementary sequence of a) and Cy5 on the 5' end. A blocker strand a'b' (the complementary sequence of ab), with two photosensitive PC-linkers embedded in the middle, is used to avoid leaking reaction of Probe 1 and 2 in solution. After incubating with the cell sample, a UV light is used to cleave the blocker, then Probe 1 and 2 will be partially hybridized only if both target biomarkers exist on the cell membrane, leading a FRET between Cy3 and Cy5. With this method, we can accurately detect the cell with two biomarkers, especially can differentiate target from a mix of two kinds of cells with the two biomarkers separately.

Abstract Text

As a member of the tree nut family, hazelnut (*Corylus avellana*) is included in the Big Eight food allergens. As with other food allergens, avoidance by sensitive patients is the only treatment option; however avoidance of hazelnut is difficult as it is often a “hidden” ingredient in pastries and chocolates. Allergic reactions to hazelnut range in severity, from rare life-threatening anaphylaxis to the more common manifestation of oral allergy syndrome (OAS). Like OAS caused by fruits and other nuts, OAS from hazelnuts is present in patients sensitized by birch pollen (*Betula verrucosa*) and is due to the cross-reactivity of homologous proteins in hazelnut and pollen, namely Bet v 1 to several Cor a 1 isoforms. Bet v 1 and Cor a 1 are part of the pathogenesis-related protein family, known as PR10 proteins, which are important for stress response and antimicrobial defense in plants. Bet v 1 and its homologs are characterized by a seven-stranded anti-parallel beta sheet that forms a hydrophobic pocket. This pocket has been shown to bind small hydrophobic compounds, such as steroids, cytokinins and fatty acids. We sought to investigate the ligand-binding ability of Cor a 1 using a fluorescence-based spectroscopic assay. We expressed recombinant Cor a 1.02 in *Escherichia coli* and purified it to homogeneity using ammonium sulfate precipitation and ion-exchange and hydrophobic-interaction chromatography. We screened many potential physiologically relevant ligands for binding to rCor a 1.02 by analyzing displacement of a fluorescent ligand, ANS, and found it can bind fatty acids, isoflavones and resveratrol.

Abstract Text

Surface-enhanced Raman spectroscopy (SERS) has been established as a powerful tool for both quantitative and qualitative analyses of environmental samples. When SERS substrates are coupled with appropriate self-assembled monolayers, compounds of interest may partition within the SERS sensing region of the substrate and highly sensitive measurements can be realized. However, fabricating reproducible SERS substrates has remained a challenge, as many methods rely on the randomized close packing of spherical colloids during the fabrication scheme. Here, we have produced a high-performance SERS substrate of aligned silver nanorods using hole-mask colloidal lithography that overcomes these traditional limitations. It can be fabricated over a large area and even patterned into a microarray format. Optimal size of the aligned nanorods was determined through finite-difference time-domain (FDTD) simulations and confirmed empirically. The resulting nanostructures were then applied toward analysis of various perfluorinated compounds, contaminants currently of high concern, within environmental samples.

Abstract Text

Five symmetric Schiff base compounds of substituted N,N'-bis(salicylaldehyde)-propylenediamines series were prepared and characterized with electron donating and withdrawing substituents (Methyl, 3', 4' and Difluoro) on the benzene ring and tested for their antimicrobial activity. The synthesized compounds were characterized by elemental analysis, FTIR and ¹H, ¹³C, and ¹⁹F NMR. Spectrophotometric titration of these compounds was performed in the pH range of 11.00 to 4.00 in aqueous solutions. Using the absorbance intensity (370 – 390 nm peak) variations with changes in pH, the relative pKa values of the protonation of the nitrogen atom of the Schiff's bases were determined. The experimentally determined values of pKa by sigmoidal non-linear regression of the pH vs absorbance for the Schiff bases ranged from pKa = 6.3 for the N,N'-bis(3'-fluorosaliclaldehyde)-propylenediamine to pKa = 7.70 for N,N'-bis(5'-fluorosaliclaldehyde)-propylenediamine. Electron donating methyl substituent on the phenyl ring, in the compound N,N'bis(3'methyl salicylaldehyde) propylemnediamine is found to make the compound less acidic; pKa = 8.51. The enhanced acidity of fluoride substituted species relative to N,N'-bis(salicylaldehyde)-propylenediamine, pKa = 8.11, is attributed to the inductively electron withdrawing fluorine on the benzene ring favoring the Keto-amine form of the Schiff's base, (250 nm peak of cyclohexadienone at 3.5 pH in the UV-Vis spectra), over the Enol-imine form. Antimicrobial activity of these compounds were measured against Escherichia coli, Bacillus subtilis, and Pseudomonas fluorescens Pf-01 using standard minimum inhibitory concentration assays (MIC) and bactericidal assays at >500 μM concentration. The activity of these compounds suggests that the difluoro ligand is capable of inhibiting growth at >500 μM but is not bactericidal at the same concentration. In addition, gram negative bacteria are the most sensitive to this class of compounds.

Abstract Text

The electrochemical proximity assay (ECPA) is a direct-readout proximity immunoassay with femtomolar limits of detection for proteins, and we have shown this technique to be capable of direct quantitation of hormone secretion from small numbers of endocrine cells. However, ECPA relies on DNA annealing at the surface of a gold electrode, which is exceptionally sensitive to temperature fluctuations. To further stabilize ECPA readout, a custom-tailored thermal regulator was created to control temperature between 0 to 100 °C. The system was designed utilizing an integrated controller for peltier modules, capable of delivering 2.2 amperes at up to 5 volts. A 30x30 mm peltier module capable of sustaining a 66 °C temperature difference was used for the thermal pumping. The hot side of the peltier module was fitted with a 40x40x23 mm heat sink and a 30x30 mm fan capable of 3.72 cubic feet per minute of airflow. The controller was driven with an in-house written LabVIEW application. The program integrates safety shutdown procedures, proportional integral derivative control, and data capture functionality. The system's resolution is ± 1 °C in the experimental setup over the course of a 2 hour run. To evaluate the system, thermal melting analysis was carried out on a DNA loop model of ECPA. A 7 base-pair DNA strand with a methylene blue label (electrochemically active) was used to model background, and a DNA loop was added to model signal. Thermal melting analysis with our system showed melting of the signal strands at 30 °C, and melting of the DNA anchor strand at 48 °C. With this novel control system, it should be possible to thermally resolve signal and background in ECPA and significantly improve its performance for direct protein quantitation.

Abstract Text

The aim of this paper is on the development of the biosensor platform capable to explore the biocatalytically initiated polymerization process. Such a platform will enable the combination of the biocatalytic process, the chemical amplification, and the plasmonic effect in one device. The ability to sequentially combine differing initiation mechanisms with this coating approach was achieved by using glucose oxidase mediated interfacial polymerization on hydrogel substrates initially polymerized in the presence of glucose and fenton reagent. This approach can be potentially applied to many different biosensing schemes based on enzymes capable of metabolizing target biological analytes in a complex environment.

Abstract Text

Phosphatidic acid phosphatase, PAP (EC 3.1.3.4), is a committed step in triacylglycerol (TAG) synthesis which is also known as Kennedy pathway. The enzyme catalyzes the penultimate step in TAG synthesis to form Diacylglycerol (DAG) which is then acylated to form TAG by diacylglycerol acyltransferase (DAG). PAP essentially controls the pool of DAG and controls how much TAG will be synthesized. Typically, PAP activity is measured by radiolabeled phosphatidic acid, which is costly and cumbersome method. We have developed colorimetric methods to measure PAP activity using dioleoyl phosphatidic acid (DPA). In this paper, we presented evidence that DPA could be substituted by α-glycerophosphate (BGP). We also performed binding experiments with biosensors using immobilized or bound DPA and BGP onto aminopropylsilane activated sensor in a BLITZ system. In both cases, the biosensors showed binding (association) and release (dissociation) from the biosensor. Taking both the enzymatic and binding data, we conclude that BGP could substitute DPA to drive down the PAP activity. These findings pave the way for BGP to substitute DPA or other phosphatidic acid whose solubility in biological buffers is an issue. Enzymologists now could perform PAP activity using nonradioactive substrate cost effectively without having the issue of adding detergent to the enzymatic mix for greater solubility of phosphatidic acid.

Abstract Text

Copper is the first and only metal to be recognized by the U.S. Environmental Protection Agency as having anti-microbial properties. In the aquarium industry, copper has long been used as an anti-algae agent by home aquarists and as a treatment for the protozoan parasite [*Cryptocaryon irritans*] a.k.a. Marine "Ich." Therapeutic levels for Ich are ca. 150 to 200 ppb; however, at concentrations greater than 220 ppb the marine life is threatened from a reduced immune response. For the aquarium industry, there is a pressing need for an analytical method that can analyze copper on the therapeutic scale, [*in situ*], with a minimum of analysis time.

While the literature is replete with methods for the analysis of copper, most of these methods are either not capable of [*in situ*] analysis or have limits of detection and quantification that are far above the therapeutic limit for copper in marine systems. Pulsed electrochemical detection (PED) of copper allows for a combination of the deposition and stripping of anodic stripping voltammetry coupled to the signal enhancement of a near-infinite scan rate offered through chrono-amperometry.

This research focuses on development of a PED waveform for the analysis of copper in marine solutions with focus on the development of an [*in situ*] sensor. Initial work was done utilizing Cyclic Voltammetry to obtain qualitative information on the $\text{Cu}^{2+}/\text{Cu}^0$ reduction-oxidation couple in the marine environment. From this data an initial waveform was developed and optimized, with emphasis being placed on having the shortest possible total time for rapid cycling. Limits of detection and quantification were obtained using the standard additions method. The sensor was validated using a blind study. Artificial seawater was obtained from the National Aquarium (Baltimore, MD) and all work was done on a glassy carbon rotating disk electrode to ensure that marine components would not react with the electrode surface.

Abstract Text

[i]Neisseria gonorrhoeae[/i] and [i]Chlamydia trachomatis[/i] are the two most prevalent bacterial sexually transmitted infections (STIs) reported to the Centers for Disease Control and Prevention (CDC). Since these infections, especially [i]C. trachomatis[/i], are most often asymptomatic they are usually not diagnosed early. Traditional laboratory diagnosis of these infections is done by culture for [i]N. gonorrhoeae[/i] and cell culture or antigen detection for [i]C. trachomatis[/i]. Recently, Nucleic acid amplification tests (NAATs) have become widely accepted and are now recommended by the CDC as the test of choice; however current NAATs are classified as high or moderate complexity and may take 1-2 days for results to become available. New assays and new platforms which provide results at the time of patient visits are urgently needed, since many patients do not return for their results when laboratory-based tests that require several days are performed. We report a quick DNA-AuNP based lateral flow nucleic acid biosensor for the sensitive detection of multiple DNA targets based on sandwich hybridization reaction. Accumulation of AuNP conjugates on the test zones enabled visual detection of nucleic acids sequences. A detection limit of 0.1nM was achieved by measuring the intensity of the red zones via a portable strip reader. Simultaneous detection of DNA from [i]Neisseria gonorrhoeae[/i] and [i]Chlamydia trachomatis[/i] strain samples was performed using this concept.

Abstract Text

Reactive oxygen species (ROS) are part of the natural aerobic metabolism of cells and are involved in various signaling and regulation processes. However, ROS can also cause oxidative stress when antioxidant defenses of the cell fail to regulate their production. Specifically, superoxide can cause cellular oxidative stress through its dismutation to hydrogen peroxide and molecular oxygen as well as by reacting with nitric oxide to produce peroxynitrite, an extremely toxic molecule. However, due to its high reactive nature, superoxide can be difficult to quantitate. Therefore, the present work focuses on a method for the quantitation of superoxide produced inside RAW 264.7 macrophage cells before and after external stimuli.

MitoSOX is a mitochondria targeted fluorescent probe that produces a specific one-electron oxidation product (2-OH-MitoE⁺) upon reaction with superoxide and was used in these studies. The reaction of MitoSOX with other intracellular hydride acceptors can generate a different two-electron oxidation product. In order to separate the different reaction products, microchip electrophoresis was elected since it has been used to analyze bulk cell lysates and can be configured later for single cell analysis studies on cell heterogeneity. The 2-OH-MitoE⁺ standard was obtained by the reaction of the probe with nitrosodisulfonate (NSD). The identity of the peak was confirmed by comparing migration times with the product formed in a xanthine/xanthine oxidase system. Finally, macrophages were incubated with the probe after stimulation and the results compared to non-stimulated samples.

Abstract Text

In this work, we present a rapid and highly sensitive approach for visual detection of microRNA (miRNA) using gold nanoparticles (GNP) coated silica nanorod (SiNR) label and lateral flow strip biosensor (LFSB). GNPs were decorated on the SiNR surface by a seeding and growth procedure. Single strand DNA probe was immobilized on the GNPs-SiNR surface by a self-assembling process, and the formed DNA-GNP-SiNP conjugate was used to construct the LFSB for detecting miRNA. The captured GNPs-SiNR by sandwich-type hybridization reactions (DNA-RNA-DNA) on the test zone of LFSB produced the characteristic color bands, enabling visual detection of miRNA. The miRNA-215 was used as a model target to demonstrate the proof-of-concept. After systematic optimization, the new LFSB was capable of detecting 10 pM of the miRNA target without instrumentation, which is 6 times lower than that obtained with the GNP-based LFSB. Such significant signal enhancement with the GNPs-SiNR label is due to the increased number of GNPs per DNA-RNA hybridization event. The GNPs-SiNR thus provides a new and sensitive nanolabel for visual detection of biological molecules on the lateral flow biosensors, and shows great promise in clinical application and biomedical miRNAs diagnosis in some malignant diseases.

Abstract Text

We will introduce a new design of SERS analyser, which is a new SERS excitation and detection setup based on the evanescent field excitation.¹ This SERS analyser has a special optorode which integrates a solid immersion lens and a SERS-active substrate, allowing for the directional excitation and emission of SERS exactly at the resonance angle. Different from the commercial and other-made “Raman spectrometers”, this SERS spectrometer integrates a metal film with enhancement activity. Its sensitivity is above the commercial Raman spectrometer and it will be promising in surface/interface SERS analysis and medical diagnosis.

Abstract Text

A major difficulty encountered in crime scenes is the ability to differentiate human blood from animal blood. Current testing kits for differentiating human from animal blood have several shortcomings. For example, in addition to being costly, they typically rely on time-consuming protocols and require the use of monoclonal antibodies. The purpose of this research project was to explore the utility of FT-IR technology for the development of a rapid, accurate, and user friendly method for discriminating human blood from animal blood; a test aimed at overcoming many of the difficulties and limitations of current testing procedures. To compare the FT-IR spectra of human blood with animal blood two types of analyses were performed. The first technique relied on the evaluation of spectra by standard classic spectroscopic methods. The second method relied on the use of Support Vector Machine (SVM) algorithm which offered a unique multivariate approach for the unbiased analysis of the data. The human samples used in this study included 107 blood specimens of which 35 were typed as blood group A, 26 as blood group B, and 21 and 25 as blood groups AB and O, respectively. The other blood specimens were obtained from animals of different sizes such as cats, dogs, horses, and mice with five samples taken from each of the animal species. Classic spectroscopic studies combined with SVM demonstrated distinct differences between human and animal FT-IR spectra, and verified the potential of the FT-IR method in a forensic setting, warranting further exploration of this technique.

Abstract Title **Effects of Fructose-Derived Advanced Glycation End Products on Acetylation of Histones in the Brain**

Primary Author Alissa Cornacchia
St. John Fisher College

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) MacKenzie Hall, Melinda Lull

Abstract Text

Objective: The objective of this study was to determine the effects of fructose and their advanced glycation end products (fru-AGES) on histone acetylation in microglia, the immune cells of the brain.

Significance: Fru-AGES primarily form as a result of non-enzymatic reactions between fructose and proteins. One result is inflammation in the brain, which can be directly correlated to increased microglia activity. Microglial activity has been shown to be associated with the acetylation of histones, resulting in a change in transcription of inflammatory genes. Elucidation of a direct link between fructose, fru-AGES and histone acetylation would increase understanding the pathophysiology of inflammatory disorders such as Alzheimer's disease.

Experimental Procedures: An immortalized rat microglial cell line was treated in vitro with control media, fru-AGES or fructose. Histone acetylation was analyzed indirectly through activity of histone deacetylase (HDAC) using the HDAC Glo I/II Assay (Promega). Chemiluminescent product formation was measuring with a spectrophotometer.

Results Obtained: Both treatments with fructose and fru-AGES showed an increase in HDAC activity compared to control by up to 35% and 20%, respectively, correlating to a decrease in global histone acetylation. This is contradictory to initial expectations, as a decrease in acetylation could result in a decrease in transcription of genes. Despite causing an initial inflammatory response, fructose and fru-AGES appear to suppress overall gene transcription.

Conclusion: Previous data show that exposure of microglia to fructose and fru-AGES results in a pro-inflammatory activated state. However, at the level of gene transcription, microglia may be desensitized and less able to respond in the long term.

Abstract Text

Preterm birth (PTB) is a birth occurring prior to 37 weeks of pregnancy; it is the most common type of complication in pregnancy, leading to neonatal deaths and newborn illnesses. At present, effective clinical methods that can assess the risk of PTB at a stage where therapeutic interventions are still possible to delay delivery are not readily available. Thus, there is a clear need for a simple, cost-effective and rapid analysis system for detection of PTBs. Esplin et al. previously discovered three maternal serum peptides, which when combined with six previously characterized protein biomarkers, provided 87% sensitivity and 81% specificity in predicting a PTB four weeks later at a gestational age of 28 weeks.¹ We are developing an integrated microfluidic platform that can extract, label, separate and quantify these PTB biomarkers directly from blood samples, to address the above mentioned need. We are optimizing individual modules of this integrated platform in a parallel fashion. We have successfully carried out microchip electrophoresis separation of several PTB biomarkers. We are also characterizing reversed-phase and immunoaffinity monolithic columns for on-chip labeling and immunoaffinity extraction of PTB biomarkers. Our ultimate goal is to integrate multiple processes, including immunoaffinity extraction, solid-phase sample enrichment, on-chip labeling, electrophoretic separation and quantification, on a single microdevice. We believe that the utility of this novel platform will extend well beyond PTB biomarker analysis to various other prospective analytes, therefore offering great potential for improving human health.

Abstract Text

This work faces the challenge to electrochemically measure neurotransmitter release from the smallest varicosities of a nerve cell. The nerve terminals found in the body wall of Drosophila larvae are readily accessible to experimental manipulation. We used the light-activated ion channel channelrhodopsin-2 (ChR2), which is expressed genetically in type II varicosities, to study octopamine release in Drosophila larvae. Here we report the development of amperometry to measure release of the neurotransmitter octopamine from individual varicosities in the Drosophila larval system by amperometry. A carbon-fiber disk microelectrode was placed onto this cellular region of the muscle and held at a potential above the formal oxidation potential of octopamine and the terminal stimulated by blue light. The results suggest that optical stimulation can be used to evoke exocytosis release in the type II varicosities of Drosophila larvae. When octopamine is released from the varicosities during stimulation, it is oxidized at the electrode and a current spike results. We use this method to quantify the amount of transmitter released and these subsecond release events. This is a new approach to study millisecond release events in the nanoliter environment of a neuromuscular junction.

Abstract Text

Within the central nervous system, histamine (HA) is involved in numerous brain functions including awakening, the control of pituitary hormone secretion, and cognitive functions. In recent studies, altered levels of HA has been speculated to be involved in brain diseases such as Alzheimer's, Parkinson's, and depression. While the general HA pathway originating from the cell bodies in the tuberomammillary nucleus (TM) is generally understood, its' similar electrochemical signature to other compounds such as adenosine and hydrogen peroxide has made it difficult to characterize in vivo. Using an optimized histamine-sensitive waveform with fast-scan cyclic voltammetry (FSCV) has now enabled us to better understand the innervations of HA within the mouse brain. In this work we utilize our novel waveform and FSCV at highly sensitive carbon fiber micro electrodes in combination with pharmacological analysis to measure HA levels in the substantial nigra reticular (SNr), cerebral cortex (CX), and ventral pallidum (VP) via stimulation of the HA cell bodies in the tuberomammillary nucleus (TM). We demonstrate that robust in vivo detection of HA using FSCV can be used to effectively study, characterize, and implicate the identification of a precise chemical profile of HA in future studies.

Abstract Text

Chemical cytometry is a form of single-cell analysis in which an individual cell is lysed, and its contents separated and detected. Combined with fluorescently-labeled reporter substrates, chemical cytometry can yield information about cell-to-cell variation in enzyme activity. To date, such experiments have been performed primarily on mammalian cells. However, cellular heterogeneity plays an important role in the biology of many species, including important non-mammalian model systems, such as [i]Dictyostelium discoideum[/i]. Application of established chemical cytometry assays optimized for human cells to new model organisms requires thoughtful adaptation of each assay step. We report on our work to apply a peptide reporter substrate for protein kinase B to [i]Dictyostelium[/i] cells. PKB is highly conserved threonine kinase involved in cell proliferation and survival in human cells and in chemotaxis during [i]Dictyostelium[/i] development. Using fluorescence microscopy, we show that methods used to load reporter peptides in mammalian cells, including pinocytosis with osmotic lysis, electroporation, and myristoylation, yield varying results in [i]Dictyostelium[/i], due to differences in its cellular physiology. We are evaluating the processing of the peptidase-resistant reporter substrate in [i]Dictyostelium[/i] lysates using electrophoretic separations in capillaries and microchips. This adaptation of a tool developed in human cell lines will open new possibilities for studying cellular heterogeneity in diverse cell types.

Abstract Text

The electrochemical proximity assay (ECPA) is a powerful technique that is capable of detecting proteins at femtomolar levels. ECPA has a wide variety of potential applications, including medical diagnostics and point-of-care testing. In ECPA, formation of a surface bound complex composed of the target protein and two DNA-antibody capture probes brings an electrochemical reporter molecule close to the electrode surface where it can be detected amperometrically. Compared to conventional ELISAs, ECPA has three advantages: lower detection limits, wider dynamic range, and shorter analysis time.

Bipolar electrochemistry has received increasing attention in recent years because of its ease of integration with lab-on-a-chip technology and its wireless readout capability. The marriage of bipolar electrochemistry and ECPA offers a new way to measure protein levels quantitatively without the need for direct electrical connection. In this study, electrogenerated chemiluminescence (ECL) was used to report on the state of the bipolar ECPA sensor. Because of the extremely low currents flowing through the bipolar electrode, we developed a signal averaging strategy in which a time dependent square wave potential program was applied across the bipolar electrode, allowing the S/N of the ECL signals to be enhanced.

Abstract Text

Three dimensional (3-D) printing technology has evolved dramatically in the last few years, offering the capability of printing objects with a variety of materials, from rubber to more rigid and transparent plastics. Printing microfluidic devices using this technology offers various advantages such as ease and uniformity of fabrication, file sharing between laboratories, and increased device to device reproducibility. One of the most unique aspects of this technology, when used with electrochemical detection, is the ability to produce a microfluidic device as one unit, furthermore allowing the reuse of the device and electrode for multiple analyses. Here we report microfluidic devices printed using two different printing methods, Fused Deposition Modeling (FDM) and PolyJet, which can be used with electrochemical detection. In both cases, we compare the fabrication process of the printing process, materials used for printing- acrylonitrile butadiene styrene (FDM method) and FullCure 720 (PolyJet method), the device design, and the results of the electrochemical detection of various concentrations of catechol. For the design of the devices, we report a comparison between thin layer electrode and wall-jet electrode system. The later system enhances analytical performance by eliminating any dead volume created at the electrode-solution interphase, increasing peak symmetry and reducing tailing. We further discuss the fabrication of custom fittings that houses the electrodes and sample inlet capillaries. Due to the varying costs, resolution capabilities and differences in materials of 3-D printers, this study provides a platform to verify versatility, reproducibility and convenient nature of this technology to produce microfluidic devices.

Abstract Text

Microfluidic mixing system has shown considerable efficiency for miniaturizing chemical and biological processes such as stimulation and modification, because of its advantages of small sample consumption, rapid sample processing, precise control of the fluids and high throughput capability. However, such mixing system combines with the substrate limits the target substrate and sometimes suffers from the interference between the microfluidic mixing system and macroscopic solid objects. Here, we have developed a microfluidic mixing chemical pen (MMCP) by combining microfluidics technology and fountain pen, which overcomes those limitations and permits region selection and free movement. The MMCP was easily made by put three capillaries into one large glass tube, which could be fabricated with good reproducibility without high cost. Two of the three capillaries were used for injection of two individual solutions and the third one was used for aspiration. Flow streams underneath the MMCP have stable boundaries under the hydrodynamic forces which act as the walls of microchannels; mixing area similar to microfluidic mixing in closed microchannels forms because of diffusion effect. Thus, the MMCP is freely moved and can easily acts on most types of solid surfaces by moving over them. We evaluate the multifunction of this concept with several models including online protein labeling, modification, protein arraying, and Ag electrode. The MMCP allows region selection and designed scanning by moving over the sample surface.

Abstract Text

Paper-based microfluidic devices (μ PADs) are capable of achieving rapid qualitative and quantitative measurements of a variety of analytes inexpensively. μ PADs relies on patterning of hydrophilic-hydrophobic regions on a sheet of paper in order to create capillary channels withing impermeable fluidic brakes on the paper. Here we present a novel, highly flexible and low-cost fabrication method using a desktop digital craft plotter/cutter and technical drawing pens with tip size of 0.5 and 1.0 mm. The pens were used with either commercial black permanent ink for drawing fluidic brakes, or with speciality in-house formulated aqueous inks. With the permanent marker ink it was possible to create barriers on paper rapidly and in a variety of designs in a highly flexible manner using a software controlled plotter/cutter - for instance, a design featuring eight reservoirs (Fig.1) can be produced within 10 s for each μ PAD. Also, using this method a reproducible line width of brakes can be achieved with %RSD < 1.5. To verify the method flexibility and performance, we further investigated the optimal viscosity range of in-house formulated inks, with a model example of aqueous solution of bromophenol blue (BPB) with the addition of poly(ethylene glycol) in order to vary the viscosity. We show that the drawing pen technique offers a favourable freedom of ink composition compared to ink-jet printing. A function test of these μ PADs was conducted by the determination of bovine serum albumin using BPB to form color complex. Lines and areas were plotted on the paper and ImageJ was used to convert the images to gray scale format before measuring the intensity of the colored area. The fabrication method using technical drawing pens provides flexibility in the used inks, short fabrication time, simplicity and low cost.

Abstract Text

We have previously shown that passively operated, polydimethylsiloxane (PDMS) microdevices allow secretion sampling from individual primary murine islets. However, fabrication of the fluidic reservoirs was time consuming and tedious, using custom-made inserts that often shifted alignment or fell over into the uncured PDMS during casting. Here, we show that 3D-printed templates allow interfacing to monolithic, microfluidic channels, permitting 3D 'landscaping' features not previously attainable with standard well punching methods. The insert defines a central well with a large reservoir region (7.5 mm) and a smaller (1 mm) well is punched in the bottom of the reservoir (see attached image). 3D modeling and printing of interface templates gives exquisite control over fluidic interfacing designs and drastically reduces batch-to-batch variability. Additional alignment and stabilizing elements were incorporated into the insert fabrication to increase their ease of use. The completed device is capable of secretion sampling from primary pancreatic islet cells loaded into the smaller central inlet. Vacuum is passively applied to each of the 8-channels over alternating time periods to collect temporally resolved samples from the islets in the central well. By flowing out into discrete wells, samples can be easily collected over varying periods of time without having to incorporate more complicated sampling methods. The large/small reservoir interface at the inlet is vital for rapid switching of stimulatory solutions without disturbing cells in the inlet and for reducing dead volume. The device will be further characterized for flow rate and channel resistances using methods previously established in our lab. After initial characterization and proof-of-concept for this device, the subsequent aim is to design a simple, in-house software program with multiple solenoid valves controlling each of the 8-channels to completely automate sampling.

Abstract Text

The pH measurement by commercialized pH paper is a confusing work because the value is arbitrarily determined based on the color changes of several pH detection zones. In this work, a new paper-based pH-measuring device (pH scale bar paper), which shape is similar to a common mercury thermometer, was developed for providing more user-friendly pH paper with original advantages such as short detection time, simplicity and low cost. The pH scale bar paper device in size of 25 x 75 mm² (see Fig. 1A) has a 5-layered structure with PET/adhesive/patterned paper/adhesive/PET, and was fabricated using wax printing, paper cutting by laser, and layer bonding by pressing. It has multiple colorimetric detection zones which respond to specific pH values with different pH indicators, and a sample solution is sequentially delivered from an inlet to the detection zones through a hollow paper channel very fast. Fig. 1B shows a prototype device with a resolution of pH = 1, indicating a successful demonstration of the proof-of-concept of this new pH-measuring paper device for a test solution (pH = 13). The analysis time was less than 30 s with the use of plasma-treated hydrophilic PET layers. The color of detection zones was changed sequentially from pH = 1 to 14 (bottom to top), and initial colors of white or light yellow were converted to dark colors if a sample had equal or higher pH than a designed value.

Abstract Text

New paper-based fluidic devices were studied for a use in liquid chromatography. A basic concept of the lab-on-a-paper (LOP) chromatography device is to separate analyte molecules under a constant flow rate condition along a stripe paper channel unlike the conventional chromatography in which the flow rate was governed by Lucas-Washburn equation : flow distance is proportional to square root of time. For achieving the quasi-stationary flow condition, our new fluidic device used a fan-shaped absorption pad-linked strip channel. The paper channels with different fan angles were fabricated by wax-printing, and its top and bottom were covered by PET layers to prevent eluent evaporation from a paper channel. From travel distance measurements of flow front, the aqueous dye solution at first moved along the strip channel under the Washburn relationship, while the channel flow rate displayed a nearly constant flow speed after the front reached the fan region. Furthermore, quasi-stationary flow became fast by increasing the fan angle, and the rate was controlled in the region of 1.4 – 2.5 $\mu\text{L}/\text{min}$, demonstrating that the absorption pad functioned as a paper pump. Our LOP chip give a chance to use a long strip channel in paper chromatography. As a preliminary test, green food dye was injected into the strip channel after developing a quasi-stationary flow, and then successfully separated into yellow and blue components.

Abstract Text

Both Polystyrene (PS) and polydimethylsiloxane (PDMS) are useful substrates for the development of chip-based in vitro mimics. A recurring issue with totally integrated devices is that if any part of the chip fails (delamination or cells dislodging), the entire experiment is compromised. The overall goal of this work is the development of a device that can integrate a substrate containing immobilized cells with electrophoresis for analysis of cell releasates. The hybrid device in this work takes advantage of the benefits of PDMS (ability to incorporate peristaltic pumps and valves) and PS (ability to embed fluidic tubing and electrodes). A Pd decoupler is used to ground the system and allow in-channel electrochemical detection for close to real-time analysis. Pneumatic valves isolate cells from electrophoretic voltages. Upon injection, analytes are separated via microchip electrophoresis and detected. Adhesion between substrates was improved with a stamping technique using chlorotrimethylsilane. The separation of dopamine and norepinephrine was optimized in highly conductive biological buffers, and this device was used to monitor the neurotransmitter release from PC 12 cells. It will also be shown that separation efficiency can be improved by lengthening the electrophoresis channel with embedded fused silica capillary. The valving chip makes injections that traverse down the channel, into a capillary loop, and back onto microchip for detection. The embedded capillary can also be used to make devices more modular in a “plug and play” manner, where a cell culture chip can be connected to an analysis chip when desired for a chip-to-chip interface.

Abstract Text

Diabetes is a metabolic disease characterized by a hyperglycemic state, which, if not effectively managed, can generate reactive oxygen species (ROS). When ROS attack endothelial cells (ECs), which line the walls of blood vessels, cardiovascular damage develops over time. Despite the strong vascular component of the disease, a suitable *in vitro* model that reflects the consequences of hyperglycemia on cell metabolism *in vivo* has yet to be developed. Conventional approaches to studying diabetes *in vitro* typically involve culturing ECs in cell culture flasks and subjecting them to elevated glucose levels. Because ECs *in vivo* experience constant shear stress as a result of blood flow, such conventional approaches are inadequate as biomimetic models of the disease. The project proposed here describes a novel method of culturing endothelial cells for several days in a microfluidic device consisting of channels fabricated in a poly(dimethylsiloxane) microchip sealed over a glass substrate. Inlets and outlets on the chip allow for flow-based experiments in which cells are continuously provided a supply of fresh media or serum. Microchannel dimensions are consistent with those of a blood vessel and the small fingerprint of the device enables multiplexing while generating little waste. This device has the potential to provide a biomimetic model of diabetes which could be coupled to a wide range of metabolic analysis strategies. This work will investigate the metabolic pathways that become damaged by hyperglycemia which will aid in the elucidation of potential therapeutic targets.

Abstract Text

Two-dimensional separations are a promising way to provide the increased peak capacity necessary to separate today's complex biomedical and environmental samples. However, current two-dimensional separations are limited by second dimension under sampling of the peaks as they elute off the first dimension. One common approach to resolve this issue is to sample the analyte peaks more frequently as they elute off the first dimension. However, the second separation must be shortened to increase sampling frequency, at the cost of separation efficiency.

We propose using micro free flow electrophoresis (μ FFE) to resolve the under sampling problem. In μ FFE analyte is continuously streamed into a planar separation channel while an electric field is applied perpendicularly. The analytes are deflected laterally based on their electrophoretic mobilities. Since μ FFE is a continuous separation technique, complicated injection interfaces are eliminated while maximizing the sampling of peaks as they elute off the first dimension. This in turn will minimize loss of peak capacity due to under sampling. In μ FFE, the effective sampling rate is only limited by the exposure time of the camera (typically 100 msec). To showcase the promising separation ability of μ FFE as a second dimensional technique, capillary electrophoresis (CE) will be coupled to μ FFE to separate a tryptic digest of bovine serum albumin. Peak capacities greater than 3000 in less than 15 minutes are expected.

Abstract Text

This abstract reports an electrokinetic manipulation to separate polystyrene (PS) microspheres in high-conductivity media, although most electrokinetic operation only focusing in low-conductivity buffers. A PDMS/glass microfluidic chip with a designed of a three-layer sandwich, and three-parallel micro-electrode was fabricated for the different size of PS microspheres separation. With optimized AC voltage and frequency, we demonstrate that 25 μm microspheres can be isolated from 5 or/and 10 μm microspheres and concentrated onto the inner electrode in dozen sec. The design of the microfluidic chip is shown in Fig.1. The microchannel was fabricated by molding PDMS with laser machined mold. The electrodes were fabricated by sputtering Ti-Au-Ti on a glass slide. Then the glass substrate with microelectrodes was sealed with the PDMS microchannel by plasma treatment. There three sizes of PS microspheres (5, 10 and 25 μm respectively) were used which were evenly dispersed into the conductive solution (10X TAE, $\sim 1.59 \text{ S/m}$) before experiment. To separate two or three sizes of microspheres, a series of electric field were applied. It was visible that, the 5, 10 and 25 μm microspheres were positioned into different equilibrium locations. In particular, almost all of the 25 μm microspheres migrated to the inner electrode, while the majority of 5 and/or 10 μm microspheres moved into the areas between the neighboring electrodes (Fig.2). Fig.3 shows that the results of the separation, in which, at the frequency range of 100 kHz-10 MHz, 5 and 25 μm , 10 and 25 μm PS microspheres can be separated. By optimized frequency and AC voltage, we demonstrated that the better of frequency for the separation of two sizes of microspheres (10 and 25 μm , 5 and 25 μm) (fig.4) and three sizes of microspheres (5, 10 and 25 μm) were 100 kHz, 2 MHz and 1 MHz separately. Meanwhile, the better AC voltage conditions for two or three sizes of microspheres separation were 14 V, 10V and 11V respectively.

Abstract Text

Exocytosis is an essential cellular process in neuronal communication. This cellular function involves vesicle fusion and vesicle content release of neurotransmitter molecules. In the quest to determine the molecules affecting exocytosis, simplified model systems, such as artificial cells are valuable tools. Model systems allow us to study the effect of different components such as various lipids on the process of exocytosis in a controlled manner. Membrane lipids including cholesterol provide the platform for carrying out and regulating exocytosis. Although cholesterol is a major component of the membrane and certainly affects exocytosis, the overall biochemical and biophysical properties have not been fully understood. The goal of this work is to use an artificial cell model and amperometry to provide information to better understand the effect of cholesterol on exocytosis. In this work we are using two different artificial cell models: one cell model based on pure lipid composition and a second cell model constructed from cell plasma membrane from a PC12 cells. Kinetic information of single vesicle release of dopamine is recorded using carbon fiber amperometry and provides information that will help to better understand the effect of cholesterol on exocytosis. The two cell models used in this work differ in the overall membrane tension, a parameter that we show with the bleb cell model can influence whether the fusion pore fully or partially distends. Hence, both partial and full distension can be mimicked using this cell model. The partial distension mode might correspond to the kiss-and-run mechanism of release from secretory cells, which has been proposed to be the major pathway of exocytosis in neurons and neuroendocrine cells.

Abstract Text

Rapid and simple measurement system of biomarkers such as luteinizing hormone and sexual hormones is required in the medical fields especially in production of livestock. Immunochromatography is one of the rapid and simplest immunosensors available, however it is not suitable for quantitative detection of biomarkers. Recently electrochemical detection technique is applied to immunochromatography for providing quantitative capability. The contact between nitrocellulose membrane and electrode is very important to improve the sensitivity. In this regards, we tried to fabricate micropyramid array electrode to improve the contact area between the membrane and electrode, and further evaluated its sensitivity to the ferricyanide ion as an electrochemical mediator by cyclic voltammetry.

Micropyramid array is fabricated with microfabrication process. Firstly, 3D photosensitive resist pattern was formed by grayscale lithography using maskless lithographic equipment. Then the photosensitive resist pattern was transferred to silicon wafer by reactive ion etching. Subsequently, Au thin-film electrode is formed on the micropyramid array by radio-frequency magnetron sputtering. The base length of micropyramid is 20 μm on a side, and its height of 10 μm . We could successfully fabricate the various pyramid array pattern easily, because of employing maskless lithographic equipment, which ultimately cut the cost and time for fabricating photomask. We evaluated the micropyramid electrode array-immunochromatography for measuring the target hormone based on sandwich assay. Target hormone is sandwiched with primary antibody and secondary antibody labeled with glucose oxidase at the test line on the membrane. After that, glucose and $\text{Fe}(\text{CN})_6^{3-}$ are added and $\text{Fe}(\text{CN})_6^{4-}$ is produced by the enzyme reaction. We measured this $\text{Fe}(\text{CN})_6^{4-}$ by electrochemical detection. The detail will be discussed. Abstract Text

Pollutants, drugs and other xenobiotics can undergo metabolic reactions mediated by cytochromes P450 and other metabolic enzymes, resulting in reactive metabolites that may cause genetic damage. Metabolite-related genetic damage generally is of two types: (1) adducts of DNA, in which the highly reactive metabolites covalently bind to the nucleobases to form adducts, resulting in unraveling of DNA and exposing 2'-deoxyguanosines (dG); (2) oxidative damage, in which the metabolite-related reactive oxygen species (ROS) reacts with nucleobases to form oxidized nucleobases such as 8-oxo-7-hydro-2'-deoxyguanosine (8-oxodG). Both adducted and oxidized nucleobases may eventually lead to genetic mutations and carcinogenesis.

Here we describe a microfluidic electrochemical array to detect adduction and oxidation in intact DNA simultaneously. The eight-sensor array is incorporated into a 60 μ m microfluidic channel connected to a pump and sample valve. The array features sensors coated with ruthenium bipyridyl poly(vinylpyridine) chloride [Ru(bpy)₂(PVP)₁₀Cl]⁺ films and osmium bipyridyl poly(vinylpyridine) chloride [Os(bpy)₂(PVP)₁₀Cl]⁺ assembled layer-by-layer with polyions. dG in intact DNA is oxidized by [Ru(bpy)₂(PVP)₁₀Cl]⁺ and 8-oxodG electively oxidized [Os(bpy)₂(PVP)₁₀Cl]⁺, providing separate electrocatalytic electrochemical responses of DNA characteristic of adduct reactions and of DNA oxidation. The same adducted and oxidized products in intact DNA can also be confirmed by high performance liquid chromatography - tandem mass spectrometry (HPLC-MS/MS).

Abstract Text

Electrochemical detection of electroactive molecules is a quantitative and sensitive methodology to characterize neurotransmitter release in vitro and in vivo. Enzymatic immobilization onto an electrode surface offers a route to indirectly detect non-electroactive neurotransmitters, such as glutamate, which are not able to be electrochemically detected with unmodified electrodes. However, fast diffusion away from the electrode surface and biological reuptake of analytes can render electrochemical biosensing of neurotransmitters challenging in vitro and in vivo. Here, we describe a bienzymatic system for amplification and electrochemical detection of L-glutamate within gold gapped electrodes. Firstly, glutamate oxidase, which converts L-glutamate into 2-oxoglutarate and hydrogen peroxide, is covalently attached to one of two individually-addressable electrode pairs within a microfabricated gold interdigitated electrode array. A second enzyme, glutamate-pyruvate transaminase, which converts 2-oxoglutarate and L-alanine back into glutamate, is immobilized on the second set of electrodes. Due to the small spacing between each type of electrode (1-2 μm), cycling of enzymatic products will occur and results in an enhancement of electrochemically-detectable hydrogen peroxide one electrode pair under a negative bias. We will show efforts to characterize redox cycling within the gapped electrodes as a function of electrode width and separation and methods to controllably immobilize each enzyme type onto a separate electrode set via polyaniline/glutaraldehyde coupling.

Abstract Text

Bilharzia is one of the Neglected Tropical Diseases (NTDs), a group of chronic disabling infections affecting more than a billion people worldwide, mainly in Africa and mostly the poor. In Kenya, these NTDs affects more than 50% of the population fueling the vicious circle of poverty and stigma that leaves people unable to work, go to school, or participate in family and community life. Highly sensitive detection and accurate analysis is essential for the early detection, treatment, and management of these diseases. Current methods of detection rely on microscopic detection which is tedious, unreliable and suffers poor sensitivity. In this work, a Nano-based immunosensor for early detection which rely on nano-immunological response between an antibody against Bilharzia conjugated to nanoparticles and Bilharzia antigen will be reported. The conjugation of the antibodies with nanoparticles combines the unique properties of the nanoparticles with the specific and selective recognition ability of the antibodies to antigens. The hybrid product has improved cellular uptake as well as the major intracellular stability and may show versatility and specificity with improved analytical signal important for rapid, sensitive and real-time point of care diagnosis.

Abstract Text

Fast scan cyclic voltammetry (FSCV) is one of a few analytical techniques which can easily make chemical measurements with submicrometer spatial resolution and subsecond temporal resolution. Because of this, it is useful for making measurements of the response dynamics of dopamine (DA) in living brains. Over the past five years, we have developed the understanding that the DA response kinetics of carbon fiber microelectrodes during in vivo FSCV experiments are strongly influenced by the local biochemistry of the working electrode recording site. We have divided evoked DA responses into two categories – Fast and Slow. Fast DA responses are those which show a DA signal upon 200 ms of 60 Hz, 250 uA stimulus of the medial forebrain bundle. Slow DA responses fail to show a DA signal under these conditions, but do give a response upon continuation of these stimulus conditions in time beyond 200 ms. Here, we have measured the vertical dimension of fast and slow DA domains in the rat striatum, and mapped their anatomical locations. We found the average vertical dimension of fast DA domains to be 1.1 mm, and the average vertical dimension of slow DA domains to be 1.9 mm. We also found that measurements of evoked dopamine made in the dorsolateral striatum were significantly faster than measurements made in the dorsomedial striatum.

Abstract Text

Whispering gallery mode (WGM) resonators enable the label-free detection of analytes based on refractive index sensing. We recently demonstrated a large scale multiplexed imaging platform where hundreds of resonators are simultaneously characterized by coupling a fluorescent dye to the resonator surface. This scheme was used to quantify several biomarkers of ovarian cancer with detection limits comparable to ELISA. Recently, we extended this technique by developing an evanescent scattering approach for characterizing the WGM resonances. Moreover, since signal levels scale with excitation power, measurements can be done with high temporal resolution using less expensive imaging equipment. This approach, therefore, offers promise for developing rapid and inexpensive sensing platforms for the multiplexed detection of disease biomarkers. Integration of WGM biosensing with capillary electrophoresis (CE) for analysis of serum proteins will be presented. The integrated platform enables specific detection of biomarkers as they elute from the CE column, which is being developed to aid in the diagnosis multiple myeloma.

Abstract Text

Biogenic amines (i.e. arginine, citrulline, aspartic acid, histamine, glutamic acid and taurine) are important compounds that play a role in a number of physiological processes including neurotransmission and inflammation. Determination of these amines in biological matrices is valuable for a better understanding of their functions in physiological and biochemical processes. Presently, capillary electrophoresis with laser induced fluorescence detection (CE-LIF) was employed to determine the trace levels of these amines in biological samples, as this technique can provide high sensitivity and separation efficiencies. Pre-column derivatization with naphthalenedialdehyde (NDA) in the presence of cyanide was employed to produce fluorescent cyanobenzoisindole (CBI) derivatives. The procedure was accomplished by combining 6.6 μM of each amino acid standard, 20 mM borate (pH 9.0), 5mM NDA and 10 mM NaCN. Due to the high degree of structural similarities between the CBI derivatives, it was necessary to optimize the CE separation by varying buffer additives and the separation voltage. A good separation of the amines was achieved in 17 min in 20 mM borate (pH 9.0) containing 1.4 mM sulfobutylether β -cyclodextrin (SBE- β -CD) and 10% DMSO using a separation voltage 25 KV and a capillary with an effective length of 62 cm and an inner diameter of 50 μm . Excitation was accomplished using a diode laser (λ_{ex} = 440 nm and λ_{em} = 490 nm). A method for the determination of the biogenic amines in microdialysis samples is currently under investigation. The ultimate goal is to transfer the method to microchip format for on-line analysis.

Abstract Text

Traumatic brain injury (TBI) is a major cause of mortality and disability in young people around the world.^[superscript 1] The initial trauma affecting TBI patients is determined at the time of injury, before medical intervention, but is generally followed by a secondary injury occurring a few days later, while the patient undergoes intense clinical treatment. Ischemia and Spreading Depolarisation waves (SD) are important secondary insults that can be detected while patients are being monitored in the intensive therapy unit (ITU).^[superscript 2]

We are developing a miniaturised wireless microfluidic biosensor analysis system that ultimately can be mounted on the patient. On-line microdialysis will be used to sample the cerebrospinal fluid (CSF) and the resulting dialysate will be monitored for changes in levels of key metabolic markers of ischemia and SD, such as glucose, lactate and pyruvate. The system consists of wireless microelectrode-based amperometric biosensors within a microfluidic flow-cell. This novel wearable system will allow monitoring patients to take place earlier, during the initial intensive periods of treatment.

Using a calibration microfluidic board to mimic metabolite changes in the CSF dialysate, preliminary results recorded with a wireless potentiostat will be presented and compared to those obtained with our existing wired biosensor.^[superscript 2]

We thank the EPSRC for funding.

Abstract Text

Carbon nanostructures offer the unique advantages of large surface area and conductivity that are suitable for electrocatalytic reactions and biosensors. Our objective is to devise scalable, stable biocatalytic systems representing complex human liver microsomes (HLM) incorporated with nanomaterials. HLM play an important role in the oxidative metabolism of drugs, and hence, studying liver microsomes by protein film voltammetry has gained significant attention at present. Liver microsomes contain membrane-bound major drug metabolizing cytochrome P450 enzymes (CYPs) and their redox partner protein, CYP-reductase (CPR). The in vivo metabolic process involves electron transfer from NADPH to the heme center of cytochrome P450 enzymes (CYPs) mediated by CYP-reductase (CPR). In the present study, we constructed a bioreactor featuring HLM and multi walled carbon nanotubes (MWNT) on the surface of graphite electrodes. The electrochemical and electrocatalytic properties of this novel biocatalytic film will be presented.

Abstract Text

Glucose oxidase (GOx) based electrodes are mostly used in the design of glucose biosensors [1] or glucose powered biofuel cells. GOx-based electrodes are suitable for the generation of electrical current, which in some concentration range is proportional to glucose concentration in the sample []. In order to increase the current generated by GOx-based electrodes redox mediators capable to transfer electrons from the active site glucose oxidase to the electrode are needed. To investigate properties of layers that are used for bioanalytical purposes, electrochemical methods, including electrochemical impedance spectroscopy can be applied. The aim of this research was advanced EIS-based evaluation of 1,10-phenanthroline-5,6-dione and glucose oxidase modified electrodes. 1,10-Phenanthroline-5,6-dione and glucose oxidase modified electrodes were analysed at different modification stages by the electrochemical impedance spectroscopy (EIS) method [2]. The gathered impedimetric data was evaluated applying advanced equivalent circuits. The study demonstrated redox mediating properties of 1,10-phenanthroline-5,6-dione deposited on graphite electrodes.

Abstract Text

The kinetics of dopamine release and uptake by neurons in the nigrostriatal pathway of anesthetized rats was studied by artificially evoking dopamine release via in vivo electrical stimulation. Dopamine release was recorded using fast scan cyclic voltammetry at carbon fiber microelectrodes. Drugs facilitating dopamine release (raclopride) and inhibiting uptake (nomifensine) were administered, allowing the dopamine overflow resulting from single-pulse stimulations to be resolved. Under these conditions, it was determined that the amount of dopamine released per stimulus pulse decreases with the application of additional pulses. Thus, dopamine release per stimulus pulse is not a constant, as has been assumed by established mathematical models; dopamine release per pulse is in fact dependent on the number of stimulus pulses applied. Differences in the plasticity of kinetic fast and slow sites were observed, with the amplitude of the response per number of pulses decaying much more quickly in slow sites than in fast, even after the application of the D2 antagonist raclopride, suppressing autoinhibition. Additionally, the resolution of one pulse stimulations allowed the size of the gap between the electrode surface and the dopamine-releasing terminal to be estimated. A single pulse was moved in time relative to the data collecting voltage scans, and a gap size of between 3.0 and 3.6 [micro]m was calculated by determining which pulse time differences resulted in a visible dopamine CV at the first voltage scan after the stimulus application.

Abstract Text

Our previously developed electrochemical proximity assay (ECPA) is a direct-readout method for analyzing proteins in the femtomolar range. In ECPA, aptamer or antibody-oligonucleotide probes are used to selectively bind to specific proteins. By coupling this binding to other oligonucleotides, one can significantly increase the stability of hybridization of thiolated-DNA (immobilized on gold electrode) and methylene-blue labeled DNA (MB-DNA). This increases the amount of MB-DNA near the gold electrode, which increases the redox current in square-wave voltammetry (SWV) scans. SWV current is thus proportional to the protein concentration. Since the process involves multiple DNA hybridizations, it is temperature sensitive. In this work, we report ECPA responses as a function of temperature using a custom-built temperature control system. To effectively control the temperature, we built a thermal regulator, controlled by an in-house written LabVIEW application. We employed the DNA-loop model which we used in our previous work to verify signal and background currents in the temperature range of 15-50 oC, with a 1 oC increment. We observed that the background was completely denatured by 30 oC, while the signal was stable (DNA hybridization) and increasing (electrochemical increase due to temperature) through a maximum at 25 oC, making S/N ratio very high at this temperature. Beyond 25 oC, the DNA-loop hybridization began to melt, with the transition centered at 30.1 oC. We were even able to observe melting of the DNA anchor from the thiolated surface strand, centered at 48.5 oC. This customized thermal regulation system should enable a greatly improved fundamental understanding of the binding and readout of signal and background in ECPA. In the short term, it should allow significant enhancements in the ECPA signal-to-background ratio.

Abstract Text

Though advances in breast cancer diagnostics and treatment have led to decreased death rates, there are limitations to current methods. Mammography is an invasive procedure that can miss up to 20% of cancers, and false positives lead to patient anxiety and potential overtreatment. Furthermore, current blood biomarkers such as CA 15-3 and CEA are not suitable for early detection. The goal of this work is to detect biomarkers indicative of early stage breast cancer in serum. Stage-indicative breast cancer proteins may be present in serum at low concentrations and undetectable by current methods such as a traditional plate ELISA. This sensitivity barrier can be overcome by utilizing single molecule arrays (SiMoAs) as a detection platform, which uses digital counting to measure single protein molecules; this method can measure concentrations of proteins 100-1,000X lower than traditional ELISA detection limits. SiMoA technology can be applied to detecting low abundance proteins toward a noninvasive, ultrasensitive blood test for breast cancer. The work presented includes assay development of several potential breast cancer biomarkers, as well as tests in healthy and patient serum and urine.

Abstract Text

Method development can be challenging for structurally similar compounds and complex ionic mixtures. Additionally, validation methods often require a column of orthogonal selectivity be used to ensure no impurities are missed. Zirconia based phases, with their inherent surface chemistry differences, offer a dramatically different selectivity when compared to silica and polymer phases. Here we investigate two of the most unique zirconia-based phases, a carbon-clad zirconia phase and a crosslinked polyethyleneimine coated zirconia phase.

To demonstrate the differences between the zirconia based, carbon-clad ZirChrom[registered]-CARB phase, we highlight a selectivity comparison versus a typical silica bonded phase for 22 non-electrolyte solutes with varying chemical properties. The analysis of a set of six structurally similar sulfated steroids will be explored to demonstrate how this orthogonal selectivity can be successfully applied.

The unique multi-modal surface chemistry of the zirconia-based, polyethyleneimine coated, ZirChrom[registered]-SAX phase can be helpful in the analysis of complex ionic samples. A discussion of the surface chemistry and multi-modal separation mechanisms of the phase will be presented. Finally the method development for a separation of six water soluble vitamins will be included as an example of how the multi-modal selectivity of ZirChrom[registered]-SAX can resolve a complex ionic mixture.

Abstract Text

This paper described a method for monitoring 3-Methyl-5-Isopropylhydantoin (MVH), a biomarker of the degradation of dimethylformamide (DMF) in hemoglobin. Cleanert MAS-B Plate with 96-well format was used for rapid clean-up of the samples. 3-Methyl-5-isobutylhydantoin (MIH) was applied as internal standard to quantify MVH in hemoglobin. A clean fraction was obtained for high throughput monitoring of MVH and detected by LC-MS/MS without further concentration. Recoveries for MVH were range from 100.4% to 102.5% with RSDs were <4.6%. LOD of MVH and MIH were 1.0ng/mL. The data highlights Cleanert MAS-B 96-well Plate with 25mg sorbent in each well is suitable to remove the matrix of hemoglobin which might interfere in the analysis of MVH by LC-MS/MS. The usage of the 96-well plate is sufficient for high throughput sample clean-up procedure prior to LC-MS/MS. This study provided a solution for monitoring cumulative exposure to DMF.

Abstract Text

Established a rapid clean-up procedure for detecting Indomethacin and Ibuprofen from human plasma. The method employed Cleanert PEP MicroPlate for sample purification which was a water-wettable polymer-based SPE sorbent. The extraction procedure using a modular design μ Elution plate allowing the number of wells to match samples numbers being processed. Analyte concentrations ranged from 5 to 50ng/mL, the analytes were eluted by 100 μ l acetonitrile and detected with LC-MS/MS. This ensured little or no analyte dilution compared with the original sample volume. In addition, the elution volume ensured evaporation and reconstitution time was minimised and throughput improved. Recoveries for the two analytes were >85% for Indomethacin and >90% for Ibuprofen. LOD of Indomethacin and Ibuprofen were 0.5ng/mL and 1.0ng/mL respectively. The data highlights the minimum elution volumes that can be achieved from the 5mg sorbent mass and the versatile nature of the modular plate design.

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Wei Junfu

Abstract Text

Established a method for detecting Telmisartan from human plasma. The method employed Cleanert SLE Plate for sample purification. The technique mimics the characteristics of liquid-liquid extraction (LLE), but unlike LLE lends itself to high throughput and automation. Cleanert SLE packed with a diatomaceous earth, each well provides a support to absorb the aqueous sample, whilst leaving the analytes on the surface - there are no interactions between the analyte and the diatomaceous earth. Analytes were subsequently eluted with a water immiscible organic solvent. The plate was packed with 600mg of sorbent, allowed a maximum load volume to 600 μ l. The top frit of the plate has been surface modified to a more hydrophilic nature which contributed to plasma samples loading. Recoveries for Telmisartan was 83.6 ~98.9%. The RSD was <4.5%. Linearity checks across the full concentration range were good. LOD of Telmisartan was 0.1ng/mL.

Abstract Text

As the medical cannabis industry evolves, applications for chemical analysis of cannabis concentrates are growing. In addition to being simply vaporized by the end user, concentrates may be used to prepare alternate dosage forms such as tinctures, topical salves, and transdermal patches. Like all pharmaceutical products and regardless of the final dosage form, potentially harmful residual solvents from the manufacturing process must be minimized and monitored.

While sample dissolution methods for residual solvents analyses exist (e.g. USP <467>), for some cannabis concentrates, it is extremely difficult to achieve dissolution in common, late-eluting solvents that will not interfere with headspace analysis. Additionally, complex matrices such as cannabis concentrates usually require matrix-matched standards to ensure accurate quantification. Through the use of full evaporation technique-headspace gas chromatography (FET-HS-GC), accurate quantification for residual solvents can be achieved to low ppm levels in concentrates without the need for matrix-matched standards.

A method was developed to quantify levels of isobutane, butane, methanol, pentane, ethanol, acetone, isopropanol, hexane, chloroform, benzene, heptane, and toluene using FET-HS-GC. Adequate resolution was achieved for all compounds with an analysis time of less than 10 minutes. Calibration curves were prepared from 5 – 500ppm residual solvents, assuming 20mg of sample. Linearity was acceptable for all compounds, with r² values ranging from 0.992 for isobutane to 1.000 for heptane. Signal-to-noise ratios at 10ppm ranged from 5.3 for isobutane to 170 for toluene.

This presentation will introduce the full evaporation technique, discuss method optimization parameters for headspace analyses, and present quantitative data collected for the work outlined above.

Abstract Text

Residual host cell proteins are an immunogenicity concern for biotherapeutics. Recently the USP released an updated chapter for residual host cell protein measurement in biopharmaceuticals, including guidance for testing the residual amount of these proteins in biotherapeutic products. It is a regulatory requirement to demonstrate clearance of residual host cell proteins following standard processing of biological therapeutics. Greater than 1000 proteins are routinely detected in the cell culture supernatant, and assessing coverage of the polyclonal reagent for a complete match is challenging. The industry gold standard approach is to utilize 2D-silver and western blotting to assess the coverage of polyclonal antibody reagent used in standard ELISA test method. 2D silver/western blot method is time consuming, tedious, and prone to reproducibility error. Analysis can vary widely resulting in significantly different coverage assessment values which in turn can cause concern to the applicability of the ELISA method. To make the 2D-silver/western more reliable, a systematic approach has been developed to assess the analytical variability and more accurately report the results. Additional techniques to assessing the polyclonal reagent and its coverage to process host cell proteins are also being developed including 2D-DIGE and 2D LC-MS. These emerging techniques have been investigated to provide a more thorough assessment of the host cell protein polyclonal reagent coverage and to improve the reproducibility of the host cell protein reagent.

Abstract Text

Preparative scale liquid chromatography can be challenging to the isolation chemist in many ways, but effective sample loading directly influences the success of compound isolation. While the objectives of prep chromatography include achieving high mass load on the column and employing rugged generic chromatography, two conflicting principles almost always play a role in the approach used to realize these objectives. First, strong solvents dissolve samples but distort chromatographic peaks due to the inability of the sample to properly interact with the column packing. Second, weak solvents as sample diluent give good chromatography but do not dissolve samples at high concentration. Low sample concentration ultimately results in large injection volumes which are difficult to handle and generally result in poor chromatography. Although these challenges are well known among chromatographers, with easy modifications to the HPLC system plumbing these issues can be addressed satisfactorily. In this study, we illustrate and compare different techniques for improving the efficiency of loading large volumes of sample for compound isolation. The impact of each technique on the overall purification efficiency will be discussed.

Abstract Text

As USP global initiative to modernize existing monographs across all compendia, objectives and criteria for the monograph modernization are discussed. Identification, assay and organic impurities tests in the USP monograph are highlighted with modern analytical techniques for the modernized monograph. A fast and reproducible Hydrophilic Interaction Chromatography (HILIC) method coupled with Charged Aerosol Detector (CAD) is developed for non-chromophoric β -hydroxylamine in metoprolol succinate and related solid dosage drug formulations. This method allows rapid quantitation of non-chromophoric metoprolol impurities in the presence of metoprolol succinate (a selective β_1 receptor blocker used in treatment of several diseases of the cardiovascular system, especially hypertension) and its potential degradants. In the presentation, USP internal monograph development strategy and monograph review process are also addressed.

Abstract Text

Dichloromethane (DCM) is both the lifeblood and main chemical waste of many pharmaceutical medicinal chemistry laboratories employing flash chromatography. The solvating power of DCM for many organic compounds when combined with its low boiling point make it an ideal non-polar solvent for this application. However, DCM is not without its health risks to the scientist or specialized solvent waste concerns. This paper will discuss a uniquely novel approach utilizing carbon dioxide to completely eliminate and/or at the very least, greatly reduce the amount of DCM and other non-polar solvents currently employed flash chromatography purifications worldwide.

Abstract Text

Chiral amines are powerful pharmacophores for creating new pharmaceuticals due to their inherent amount of structural information and their ability for hydrogen bonding, yet their analysis remains a challenge. Recently a novel class of chiral stationary phases (CSP) based on cyclofructan has been developed. Cyclofructans are cyclic oligosaccharides that possess a crown ether core and pendent fructofuranose moieties, which have been successfully derivatized. Aliphatic derivatives of this sort have shown "class" selectivity towards primary amine containing enantiomers. This is well documented. However, lab technicians often prefer to only use the columns "on-hand" or those that are already in their chiral screening unit. Herein, we show a simple comparison of the increased number of hits obtained by using one cyclofructan based column for screening 30 chiral primary amine separations versus using 6 cellulose and amylose based columns. Additionally, the time saved from only screening 1 column instead of 6 columns is demonstrated. Other topics that will be discussed include the amount of solvent that can be saved using the proper screening tools, any complementary separations that are observed between phases, and the effect of using manufacturer recommended screening mobile phases.

Abstract Text

This poster was a comparative study about 3 kinds of sample pretreatment processes to extract Arachidonic Acid (AA) from plasma, which involved Protein precipitation 96-well plate, Brand W 96-well plate and Cleanert MAS-M 96-well plate. Protein precipitation method enjoyed a convenience due to its minimum procedures, but its recoveries of AA were 129.32%~149.02%, implying the worst purification effect which caused the matrix enhancement on mass spectrum. The recoveries of AA on Brand W 96-well plate were 5.45%~70.15%, while the recoveries of Cleanert MAS-M 96-well plate were 99.19%~106.38 which ensured an extraction procedure without reconstitution to support a rapid, high throughput assay of AA in plasma.

Abstract Text

USP methods are used widely in the pharmaceutical industry and are often not optimized for use with modern instrumentation and packing materials. As it becomes increasingly important to boost throughput in the modern laboratory, new instrumentation and smaller particle size packing materials are allowing scientists to achieve these goals while also realizing cost savings in terms of man-hours and solvent usage. In this poster we investigate the use of 3um YMC-Triart C18 and 2.7um YMC-Meteoric Core C18 stationary phases for improving a USP assay method for chlorhexidine gluconate.

Abstract Text

With the growth of high blood pressure and heart disease population, related drugs such as β blockers become the focus of attention. So a simple and efficient sample preparation technique is necessary. This study was carried out by using solid phase extraction cartridges with a format of 96-well plate and LC-MS/MS detection for the analysis of metoprolol and propranolol in human plasma. The plasma was spiked with the two β blockers at a concentration range from 1 to 5 ng/mL. The LODs of metoprolol and propranolol was 0.02 ng/mL and 0.1 ng/mL, The method is rapid and efficient with the recovery range from 84.2% to 92.2%. The results indicate that with 5 mg packing material of Cleanert PEP with a format of 96-well plate β blockers in human plasma can be extracted effectively and eluted with a small volume of the eluant.

Abstract Text

A low-cost, compact single-quadrupole mass spectrometer was evaluated for pharmaceutical analysis in supporting method development of stability indicating assays and cleaning verification testing. The advantages found were: easy to use and maintain, sensitive, and excellent software integration of UV and MS data in Acquity UHPLC Empower systems with automated annotation and reporting functions. Some of limitations found were: not very “portable”, electrospray ionization only, no adjustment needed or possible, and “not yet integrated with other vendors’ HPLCs”. The poster will include a description of the system, schematics and an Empower instrumental method. Case studies shown will include 1. a stability-indicating assay with a peak table containing UV and MS data plus system suitability values for each peak; 2. A generic cleaning verification method of 12 new chemical entities with automated annotations of UV and MS spectra indexed to each peak and performance data of the UV and MS channels.

Abstract Text

Little cigars (LC) are one of several tobacco products not currently regulated under the authority given by the Family Smoking Prevention and Tobacco Control Act signed in 2009. With the exception of being wrapped in paper derived from tobacco, they physically resemble cigarettes (e.g., size and shape). There is little information available on LC so a study was conducted to compare similarities and differences within the tobacco filler and resulting smoke chemistries. Smoke collected from 15 brands of LC—using the ISO regime (35 mL puff volume; 2 sec puff duration; 60 sec puff interval) and Canadian Intense (CI) regime (55 mL puff volume; 2 sec puff duration; 30 sec puff interval)—was analyzed for “tar”, nicotine, and carbon monoxide (TNCO) deliveries using gravimetric, gas chromatography-flame ionization detection (GC-FID), GC-thermal conductivity detection (GC-TCD), and non-dispersive infrared (NDIR) analyses, respectively. Although a CORESTA recommended method exists for TNCO measurements in cigar smoke, the ISO and CI smoking regimes were used in order to compare LC smoke data to traditional TNCO smoke data from some of the top, select U.S. cigarette brands. Among the brands tested nicotine levels between LC and cigarettes were comparable under ISO and CI smoking regimens; however, tar deliveries for LC were generally higher (ISO: LC 18.5±5 mg; CI: LC 46.5±4.8 mg; ISO: cigarettes 12.2±4.7 mg; CI: cigarettes 32±4.6 mg tar).

The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Abstract Text

The Cannabis plant has been known for centuries for the medicinal properties of its extracts and the medical benefits. Using Centrifugal Partitioning Chromatography (FCPC by Kromaton), an interesting approach has been developed to obtain pure fractions of Cannabinoids. The process was optimized for methanol extracts containing a mixture of Tetrahydrocannabinol (THC), Cannabidiol (CBD), and Cannabigerol (CBG) and respective isomers. Due to the selective partitioning nature and discrete stagewise operation of the FCPC device, pure fractions of the constituents with very similar molecular structures can be obtained in semi-preparative, preparative, and production quantities.

Abstract Text

With the continued importance of biotherapeutic proteins, comprehensive characterization is a prerequisite. It is of paramount importance for the production process to be highly consistent and robust, and that any change in process related impurities that could impact clinical outcomes and immunogenicity are avoided. Characterization of monoclonal antibody (mAb) primary structure using reversed-phase liquid chromatography is a key activity in bio-pharma discovery, development and QA/QC. Comprehensive characterization requires the analysis of intact, heavy and light chains, and Fc and Fab regions of the antibody using liquid chromatography often coupled with high resolution mass spectrometry. Increases in the speed and resolution offered by the HPLC columns used in these separations facilitate improvements in the quality of characterization data.

The speed and resolution of HPLC analyses can be improved through the use of HPLC columns packed with superficially porous particles (SPP). Compared to similarly sized totally porous particles, SPP columns offer improved efficiency and performance. This is primarily due to a shorter mass transfer distance and substantially narrower particle size distribution. The majority of existing SPP columns range in pore size from 90A to 120A. More recently, however, wide pore SPP columns have been made available with pore sizes >300A. These wide pore SPP columns are ideally suited to analyze large biomolecules, such as mAbs.

This report will show the advantages that optimized particle morphology and bonding chemistry used in reversed-phase HPLC columns can bring to challenging mAb separations.

Abstract Text

Glycosylation is a dynamic biologically active post-translational modification which is a critically important and elaborately complex post-translational modification that requires control, monitoring and understanding during all phases of glycoprotein drug development, processing and manufacture. The structural profile of both N linked glycan must be elucidated completely during the development of new biological pharmaceutical products and throughout the development of Biosimilars or Biological follow-on products.

Utilizing novel glycan sample preparation methods and detection by fluorescence and mass spectrometry, we present a total workflow solution for the analysis of human IgG N-linked glycans. Specifically, this work is based on novel HILIC (amide-based) columns which enable high resolution and significantly reduced glycan elution times compared to currently available HPLC technologies. HILIC separations using both sub 2 μ m fully porous and 2.7 μ m superficially porous columns were used to demonstrate UHPLC and HPLC high-throughput solutions for the rapid analysis of glycosylated proteins.

Abstract Text

When running impurity profile analysis, dynamic range of the detector is one of the most important parameter. Current norms in the pharmaceutical industry require at least 3 orders of magnitude in order being able to quantify 0.1% impurities. Running low dynamic range detector analysis often requires a multi injection sequence with external calibration, since it is impossible to get a single injection chromatogram with a non-saturated major peak, and minor peaks simultaneously. ELSD is a nearly universal technique that should be considered as an advantageous alternative for UV detection in impurity profiling, since response factor is generally tighter than with UV detectors, providing a more accurate picture of impurity profile. However, in some cases, ELSD does not provide enough dynamic range to assess impurity profile within one chromatogram. A new generation ELSD equipped with a patented feature (SAGATM, automated adjustment of the dynamic range) is shown to provide an efficient way to override this limitation, providing more than 4 orders of magnitude of dynamic range in a single setting, allowing the impurity profiling within one injection. This new ELSD feature can also be used advantageously in purification techniques, where higher dynamic range allows better monitoring of the purification process, avoiding saturation of the detector without compromising sensitivity of minor impurities.

Abstract Text

Sutherlandia frutescens commonly known as cancer bush is widely distributed throughout southern Africa and is used as a traditional medicine for the treatment of a wide variety of ailments. *S. frutescens* produces a range of well-known secondary metabolites with biological activity. Although several compounds with medicinal properties have been isolated from extracts of the plant, no reports exist concerning the effect of contaminated soils on the production of such metabolites. In this study *S. frutescens* specimens were collected from acid rock mine dumps and the possible alteration in the profile of secondary metabolites due to oxidative stress was evaluated by determination of total phenolic compounds, quantification of flavonoids using HPLC, metabolomic profiling using LC-MS and bioactivity of *S. frutescens* extracts. The antioxidant activity of extracts obtained from plants growing in acid rock mine dumps was significantly higher than the activity of extracts from control plants. This could be attributed to the high levels of total soluble phenolic compounds, kaempferol and quercetin produced by specimens collected from the mine sites. Kaempferol and quercetin are flavonoids with well-known antioxidant activity. Four flavanol glycosides (Sutherlandin A, B, C and D) and the tritepernoid Sutherlandioside B (SU1) were identified using UV spectra and confirmed using TOF-MS. Sutherlandins and Sutherlandiosides are biomarkers of *S. frutescens* used for quality control. The theoretical masses of Sutherlandins A-D (740.1800, 740.1800, 724.1851 and 724.1851) corresponds to the ions detected using ESI: m/z 739.1720 [M-H]⁻; m/z 739.1729 [M-H]⁻; m/z 723.1793 [M-H]⁻ and m/z 723.1783 [M-H]⁻. The fragmentation pattern is similar to that reported previously for natural populations of *S. frutescens*. The SU1 is reported to have anticancer activity and the theoretical mass of SU1 (652.4186) reported in literature corresponds to the mass obtained in this study (651.9348).

Abstract Text

Retention time precision is extremely important in being able to accurately compare results. Traditionally, retention time precision was always attributed to flow characteristics, such as fluctuation in flow rate and gradient imprecision, in an LC system. However, with UHPLC a point has now been reached where other factors, such as pressure and speed, play major roles. Internal friction results in viscous heating and this can cause non-uniform temperature profiles. At injection the sample is pressurized from one bar to pressures above 1000 bar with the switch of a valve and peak widths can be so narrow that the data collection rate can become insufficient accurately profile the peak. Finally, there are issues with gradient formation at pressures above a 1000 bar. In this work, we will look at all the aspects of a UHPLC system and discuss how chosen parameters can influence retention time. We will show that more factors are important than just pump flow and gradient stability, and that it is possible to generate very accurate retention time precision at the top of the UHPLC operating range.

Abstract Text

Accurate and reproducible analytical methods are a critical component of successful drug product development. In parallel to formulation and process optimization, analytical method optimization is conducted to ensure the key critical quality attributes (CQAs) are characterized appropriately. It is critical that optimized methods are in place by the time of process scale-up and Formal Stability Studies (FSS) in order to be sure product decisions are based on high quality data. Quality by Design (QbD) and DOE (Design of Experiment) approaches can be applied during method development to facilitate an understanding of both effects and variation within multiple experimental factors as well as to characterize the overall precision and robustness of the methods.

In this example, the suitability of the assay/degrade method has been evaluated for an active pharmaceutical ingredient (API 1) currently in formulation development as a fixed dose combination (FDC). An HPLC method was initially developed using a one-factor-at-a-time (OFAT) approach, where each variable was changed sequentially until suitable methods were identified. To increase the understanding of method capabilities and robustness, a QbD approach using statistical DOE was employed. Robustness testing was conducted to identify each method's "design space," or experimental region in which changes to method parameters will not significantly affect the quality and results of the method. This was done by introducing variations in method parameters and evaluating the impact on method output. Overall method variability, reported as Gauge R&R, was determined by evaluating the sensitivity of key method attributes to variables such as HPLC system, column, standard preparation, and analyst in order to quantify the final method capability.

Abstract Text

Increased efficiency in HPLC columns with fully porous particles (FPPs) can be achieved by using smaller particle size at the cost of an increased back pressure. In comparison, superficially porous particle (SPP) contains a thin porous outer shell with a solid core and provides extraordinary efficiencies. A 2.7- μm SPP provides efficiency of a sub 2- μm FPP but retains the backpressure of a 3- μm FPP. SPPs also has a very small particle size distribution which results in higher packing density and a more uniform bed, providing overall increased efficiency. In this work, chiral stationary phases (CSPs) based on derivatized cyclic oligosaccharides and macrocyclic glycopeptides are bonded to SPPs to provide unmatched efficiency. The chromatographic performance of a CSP bonded to a 2.7- μm SPPs is compared to columns packed with 5- μm and 3- μm FPPs. The difference in selectivity and resolution of analytes at constant elution strength and constant retention are compared for these columns. Greatly reduced analysis time and significant saving in mobile phase when using SPPs are discussed.

Abstract Text

Mechanism of chiral separation on liquid chromatography is very complicated, and the separation is made by complex combination of various interactions, such as hydrophobic, hydrogen bonding, dipole-dipole, and $[\pi]-[\pi]$. This makes method development of chiral separation difficult. Therefore, the column screening is commonly recognized as the first stage of separation method development. The fast column screening is the key driver for the rapid establishment of separation method.

Recently, we developed chiral stationary phases consisting of polysaccharides derivatives immobilized on 3 $[\mu\text{m}]$ silica gel particle. The new material is ideal for the fast method screening due to the high column efficiency across a wide range of flow rate. Moreover, it shows separation selectivity identical to conventional materials in 5, 10, and 20 $[\mu\text{m}]$ particle sizes. This feature enables predictable method transfer from ultrafast separation method to conventional method using 5 $[\mu\text{m}]$ material, and even to preparative method.

In this poster, we will present an ultrafast method screening of chiral separation utilizing the 3 $[\mu\text{m}]$ chiral separation column through some applications. We will also show the possibility of further reduction of method screening period by a combination of the column and supercritical fluid chromatography (SFC).

Abstract Text

The role of chiral separation is becoming more and more important especially in pharmaceutical industry, and the demand for isolating an enantiomer with high purity is increasing. However, there are two hurdles to be overcome; difficulty in method development and cost effectiveness of purification.

We have recently developed various chiral stationary phases coated/immobilized with polysaccharide derivatives. The coated phases give great resolution and the immobilized phases offer wide range of solvent compatibility. These phases greatly contribute to reduction of method screening period by combining column screening and mobile phase screening.

The separation method developed at analytical scale can be easily and linearly scaled up to purification from milligrams to kilograms process by using preparative scale column and LC-Forte/R preparation LC system. In addition, the efficacy of purification is improved by applying recycling preparative method of LC-Forte/R. This recycling method is also applicable to cases where ideal resolution is not achieved at method screening stage.

In this poster, we will show an example of method development including column and solvent screening at analytical scale, and then method transferring to purification scale. We will also estimate the purification efficacy of recycling LC method.

Abstract Title **Utilizing Alternative Selectivity Provided by the Novel High-Coverage C18 Phase based on Robust Hybrid Particles High-Coverage C18 Phase for UHPLC/HPLC Method Development**

Primary Author Takashi Sato
YMC Co., Ltd

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Ernest J. Sobkow, Noriko Shoji, Takatomo Takai

Abstract Text

More than 90% of reversed-phase UHPLC/HPLC analyses have been considered to be feasible using C18 phases. Recently, use of inorganic/organic hybrid particle based C18 phases is increasing due to their high efficiency and good chemical stability/long lifetime, and, so far, a number of hybrid particle based C18 phases have been marketed by various vendors. However, most of those phases have been developed based on a strategy of making a "Standard C18" that has moderate hydrophobicity and hydrophilicity. This sometimes impeded the flexible method development.

In order to enable a wide variety of method development using C18 phase, we developed a new high coverage and fully-encapped C18 phase based on robust hybrid particle. This phase offers complementing selectivity to standard C18 phases, rendering it efficacious in separating hydrophobic drug substance from structurally similar impurities. Also, its chemical durability, especially under neutral/alkaline conditions, enables the rapid optimization of mobile phase conditions without limitation of the usable pH range.

In this poster, we introduce differential characteristics between this new C18 phase and our standard hybrid based C18, Triart C18. We also show some examples of the efficient method development utilizing these high-coverage and standard C18 phases.

Abstract Title **Ultra-High Speed Analysis of USP Methods Conforming to the New USP General Chapter 621 Allowed Limits**

Primary Author Kenichiro Tanaka
Shimadzu Scientific Instruments, Inc.

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) William Hedgepeth

Abstract Text

The United States Pharmacopeia (USP) defines allowed adjustments of HPLC and GC parameters in the general chapter <621> chromatography. If the system suitability is met, method parameters can be changed within the allowed limits without revalidation. The general chapter 621 was revised in the first supplement to USP37-NF32 published on February 1st 2014 and became official August 1st 2014. The feature of the new general chapter 621 is that a column packed with small particles can be used as long as column length and particle ratio (L/dp) are kept constant between the designated and modified column. This enables the high speed analysis of USP methods more than ever. In this poster, an adjustment of a USP method for speed will be shown. The USP designates the use of a 4.6 × 150 mm, 5 μm, L1 (ODS) column and a 0.8 mL/min flow rate for the impurity analysis of sulfacetamide. If a 2.0 × 50 mm, 1.6 μm, L1 column is used, L/dp is kept constant, so there is no need to revalidate the method. The new flow rate after method transfer is calculated to 0.47 mL/min according to an equation in the general chapter 621. This high speed method was run on a Nexera X2 UHPLC system. As a result, analysis time and solvent consumption were reduced to 1/10 and 1/15, respectively, with the system suitability requirements met. Additionally, running a USP method on the Nexera X2 UHPLC system will be shown. The assay for timolol maleate ophthalmic solution was run on the Nexera X2 system without changing method parameters. The system suitability requirements were easily met on the UHPLC system similar to a standard HPLC system. This result means that this system is also suitable for those who are running traditional USP methods on a standard HPLC system and are considering the adoption of a UHPLC system for high speed analysis of USP methods in the future.

Abstract Text

The oligosaccharide component of glycoproteins is a key determinant of their function. Changes in the number, type, composition or linkage pattern of these glycans may serve as a biomarker of disease or influence the efficacy of a biotherapeutic product. For this reason, the ability to correctly identify and measure these glycans is of scientific interest, and to do so reliably, quickly and inexpensively is of practical benefit. This work explores direct detection of native glycans as an alternative to the common techniques for glycan analysis that rely on derivatization reactions to render glycans detectable. The lack of a detectable chromophore in native glycans is overcome by using HPLC with charged aerosol detection, a detector that can quantitatively measure any non-volatile compound.

N-linked glycans were released from proteins by PNGase-F. The native glycans were separated by ultra high performance liquid chromatography (UHPLC) on a column that employs both weak anion exchange and reversed-phase separation mechanisms, thus resolving glycans based on charge, isomerism and size. This unique selectivity resolves difficult to separate isoforms that are not resolved by conventional column types. The native glycans were detected directly without derivatization by using charged aerosol detection. Glycans released from various proteins were analyzed including those from bovine fetuin and monoclonal antibodies. Quantitative performance including precision, detection limits and dynamic range is presented. Typical figures of merit include sensitivity at the low-nanogram on-column level, dynamic range over two orders of magnitude, and peak area precision typically less than two percent RSD. By responding directly to any non-volatile compound, charged aerosol detection is able to measure directly native unlabeled glycans, yielding simple, accurate and precise estimates of relative concentration even in the absence of pure primary standards.

Primary Author Jonathan R. Damsel
Cleveland State University

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) John F. Turner

Abstract Text

Spectral imaging offers many advantages over more invasive, destructive analytical techniques and yields maps of chemical composition as well as differences in the physical characteristics of the sample, depending on the spectral modality employed. To date, narrow-band methods like Brillouin inelastic scattering spectroscopy have not been adapted for turn-key line-scan or wide-field imaging applications due, in part, to the lack of suitable wavelength filters. The Brillouin modality results from the interaction of incident photons with the acoustic phonons of the sample and Brillouin imaging would be useful for optically mapping the elastic properties of the sample nondestructively. The challenge is developing suitably narrow-band image filters. Recently the Brillouin spectrum has been resolved using a virtually imaged phased array (VIPA), which can be thought of as a modified side entrance Fabry-Perot etalon employing a range of incident angles. In the work presented here, we have developed and characterized several narrow-band VIPAs. A fully generalized dispersion equation has been developed which relates the input optical field to the VIPA response for both isotropic and anisotropic dielectrics. Hence, the dispersion relation is well suited for designing tunable VIPA elements that would enable high spectral resolution in a fixed image plane. In addition to the full theoretical description, validation studies as well as the design of a Brillouin imaging system are presented.

Abstract Text

Surface enhanced Raman spectroscopy (SERS) can greatly enhance the signal from the Raman-active molecules that have been adsorbed onto specially prepared metal surfaces. The selectivity and the high sensitivity of SERS make it a superior method to Raman spectroscopy. The advantage of SERS technique is that it greatly enhances the signal from the Raman-active molecules, which have been adsorbed onto specially prepared metal surfaces. Normally the factor by which the signal is enhanced is 10^4 - 10^6 . In certain cases it may be as high as 10^{14} . Raman Spectroscopy is surface selective and its sensitivity is very low. Nanostructures based on gold and silver are widely used for analytic adsorption in SERS method. In this study, we will discuss the comparative SERS analysis of meta-anilines, ortho-anilines, and para-anilines using silver colloids. The roles of aniline substituents including halogens, nitro, methoxy, methyl, isopropyl, and tert-butyl groups are elucidated by SERS analysis with an excitation wavelength of 785 nm. The SERS enhancement factors and detection limits for aniline and its mono- and di-substituted aniline derivatives are determined and compared. Both the steric requirements of chemisorption and the inductive effects of electron-withdrawal due to the substituent groups affect the signal intensities. The colloidal nanoparticles were also deposited onto copper surface for surface-enhanced infrared analysis (SEIRA) of the aniline derivatives. The characteristics of their adsorption onto metal surfaces and enhancement factors of SERS and SEIRA are discussed in terms of the computational modeling of the aniline structures. The potential for using SERS and SEIRA for environmental monitoring of the aniline derivatives will be presented.

Abstract Text

Cavity Ring Down Spectroscopy(CW-CRDS) is a technique in which the rate of absorption is measured. Because of its many advantages, it has given possible potentials as a reference instrument with calibration-free. In order to use reference standard instrument, interference from other gas components should be precisely tested. Many commercial instruments have been widely used in the determination of trace gas components in recent years. Nevertheless, their internal correcting procedures of interference have been remained as company confidential. So, it is difficult to study commercial instruments for reference standard instrument.

In order to study and apply CRDS to reference standard instrument, we have constructed a CRDS system of methane with precisely controlled temperature and pressure module. In this presentation, we explained the constructed system and preliminary results. Experimental setup of constructed CW-CRDS are shown in attached Fig. For the determination methane, DFB laser diode(NTT electronics Inc., wavelength, 1650 nm, 15 mW) was used. Optical switch(Agiltron, model, 300 ns nano-speed) with circulator(Flyin Optronics Co.) were also used to switch off the amplified cavity signal and prevent reflected light. And mirrors(CRD Optics, 99.95%) in gas sampling cavity of 30 cm were used and PZT(PI, length, 13 mm) was attached to the exit mirror. InGaAs photo-receiver(Newport, 125 MHz) was assisted as a detector. In order to maintain stable temperature and pressure, precise feedback system of flow, temperature and pressure was constructed and sample cavity was placed in the system.

As a preliminary result, it was observed that the temperature and pressure were controlled with in 0.1 C and 0.2 mtorr. Transient CRDS signal was also observed as shown in attached Fig. And about 2 % difference of methane signal was observed between reference 2 ppm methane in dry air matrix and air matrix with 50 % RH.

Abstract Text

Infrared spectroscopy has traditionally been a preferred method for analyzing fuels and lubricants. We will describe a novel liquid sampling device for the analysis of viscous materials that is both fast and accurate and can be applied to many of the ASTM methods developed for analyzing biofuel content, oil additives and conditioning monitoring. The basis of this instrument is a high precision, variable pathlength transmission accessory that can be automatically optimized for an application or even for different components in a single sample. We will present the application of this technique in several areas and discuss the advantages of this approach to the analysis of viscous liquids that are difficult to measure in sealed liquid cells.

Abstract Text

The self-assembly of octapeptides derived from human islet polypeptide (hIAPP)22-29 and its two fluorinated derivatives were monitored by vibrational spectroscopy (Raman and IR). These octapeptides (NFGAILSS) which differs only on the absence and presence of fluorine in the aromatic group (phenylalanine) aggregated immediately upon dissolution in aqueous samples. Results from Raman and IR (second derivative) spectra of solid samples showed common peaks among the three octapeptides such as the amide band found around 1675 cm^{-1} . This is due to the common backbone structure possessed by samples before and after self-assembly. In addition, peak differences can also be observed among the three samples which is due to the presence and absence of fluorine.

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Mustafa Culha

Abstract Text

The development of three dimensional (3D) tissue cultures has been gained big attention by the pharmaceutical companies for drug discovery studies. The 3D cultures are able to accelerate the researches during drug discovery process by creating a greater similarity between the cultured cells and the living organism, and providing a continuously available in vitro disease models leading to more useful data and relevant research on differentiation, drug metabolism, gene and protein expression, general cell function, morphology, proliferation, response to stimuli and cell viability. To obtain molecular information about the cellular responses upon drug exposure, the molecular techniques including immunoblotting, fluorescence labeling based on detection of the caspases, LC3 and p62 protein levels, phosphatidylserin and DNA labeling, and DNA fragmentation are routinely employed. However, these techniques are destructive, high cost and limit the monitoring of long-term effect of drugs on the same sample. The aim of the study is to develop a rapid, cost effective noninvasive, nondestructive, and label-free cell death monitoring technique in 3D tissue cultures for in situ detection of cell death by Raman and surface enhanced Raman spectroscopy. The spheroid cell model was used as a model 3D culture in this study. The spectral changes from intrinsic "finger-print" spectra of anti-cancer drug treated cells showed that this study will provide a new area for monitoring of the cell death in a rapid and cost effective way compared to molecular based techniques.

Abstract Text

The analysis of gases using Raman spectroscopy is difficult because of the low gas density. In previous work we demonstrated 10-20 fold enhanced Raman signals for gas measurements using a silver-coated multipass capillary cell (MCC). The MCC provides enhanced Raman signals by increasing the interaction volume between the laser and the gas inside the cell. The advantages of the MCC are easy alignment and simple construction. In more recent work fiber-optic probes are being used to couple a spatial heterodyne Raman spectrometer (SHRS) to the MCC. The use of a fiber-optic probe makes optical alignment between the MCC and the spectrometer much easier while allowing better light collection. The large acceptance angle, wide field of view of the SHRS, and the absence of a slit allows large optical fibers to be used without loss of light. This in turn allows larger MCCs to be used which should provide improved overall sensitivity. In this paper new types of fiber-optic Raman probes, designed specifically for coupling to an MCC will be described and the performance evaluated. Also, the ability of the SHRS to efficiently collect Raman scattered light from large diameter MCCs will be discussed.

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Ivan Stangel

Abstract Text

The irradiation of dental caries (“tooth decay”) by focused microwave energy (FME) may constitute a novel approach to their non-invasive management. We hypothesize that killing the caries-causing bacteria with FME promotes a local pH shift that is conducive to spontaneous remineralization of lesions. The objective of the present work was to test the hypothesis that microwave irradiated caries preferentially remineralize compared to controls. To test the hypothesis, artificial caries were induced in tooth fragments, which were subsequently exposed to FME. The FME samples and their controls were then exposed to remineralizing solutions. The degree of remineralization of the samples as well as their surface chemistry was determined using FT-Raman spectroscopy, a technique that provides insight into both the surface structure in general, and the distribution and concentration of calcium phosphate species. Given its ease of use and non-destructive nature, FT-Raman compares well to alternate methods of mineralization determination, such as scanning electron microscopy, hardness testing or 3-D imaging. Since remineralization is heterogeneous, the automated spectral collection facility of the FT-Raman instrument was used to obtain detailed surface mapping that provided insight into the distribution of phosphate species. The results of the FT-Raman interrogation showed significant variation in organic and mineral phase concentration, and that FME exposed samples had preferentially remineralized. We concluded that FME of caries may provide an alternate method of treatment, and that FT-Raman mapping provides an easy method for rapidly processing samples for the evaluation of mineralization.

Abstract Title **FTIR Method Validation for Moisture Analysis in Arsine Cylinders**

Primary Author Andrew Fleming
Matheson Tri-Gas

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s)

Abstract Text

Arsine is a key gas used in many semiconductor process systems, and it is essential for manufacturing, and analytical, procedures to meet tight specifications for this product. It is necessary to be able to produce and analyze arsine which has low parts per billion (ppb) levels of moisture contamination to meet the demands of customers. Fourier Transformed Infrared Spectroscopy (FTIR) is capable of consistently providing accurate moisture data down to the low ppb range, and additionally provides real-time data that allows changes over time to be closely observed. This makes FTIR dynamic enough to monitor effects of environmental changes, such as temperature, for finite vessels, as well as introduction of upstream moisture contamination for continuous flows. An MKS FTIR analyzer was used to develop a moisture analysis method for analyzing pure arsine for trace levels of moisture. The method was developed and tested under controlled laboratory conditions at a Matheson Tri-Gas Inc. facility. A certified dry pure arsine vessel was diluted downstream with doped gas of a known moisture concentration. A calibrated moisture generator using a NIST traceable moisture standard was used to dope the dry arsine flow at different concentrations levels ranging from above to below accepted product tolerances. The experiment tested the predetermined parameters of: linearity, repeatability, accuracy, and minimum detection limit (MDL). This study will demonstrate the successful analysis of trace moisture in Arsine and will meet our criteria for success for a measurement capability assessment of this method. The FTIR was able to achieve a 16ppb MDL, an R2 value of 0.9993 for linearity, the relative standard deviation was 1.33% in the repeatability test, and the overall accuracy was greater than 95% (error $\leq\pm 5\%$) for the measurement of trace moisture in arsine.

Abstract Text

Cotton fiber consists of natural cellulose I component and its end-use qualities depend on the amount of cellulose deposited during the growth. The term fiber maturity has been used to describe the degree of cellulosic development or the secondary cell wall thickening of fibers. Useful information about fiber maturity is of value to cotton breeders and growers for cotton enhancement and to textile processors for quality control. Undoubtedly, current-in-use cotton maturity measurements can meet the expectations from very differing fiber researchers. However, one of challenges is how to provide accurate maturity information on limited cotton fibers from breeders. To this point, FTIR technique, being structure sensitive and capable of microsampling, was examined as a potential to be applied in the rapid, non-destructive, and routine determination of cotton fiber maturity and crystallinity.

Abstract Title **Impact of Water Absorption on Molar Absorptivity Measurements of Solutes Dissolved in Aqueous Media over Near Infrared Wavelengths**

Primary Author Ariel Bohman
University of Iowa

Date: Monday, March 09, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Mark A. Arnold

Abstract Text

Accurate molar absorptivity values are critical for developing meaningful computer simulations of near infrared spectra. Such models are needed to provide insight into the selectivity, sensitivity, and limit of detection of $[i]$ in situ $[/i]$ near infrared spectroscopic measurements, particularly for complex samples of biological origin. Molar absorptivity measurements require knowledge of all mechanisms of radiant power loss during a transmission experiment. Besides attenuation by absorption processes, reflective losses at each interface (air/window and window/solution) must be considered. In one common approach, reflective losses are estimated using the Fresnel equations with knowledge of the refractive index for each medium in the optical path. For situations where the sample of interest does not significantly absorb radiation over the targeted wavelength range, reflective loss terms can be eliminated by using the difference between two transmission measurements at two different path lengths.

This research focuses on accurate molar absorptivity measurements for solutes dissolved in aqueous media over near infrared wavelengths. Accurate measures of solute molar absorptivity demand correction for reflective losses, the impact of solvent absorption on reflective losses and light attenuation due to solvent absorption. A general expression is derived that considers the effect of solvent absorption on molar absorptivity measurements for solutes dissolved in an absorbing solvent. Molar absorptivity values determined with this expression reveal relative errors as high as 90 % when solvent absorption is not considered. Magnitude of such errors depends on both path length and wavelength.

Abstract Text

In this lecture, we shall review our recent work towards the development of electrochemical imaging of biological cells and tissues.

First, we shall present the design and fabrication of soft electrode probes for scanning electrochemical microscopy (SECM), which include microchannels to afford the delivery of chemical effectors or the sampling of solutions in the area of interest. We shall show images of tyrosinase activity on different substrates, for instance for imaging black spots on a banana skin and more important for imaging cancer tissues. We shall also describe how we can perturb the local chemical environment and measure cells' response both electrochemically or optically.

In the second part, we shall present the working principle of electrostatic spray ionization (ESTASI), which is a contactless pulsed technique recently developed to generate ions from different substrates for mass spectrometry analysis or imaging (MSI). We shall present the coupling of separation techniques such as thin layer chromatography or gel electrophoresis with MS. We shall also present some results for ESTASI-MSI of cells.

Abstract Text

We report electrochemical measurements and simulations of the behavior of a thin-layer cell comprising either gold or platinum electrodes separated by 30 to 200 nm of supporting electrolyte. We demonstrate that the electrical fields extending from the electrodes modifies the transport of redox ions, giving rise to new current-voltage responses, and in some instances, completely blocking the redox reactions. The current-voltage response of these electrochemical cells are in semi-quantitative agreement with finite-element simulations based on a Stern-Gouy-Chapman model to account for the electric field extension from the electrode surfaces.

Abstract Text

Nanostructured surfaces can be designed with unique optical and physical properties for the fabrication of biosensors, metamaterials and magnetic materials. In this talk we demonstrate a simple low-cost, large-area fabrication method that employs a combination of colloidal lithography and nanoscale electrodeposition to make metallic, semiconductor and polymer nanoring arrays. This nanoscale electrodeposition strategy allows for the independent control of the nanoring diameter, thickness and spacing in the array. These metamaterial surfaces can be used to create simple yet sensitive plasmonic refractive index biosensors, optical materials including dichroic filters and split-nanoring resonators, and magnetic storage materials such as flux closure nanoring arrays. Additionally, related nanofabrication methods are used to make nanowire diffraction gratings and biomimetic nanocone arrays. For biosensor applications, these nanostructured surfaces can be combined with enzymatic and nanoparticle signal enhancement strategies to detect both protein and nucleic acid biomarkers at femtomolar concentrations.

Abstract Text

Due to the combination of the world's increasing energy demand and concerns of fossil-fuel combustion induced climate change, there is an imminent need to switch to carbon-free renewable energy sources such as solar. Solar irradiation is diurnal and intermittent, however, making it essential to store a large fraction of the converted energy. For these reasons photochemical water splitting to generate renewable hydrogen has attracted a lot of attention. Storage and transport of low-density hydrogen gas is problematic, however, making the conversion to higher energy density fuels attractive. One option is the storage of renewable hydrogen as ammonia since it has a relatively high energy density, is carbon-free, and can be potentially be decomposed back to nitrogen and hydrogen with less than 0.1 V (compared to over 1.23 V for water electrolysis) or used in a direct ammonia fuel cell. In practice, however, large overpotentials are required to drive the overall ammonia electrolysis reactions resulting in poor conversion efficiencies. We have therefore been investigating reducing the ammonia electrolysis overpotentials through homogeneous and heterogeneous catalysis. Results of electrocatalytic ammonia splitting in non-aqueous solvents as well as in liquid ammonia at metal and metal oxide surfaces will be discussed. In addition, initial results of the electrocatalytic reduction of N₂ will be presented.

Abstract Text

In this presentation I will discuss the development of a high-efficiency, dual channel-electrode (DCE) generation-collection system and its application for interrogating redox-active surface-adsorbed thin films. DCE systems consist of two electrodes configured on the base of a microfluidic channel. Under laminar flow conditions, a redox reaction can be driven on the upstream generator electrode, and the products carried by convection to the downstream collector electrode where the reverse redox reaction occurs. One significant outcome of our study is that simple fabrication techniques can be used to prepare DCE systems that have collection efficiencies of up to 97%. This level of efficiency makes it possible to quantitatively measure the charge associated with redox-active thin films interposed between the generator and collector electrodes. This is important, because it provides a means for interrogating species that are not in sufficiently close proximity to an electrode to enable direct electron transfer or electroactive films adsorbed to insulating surfaces. Here, the method is demonstrated by comparing results from this indirect surface interrogation method and direct electroreduction. These experimental results are further compared to finite-element simulations.

Abstract Text

The capability to separate and analyze a wide range of proteins in complex systems remains a prime requirement in the biochemical sciences. Protein separations are especially difficult as these large molecules can assume different conformations, association states and amphoteric features presented to chromatographic surfaces. Combining high performance liquid chromatography (HPLC) and ultra high performance liquid chromatography (UHPLC) with mass spectrometry (MS) has proved to be an effective approach for solving difficult problems involving protein analyses. Considerable effort has been made to develop columns for separating proteins with high efficiency for reversed-phase, ion-exchange, hydrophilic interaction liquid chromatography (HILIC) and hydrophobic interaction chromatography (HIC). Even so, many situations still exist where insufficient resolution is available for accurate protein analysis even when high-resolution MS is available. This presentation discusses new approaches for obtaining superior protein separations with columns of highly-efficient silica particles, new techniques in the use of MS-friendly mobile phases and effective methods for changing protein selectivity (band spacings) by column type and organic mobile phase modifiers.

Abstract Text

A number of manufacturers now offer a two-dimensional liquid chromatograph instrument. Some of these employ the comprehensive mode, whereby small volumes of a zone exiting the first dimension column are injected into the second dimension column after collection in a sample loop. This process is repeated throughout the separation. The usual case is that the first dimension column is run slowly to give the second dimension separation enough time to fully elute the zone(s) before the next sample is injected.

Another way to do this is to collect narrow fractions of zones and then run them on another column sequentially, perhaps overnight, and then reassemble the chromatographic information. This is referred to as the "offline" method.

Which method is the best use? In some cases this depends on what the goal is – does the analyst only need some zones from the first dimension and then selectively runs this area? Or does the zone crowding (i.e. saturation) dictate that a comprehensive experiment can't resolve the complexity, for example in a top-down proteomics experiment.

In this presentation we will use theory and experiment to generate guidelines on when the comprehensive experiment can't keep pace with high saturation samples and when the off-line collection must be performed. In addition, using mass spectrometry to resolve some of the high saturation will be discussed in terms of a compound statistical overlap theory of chromatography/mass spectrometry.

Abstract Text

Column selectivity is determined by various solute-stationary phase interactions. For the case of type-B alkylsilica columns, five such interactions contribute to column selectivity: hydrophobic, steric, ionic, plus hydrogen bonding to acidic or basic sites in the stationary phase. By means of the hydrophobic-subtraction model it is now possible to characterize any reversed-phase column in terms of five related column properties (H, S*, C, A and B). Apart from the case of column hydrogen-bond basicity (B), the remaining column properties H-A are well understood and can be described by specific column properties such as ligand length and density, pore diameter and end-capping. However, the nature of stationary phase sites for hydrogen bonding with acidic solutes is still in question. The present study will review what is known about column hydrogen-bond basicity, which in turn suggests that vicinal silanols are responsible.

Abstract Text

Supercritical fluid chromatography (SFC) was first demonstrated some fifty years ago but it has faced a number of highs and lows. Now that some manufacturers have taken it in their hands to produce high-quality robust machines, SFC is presenting a new face to analysts looking for fast, high efficiency, economical and ecological methods. Not only the machines have improved, but the way to practice the method has somewhat evolved with time. Packed columns, identical to those used in HPLC, are now preferred over GC-type capillary columns. This means that SFC has benefitted of the technical progress on silica particles (superficially porous particles and sub-2 μm particles) in the same manner as HPLC. But SFC has the additional advantage of a low viscosity mobile phase, resulting in very high efficiency even with low pressure drops. Also the composition of mobile phase is now considered in a more flexible manner than it used to be, with varied mixtures of carbon dioxide, co-solvents and additives. As a result, the polarity range of the compounds that are amenable to the technique has significantly extended. In this presentation, an overview of the current practice and possibilities offered by this versatile technique will be exposed, with many examples taken from varied application areas (pharma, cosmetics, food science, environment...).

Abstract Text

Many larger pharmaceutical companies have replaced or abandoned high performance liquid chromatography (HPLC) for chiral analysis and semi-preparative chromatography, replacing it with supercritical fluid chromatography (SFC). In the past, chiral analysis in drug discovery was the main application area for SFC, since it is much faster, cheaper to operate, produces much smaller fractions of all organic solvent, and is considered "green". With recent improvements in instrumentation, particularly lower UV noise, SFC is likely to expand into many other industries, particularly since it is orthogonal to rHPLC.

Surprisingly, most smaller pharma companies continue to use HPLC for these purposes. Similarly, a review of the content of the journal "Chirality" over a years time reveals almost no mention of SFC. A major reason for this difference is the lack of academic training in SFC. There are probably less than 2 dozen SFC's in academic labs around the world. There is a strong need for both fundamental and applied academic research in SFC.

Abstract Text

Sampling and ionization of analyte under ambient conditions are critical for modern mass spectrometry (MS) studies. The sampling size and ionization approach largely determine to which extent a specific MS method can be applied. Recent developments in bioanalytical MS areas, including single cell analysis and MS imaging (MSI) of biological tissues, greatly depend on the advancements in sampling and ionization methods. We are developing a miniaturized multifunctional device, the Single-probe, for multiple research aims.

To fabricate a Single-probe, a dual-bore quartz tube is pulled to a sharp needle (tip size $<10\ \mu\text{m}$), and one fused silica capillary (providing sampling solvent) and one nano-ESI emitter are glued into both bores of quartz needle. A small liquid junction ($<10\ \mu\text{m}$) is formed between two bores at the Single-probe tip for sampling small targets, and the sampled species is immediately ionized by nano-ESI emitter for MS analysis. The Single-probe has been coupled with a Thermo LTQ Orbitrap XL Mass Spectrometer for studies in two different research areas. (1) MS of living single cells. The tip of the Single-probe is small enough to be inserted into living individual cells, and the intracellular compounds are sampled and ionized for direct MS analysis in real-time. A variety of cancer cell lines and anti-cancer drugs have been involved in studies. We have detected cell metabolites, anti-cancer drugs, and cellular species induced by anti-cancer drug treatment. (2) MSI studies: This set-up can be used to sample compounds on surfaces; scan was performed by moving tissue position placed on a X,Y,Z stage system. We have obtained high spatial resolution ($<10\ \mu\text{m}$) under the ambient conditions using the Single-probe MSI device. We have applied our technique to biological tissues and reconstructed the spatial distributions of species of interest on plants or animal tissue slices.

Abstract Text

Lipids isomers with different C=C bond locations have dramatically different chemical, biophysical, and biochemical properties. Their relative ratios are important indicators for the variations in their biosynthesis pathways, which is highly relevant to the disease study and diagnosis. Our group recently showed that the locations of C=C within a lipid molecule can be determined in a sensitive and confident fashion by coupling Paternò–Büchi (P-B) reaction and subsequent tandem mass spectrometry (MS/MS). The P-B reaction proceeds via [2+2] addition between the UV (254 nm)-excited acetone and a C=C bond of a lipid, forming a product with mass 58 Da higher than the intact lipid. This P-B reaction product can be mass isolated and further subjected to collision-induced dissociation (CID). Collisional activation of the P-B reaction products produces diagnostic fragment ion pair mass separated by 26 Da, which are specific to the C=C bond location within a lipid acyl chain. The above method allows simultaneous characterization of multiple lipid C=C isomers from mixtures. More importantly, the relative intensities of the diagnostic ions can be used to quantify each isomer. The potential and scope of this method is demonstrated with lipid extracts from biological samples (tissues and blood) for simultaneous unsaturated lipid characterization and quantitation.

Abstract Text

Photodissociation of peptide ions is one of the fragmentation methods used to tease out peptide sequence and apply it to protein analysis.

Peptide ions absorb in the IR and far UV regions that have been extensively used for photodissociation and mass spectrometric analysis. In contrast, peptide ions do not have natural chromophores to absorb in the near UV region. We report two kinds of experiments that allow photodissociation of peptide ions in the near UV region at 355 nm.

Experiments of the first kind use artificial chromophores that are introduced into the peptide sequence in the form of photoleucine (L*) or photomethionine (M*) residues. These are L-2-amino-4,4-azido-pentanoic acid and L-2-amino-5,5-azidohexanoic acid residues containing the diazine ring which absorbs light at 350-370 nm and makes the peptide ions amenable to near UV photodissociation. L* and M* are introduced in the peptide sequence by standard solid-phase synthesis, or they can be incorporated into proteins by expression where they replace the natural L and M residues. The other kind of experiment does not require a photoactive label. It combines electron-transfer dissociation (ETD) with photodissociation, where ETD generates a new chromophore to be probed by photodissociation at 355 nm. Examples of both methods will be presented.

Abstract Text

There is evidence that epimerization, which occurs when a single amino acid converts to the D-configuration, is an important spontaneous post-translational modification (PTM) that occurs as a function of aging. Epimerization leads to no change in mass and it is significantly more difficult to detect than the other PTMs, which may explain why epimerization has received significantly less attention. Quantitative analysis of peptide epimers is typically carried out by calculation of an R value that corresponds to the degree of difference between the two fragments that change the most in the MS2 spectra obtained from each isomer. Recent work has demonstrated that radical directed dissociation (RDD) yields the highest R values for epimer detection and has the advantage of the greatest flexibility in terms of charge state selection.

In the present work, we describe characterization of isomeric PTMs in sheep crystallins extracted from the eye lens. The results from both RDD and CID on LC separated peptides were combined to improve isomer identification. A short exclusion time and a target peptide mass list were used to ensure that each peptide was examined multiple times to allow for comparison of the relevant tandem mass spectra. Three crystallin proteins (α -, β -, and β 3-crystallin) were identified from the ovine database with excellent sequence coverage. Several additional proteins that are predicted to be associated with crystallin are also identified from the newly released sheep genome. Many previously uncharacterized sites of isomerization for crystallins were identified. The results illustrate that the greatest degree of isomerization and epimerization occurs in the disordered N-terminal and C-terminal regions of α - and β -crystallin, which are abundant and important proteins in the lens that function as chaperones and also serve as structural elements.

Abstract Text

Native mass spectra of proteins and protein complexes often contain narrow charge-state distributions and wide peaks, which makes assigning charge states challenging and can limit the accuracy of native mass spectrometry experiments. These complications are exacerbated when samples contain mixtures of proteins or oligomeric states. Here we use Cation to Anion Proton Transfer Reactions (CAPTR) reactions to generate charge-reduced product ions. CAPTR is analogous to ion/ion proton transfer reactions pioneered by McLuckey and coworkers to aid in the analysis of peptides and other analytes (*J. Am. Chem. Soc.* **2013**, *135*, 947–965). Using CAPTR, we have detected the lowest charge state below m/z 100 000 for a series of protein complexes ranging from 12–468 kDa. Charge states are assigned unambiguously using the additional charge-reduced peaks, which enables accurate oligomeric state and mass assignments. Additionally, we demonstrate the ability to separate proteins in a mixture by reacting ions selected from a congested m/z region containing contributions from multiple protein complexes. Using this approach, we observed a >2000 fold increase in the resolution of two components from that mixture. The improved resolution of the CAPTR products is attributable to selecting precursor ions of similar m/z but different z ; thus, the resolution increases following each proton transfer reaction. Lastly, collision cross sections of several protein complexes were determined. These results show a reproducible, but subtle range of collision cross sections (–3% to +3%) for protein complexes as a function of charge state. Our results show that CAPTR is an efficient method to manipulate the charge states of native-like ions, which we use to accurately assign charge states, separate complex protein mixtures, and probe the relationship between charge state and protein structure.

Abstract Text

Intense research effort in low-temperature (or cold) atmospheric plasma application in bioengineering led to foundation of a new field, plasma medicine. Low temperature plasmas (LTP) produce chemically reactive species including reactive oxygen species (ROS) such as O, O₂⁻, and OH and reactive nitrogen species (RNS) such as NO and NO₂. These species are known to have biological effects on prokaryotic and eukaryotic cells, such as the peroxidation of lipids and proteins. In addition, they are known to trigger signaling pathways in biological cells.

Although LTP has been shown to be lethal to bacteria, under some conditions it appears to cause little damage to mammalian cells. Having different structure and morphology than prokaryotes, mammalian cells exhibit different responses to physical and chemical stresses. The ability of LTP to kill bacteria and to accelerate the proliferation of specific tissue cells opened up the possibility to use plasma for the healing of chronic wounds such as diabetic ulcers. Tens of thousands of amputations occur every year in the US alone because of the inability of present medical methods to heal chronic wounds.

The most recent research area of plasma medicine is the interaction of LTP with cancer cells. It has been demonstrated by several investigators that LTP can induce apoptosis (programmed cell death) in various cancer cell lines. In addition, LTP treatment affects preferentially the cell cycle of cancer cells. This opened up the possibility that LTP could be the basis of a new cancer therapy. So far both in vitro and in vivo experiments have been carried out with encouraging level of success, but no clinical trials have been attempted.

The above mentioned biomedical applications seem to usher a new transformational approach to healthcare based on LTP technology. In this presentation a review of the research achievements accomplished in the last decade will be presented.

Abstract Text

Over the past two decades, there has arisen increasing interest in liquid-electrode-supported glow discharges as alternative sources for atomic optical emission spectrometry (OES). Among these sources, the solution-cathode glow discharge (SCGD) has received substantial attention due the many advantages it offers over more conventional plasma sources for atomic spectrometry, such as the inductively coupled plasma (ICP). Simple and inexpensive to construct, the SCGD operates in the ambient atmosphere (requiring no compressed gases), samples directly from a flowing stream of sample solution (eliminating the need for a nebulizer), is driven by low, direct-current power (typically <70 W), yields surprisingly uncluttered emission spectra, and produces detection limits that are comparable to or better than those obtained with radially viewed ICP-OES.

Many past studies of the SCGD have revealed that elemental and molecular emission are not spatially homogenous throughout the source, but rather conform to specific zones within the discharge. Exploiting this inhomogeneity can lead to improved analytical performance if emission is collected only from the regions of the discharge where analyte species emit strongly and background emission (from continuum, elemental and/or molecular sources) is lower. Here we will present a comparative study of the effects of spatial selection on the analytical aspects of the SCGD, with emphasis on detection limits, precision and linear range. Use of spatial selection to reduce or eliminate matrix effects will also be evaluated.

Abstract Text

Plasma-based ambient desorption/ionization mass spectrometry (ADI-MS) has attracted considerable attention in many fields because of its capacity for direct sample analyses. We have developed a high-power pulsed microplasma jet as a plasma desorption/ionization source. In the plasma jet, a micro hollow cathode discharge is generated in a small hole (500 μm in diameter) using a pulsed high-power supply. This system can realize a maximum power density of $5 \times 10^8 \text{ W/cm}^3$. The measured electron number density and excitation temperature were $3.7 \times 10^{15} \text{ cm}^{-3}$ and 7,000 K, respectively. But the gas temperature was less than 60°C because it is a non-thermodynamic equilibrium plasma. And the plasma potential was made almost zero. Therefore, the plasma does not give thermal and electric discharge to the target. Thus, we can apply it directly to human skin such as shown in the figure. To demonstrate the analytical capacity of ambient desorption/ionization mass spectrometry, the plasma was applied to direct solid sample analysis of the active ingredients in pharmaceutical tablets. Caffeine, acetaminophen, ethenzamide, isopropylantipyrene and ibuprofen were successfully detected. Application to living tissue was also demonstrated, and isopropylantipyrene on a finger was successfully analyzed without damaging the skin. The limits of detection (LODs) for caffeine, isopropylantipyrene and ethenzamide were calculated, and LODs at the picogram level were achieved. We applied for organic mass spectrometry of Chemical Warfare Agents (CWA) for strengthen counter-terrorism for such as Tokyo Olympic 2020. To evaluate the analytical performance, VX of 1 μg on the Teflon plate was directly irradiated by air plasma and analyzed by using the mass spectrometer. As a result, the protonated VX was successfully detected with low fragmentation and LOD of VX was 0.13 pmol. The analytical results of other CWA such as GA will be presented.

Abstract Text

Glow discharge plasmas have a long-standing analytical history as large, stand-alone laboratory scale instruments. In contrast the physical scaling permits micro-plasma operation at atmospheric pressure while reducing power requirements, thereby permitting mobile analysis. The energetic species in a non-thermal, i.e. "cold" plasma dissociates species of interest and electronically excites the elemental constituents. The atomic emission spectrum serves to identify the compound and ideally its molecular composition with intensity corresponding to concentration. For some operational regimes and species, emission from OH*, CH* and often C2* diatomic radicals is also produced. Such emission further aids compound detection and identification. Detection and identification of acetone, ethanol, heptane, toluene, and nitrobenzene is demonstrated. Limits of detection extend to parts-per-billion levels for some species such as nitrobenzene. Results will be shown for differentiation of classes of organic compounds such as alkanes, aromatics and oxygenates. Application for C/H ratio measurements of soot and other carbonaceous materials will also be presented.

Abstract Text

The liquid sampling-atmospheric pressure glow discharge (LS-APGD) holds a unique position among the other atmospheric pressure glow discharges as it has demonstrated abilities in atomic emission, elemental mass spectrometry, molecular mass spectrometry, and ambient desorption mass spectrometry. These base capabilities are multiplied as the sample forms that are amenable to analysis include liquids, bulk solids, solution residues, and aerosols generated by laser ablation. This versatility is achieved on a very small platform, with minimal supporting utilities. Specifically, the plasma is ignited between an electrolytic solution that is introduced at flow rates of 10-200 microliters/min at discharge currents of <60 mA, and d.c. powers of <50 W. The counter electrode can take the form of a solid metal, or a hollow metal capillary, which allows the introduction of a counter flow of sheath gas or the entrainment of aerosol sample material. The discharge volume is set by the electrode gap, but is usually on the order of 1 cubic millimeter. As such, the power densities realized are greater than 10 W/cubic millimeter; a factor of 100-times greater than the ICP. In this presentation, we will describe the design and fundamental operational aspects of the LS-APGD as they pertain to the various spectroscopic sampling modes. The versatility of the source will be graphically demonstrated as the microplasma is converted between an elemental/isotopic ionization source, a source for direct speciation of organometallic compounds, and an ambient desorption MS source in a matter of minutes. It is believed that the LS-APGD microplasma holds a unique place among its peers and warrants investigation across many fields of chemical analysis.

Abstract Text

Novel nanofluidic platforms for the analysis of single DNA molecules will be discussed with applications including single-molecule electrophoresis and searching for sequence variations in double-stranded DNA such as methylation patterns or drug-induced abasic sites. The nano-scale channels are produced in thermoplastics using Nanoimprint lithography (NIL) from resin stamps and Si masters. The masters are made using a combination of conventional optical lithography (microchannels) and focused ion beam milling (nanochannels). Thermoplastics can serve as viable alternatives to glass and quartz for nanofluidic devices because of their diverse surface chemistry, optical transparency and the ability to be manufactured in a high production mode using NIL. NIL has proven to be successful in patterning structures to sub-10 nm dimensions with the ultimate resolution determined by the minimum feature size associated with the imprinting tool. In fact, we have made channels as small as 18 nm (width x depth) using NIL. In this presentation we will discuss the electrically driven transport dynamics of both small (deoxynucleotides monophosphates, dNMPs) and large (DNAs) molecules traveling through thermoplastic nanochannels. The effects of scale (i.e., cross-sectional area of polymer nanochannel), electrical double layer overlap producing non-plug-like flow profiles, surface chemistry, surface charge, nano-scale surface roughness and electroosmotic flow (EOF) will be discussed and the effects of these parameters on separation efficiency for nano-scale electrophoresis presented. Data will be also be shared on detecting the presence of DNA damage in genomic DNA by labeling the damaged (abasic) sites specifically with a fluorescent dye. Stretching the DNA in a nanochannel allows for direct reading of the location and frequency of these damaged sites to infer drug efficacy.

Abstract Text

Thin membranes are a compelling structural element for the fabrication of devices to deliver unique nanoscale sensing and manipulation capabilities. I will discuss two silicon nitride membrane-based devices: the first, a fluid cell with <100nm-high flow channel for transmission electron microscopy (TEM) studies of liquid samples, and the second, a nanopore-based electronic single-molecule manipulation and sensing platform.

TEM has proven to be a tremendously powerful tool for revealing the nanoscale structure of fixed samples, but the ability to directly probe native structures in solution and to probe solution structural dynamics has remained a compelling but challenging goal. We have developed a nanofluidic sample cell designed to unlock the full potential of TEM for the study of samples in solution. Key to the approach is the ability to confine and flow thin layers of liquid between thin, so-called electron-transparent windows. I will present high resolution TEM movies of nanoparticles in solution and discuss the implications of this imaging and fluidic handling capability.

Nanopores are nanometer-scale channels fabricated into thin membranes. When properly configured, they can be used for single-molecule-sensitive studies of intermolecular interactions by force spectroscopy, and for chemical sensing in solution by resistive pulse sensing. I will discuss methods to fabricate, characterize and enhance nanopores for such single-molecule studies. Particular emphasis will be placed on surface chemical modifications of silicon nitride membranes to control pore size, surface charges and surface functional group presentation.

Abstract Text

We use isotachophoresis (ITP) to achieve fast and specific analyses of molecular targets in complex mixtures. We use ITP to preconcentrate and purify; molecular recognition for specificity; and ITP to control and increase the rate of chemical reactions between molecular probes and target macromolecules. ITP is an electrophoresis technique that uses two buffers which include a high mobility leading electrolyte (LE) and a low mobility trailing electrolyte (TE). Sample species with mobilities bracketed by those of the LE and TE focus into the TE-to-LE interface. For trace sample concentrations, multiple species focus in so-called peak mode wherein multiple analytes mix and strongly overlap within an order 10 μm wide ionic concentration shock wave. This co-focusing mixes target species and preconcentrates them to accelerate reactions. We have integrated DNA and RNA extraction with sequence-specific quantitation using a variety of mobile and immobile cDNA probes. We preconcentrate target and probe molecules by $>10,000\times$ into select reaction volumes ranging from 1 to 100,000 pL. We achieve hybridization reactions which would normally take 4 days in 30 seconds. We have shown specific and sensitive detection of target sequences in order 5 minutes with little or no off-chip sample preparation, and without target amplification.

Abstract Text

Single pores in resistive-pulse technique have been successfully used for the detection of cells, viruses, particles, and even molecules such as DNA and proteins. We have investigated application of pores with undulating opening diameter for the detection of particles and characterization of their physical properties. The resistive pulses generated by polymer spheres passing through these pores had a repeatable pattern of large variations corresponding to these diameter changes. We showed that this pattern of variations enabled the unambiguous resolution of multiple particles simultaneously in the pore, that it could detect transient sticking of particles within the pore, and that it could confirm whether any individual particle completely translocated the pore. These results have practical importance for increasing the speed of resistive-pulse sensing, optimizing the detection of specific analytes, and identifying particle shapes. We also showed pores with undulating opening diameter developed local pressure drops, which were sufficiently large to probe mechanical properties of passing objects. Application to hydrogels as well as biological cells will be discussed.

Abstract Text

Virus assembly is a highly coordinated process in which hundreds of subunits react to form complex and symmetric particles. Single-particle methods that examine the mechanisms by which capsid reactions occur are lacking, and measurement of low-abundance intermediates on path to forming complete particles is particularly challenging. We are using resistive-pulse sensing as a label-free, nondestructive technique to characterize the assembly of Hepatitis B Virus Cp149 dimers into T = 3 and T = 4 symmetry capsids in 1 M NaCl. This single-particle method permits real-time detection of both capsid formation and intermediate depletion and has sufficient sensitivity to monitor assembly at dimer concentrations as low as 50 nM, well below the pseudo-critical dimer concentration. Assembly reactions below, near, and above the pseudo-critical dimer concentration reveal three distinct regimes of assembly. Below the pseudo-critical dimer concentration, where the early steps of assembly are rate- and product-limiting, the ratio of T = 3 to T = 4 capsids increases with decreasing dimer concentration. In contrast, far above the pseudo-critical dimer concentration, incomplete particles assemble rapidly, become kinetically trapped, and slowly anneal into T = 4 capsids. These single-particle measurements have provided new insights into assembly paths and energetics.

Abstract Text

The complexity of biological samples poses a major challenge for reliable compound identification in both NMR and mass spectrometry (MS), a problem that is of major concern in the field of metabolomics. The presence of interfering compounds that causes additional peaks to appear in the spectrum can make interpretation and assignment difficult. To address this issue, we have proposed a new approach we call RANSY[1], which extracts the ¹H signals related to the same metabolite based on peak intensity ratios. The RANSY algorithm calculates the ratio of the peaks in the NMR spectrum with a peak of interest called the "driver peak," and then divides that ratio by its standard deviation across the sample set. We have recently extended this approach to mass spectrometry as well (RAMSY)[2], which facilitates identification of unknown compounds in complex MS spectra. RAMSY works a very similar principle that, under a given set of experimental conditions, the abundance/intensity ratios between the mass fragments from the same metabolite are relatively constant. Therefore, the quotients of average peak ratios and their standard deviations, generated using a small set of MS spectra from the same ion chromatogram, efficiently allow the statistical recovery of the metabolite peaks and facilitate reliable identification. RAMSY has been applied to both GC-MS and LC-MS/MS data to demonstrate its utility. The performance of RAMSY is typically better than the results from correlation methods. RANSY and RAMSY promise to improve the process of unknown metabolite identification for NMR and MS users in metabolomics and/or other fields.

Abstract Text

We develop a novel peak detection algorithm for the analysis of comprehensive two-dimensional gas chromatography time-of-flight mass spectrometry (GC×GC-TOF MS) data using normal–exponential–Bernoulli (NEB) and mixture probability models. The algorithm first performs baseline correction and denoising simultaneously using the NEB model, which also defines peak regions. Peaks are then picked using a mixture of probability distribution to deal with the coeluting peaks. Peak merging is further carried out based on the mass spectral similarities among the peaks within the same peak group. The algorithm is evaluated using experimental data to study the effect of different cutoffs of the conditional Bayes factors and the effect of different mixture models including Poisson, truncated Gaussian, Gaussian, Gamma and exponentially modified Gaussian (EMG) distributions, and the optimal version is introduced using a trial-and-error approach. We then compare the new algorithm with two existing algorithms in terms of compound identification. Data analysis shows that the developed algorithm can detect the peaks with lower false discovery rates than the existing algorithms, and a less complicated peak picking model is a promising alternative to the more complicated and widely used EMG mixture models.

Abstract Text

The goal of large-scale metabolite profiling is to compare the relative concentrations of as many metabolites extracted from biological samples as possible, however, identifying the structures of the thousands of ions detected by QTOF and Orbitrap mass spectrometers is prohibitively time intensive. Here we describe a scheme for using QqQ mass spectrometers to perform large-scale metabolite profiling to facilitate high-throughput structural characterization. First, we identify common fragmentation products from METLIN's experimental MS/MS data. Then, we model the likelihoods of each precursor in METLIN producing each common fragmentation product. From these likelihood estimates, we pick ensembles of common fragmentation products that minimize our uncertainty about metabolite identities and can therefore be used to build MRMs for thousands of compounds from the METLIN database. We demonstrate the application of our approach by characterizing metabolic alterations associated with inflammation in astrocytes and oligodendrocytes.

Abstract Text

The stable isotope assisted metabolomics (SIAM) uses stable isotope tracers (e.g. 2H , 13C and/or 15N) to support studies of biochemical mechanisms. It is able to discern the originating pathways and effectively measure the levels of metabolites associated with a particular pathway, if multiple pathways result in the same product metabolite. We have developed a bioinformatics platform to process LC-MS and GC-MS experiment data acquired from SIAM projects. The developed bioinformatics platform includes capability of mass spectrum peak picking, deconvoluting overlapped isotopic peaks of isotopologues, metabolite assignment, cross sample alignment, normalization, metabolite quantification, and correlation network analysis. The metabolite assignment in the LC-MS data is achieved based on m/z value and the isotopic peak profile matching, which by mass spectrum matching and retention index filtering in analysis of GC-MS data.

SIAM follows the fate of the heavy atoms and their incorporation into a multitude of metabolites produced from the labeled tracer. This not only helps identify and quantify isotopologues, but it also can determine the position of the labeled atom in a molecule, leading to exact biochemical pathway assignment. Our developed bioinformatics platform has been validated using mixtures of compound standards, spiked-in experiments, and further applied to multiple biological experiments.

Abstract Text

The NIH West Coast Metabolomics Center at UC Davis employs accurate mass GC-QTOF MS and reverse phase as well as HILIC UPLC-QTOF MS platforms to screen for metabolic differences in blinded human cohort samples, for example in lung cancer or cardiovascular studies. Comprehensive analyses of these samples identifies over 150 primary metabolites and more than 300 individual complex lipids in lipidomic screens, in addition to specific metabolites such as S-adenosylmethionine, 1-methylnicotinamide, trimethylamine-N-oxide, carnitines, betaines or other polar cationic metabolites. While our focus is to reveal metabolic dysregulation that precedes or informs about human diseases, human cohort studies benefit from information that can further stratify or constrain groups of subjects and that could complement tools such as Food Frequency Questionnaires or co-medication information. Untargeted metabolomics with comprehensive mass spectral fragmentation analysis can yield such data. We give examples how the NIH West Coast Metabolomics Center found dozens of pharmaceutical agents in human lung tissue as well as in blood plasma of larger cohort studies. We highlight how the general metabolomics workflow helps detection and unambiguous identification of xenobiotics such as food components, pharmaceuticals as well as illicit drugs. We regard these results as significant validation towards the concept of comprehensive exposome analysis.

Abstract Text

Carbon materials have been used over the years in energy storage and conversion, chemical analysis and separations. The widespread interest in carbon stems from its low cost, mechanical strength, chemical stability in a variety of environments and diversity of surface chemistry. Nonetheless, advances in the fundamental understanding of the structure of electrified interfaces formed at various carbon materials and how this structure affects adsorption, charge-transfer kinetics and redox reaction mechanisms remain to be gained. This is particularly true for the novel sp^3 (diamond) and sp^2/sp^3 (tetrahedral amorphous carbon) electrodes. A more complete understanding of structure-property relationships will serve as the foundation for the next-generation of electrochemical sensors and detectors with these materials.

We are developing an improved understanding of structure-property relationships of boron-doped nanocrystalline diamond and nitrogen-incorporated tetrahedral amorphous carbon (ta-C:N) thin-film electrodes. ta-C:N is a composite material consisting of sp^2 and sp^3 -bonded carbon. Impurities can be incorporated during growth further adding to their complex structure. These films typically possess 40-60% sp^3 -bonded carbon. It has been widely used as a protective coating due to its hardness, high wear resistance and low coefficient of friction. The growth temperature for ta-C is usually from 25 to about 100 oC. This means that non-traditional materials, such as plastics, can be used as substrates for deposition. ta-C films generally need to be grown thin (100's of nanometers) in order to minimize internal stress. Stressed films tend to delaminate from a substrate. We will report on the characterization and basic electrochemical properties of these new electrode materials and highlight some electroanalytical uses (FIA-EC) such as for the detection of the drug, propranolol.

Abstract Text

There has been recent interest in exploring the use of various nanomaterials as adsorbent media for chromatography; among these are the carbon-based nanoparticles carbon dots (C-dots) and nanodiamonds (NDs). We have developed strategies to modify the surface of silica materials with such nanoparticles. Both, silica and monolithic structures have been used as support materials. Of particular interest have been the ND-modified silicas. Nanodiamonds having an oxidized or a hydrogenated surface were attached to silica. The degree of hydrogenation on the NDs can be controlled by manipulating experimental parameters. After physicochemical characterization, we explored the adsorptive characteristics of these materials using liquid chromatography (LC) and supercritical fluid chromatography (SFC). The initial findings suggest that non-hydrogenated ND-modified silica provided ion exchange sites as well as hydrophilic interactions while the hydrogenated ND-modified silica provided more hydrophobic interaction. In this occasion, we will present details of the NDs attachment to silica materials, characterization, as well as the findings of our chromatographic testing.

Abstract Text

Fluorescent carbon nanodots (FCNs) have recently received significant attention because of their attractive properties: chemical inertness, biocompatibility and low toxicity. They are considered as promising materials for bioimaging, photocatalysis, sensing, and photovoltaic applications. The confined sp²-carbon conjugation surrounded by chemical functional groups can produce bright, photostable, and tunable photoluminescence. While research has been actively conducted to promote brightness and modulate the optical properties of FCNs, the fundamental understanding of detailed emission mechanisms and structure-property-function relations is still incomplete. Our recent progress in controlling the structure and chemical functionalities of FCNs will be presented. For the optical characterization of carbon dots, single molecule and ensemble spectroscopies were successfully carried out to unveil complicated photophysics and multi-chromophoric nature of FCNs. The application of variously functionalized FCNs for the imaging of cancer cells and their biocompatibility will be also presented.

Abstract Text

A nanocarbon film electrode was used to measure some biomolecules. The film was formed by using the electron cyclotron resonance (ECR) sputtering method that provided a nanocrystalline sp^2 and sp^3 mixed bond structure with an atomically flat surface (surface roughness of 0.05-0.1 nm). This film electrode has excellent properties including a wide potential window, low background current and little surface fouling while maintaining relatively high electrode activity for various biomolecules. These characteristics allow the detection of biomolecules with higher oxidation potentials. For example, this nanocarbon film ($sp^2/(sp^2+sp^3)$ ratio=0.6) electrode can measure all the DNA bases (including the DNA base derivatives e.g., 5'-methylcytosine and 8'-hydroxy 2'-deoxyguanosine) more quantitatively than conventional carbon-based electrodes. Moreover, due to their good electrochemical stability, these sp^3 -containing carbon electrodes are suitable for long-term analysis including as the electrode of an HPLC detector for detecting various biological compounds. We also used the nanocarbon film electrode to detect some biomolecules with a low concentration such as lipopolysaccharide (LPS). The nanocarbon film electrode was modified with poly- ϵ -lysine (ϵ -PL) with a high affinity to LPS. LPS was captured on the modified electrode, and then ferrocene labeled polymyxin B (FcPMB) was captured on the LPS adsorbed electrode via the LPS-PMB affinity interaction. The adsorbed FcPMB provided an amplified response with Fe^{2+} ions, and the current response was dependent on the amount of captured LPS (LOD=2.0 ng/mL). This was due to the efficient accumulation of the obtained current for LPS and the very low noise made possible by the ultraflat surface. Here, we will present the basic properties of the sputtered nanocarbon film and its applications to the electrochemical detection of some biomolecules.

Abstract Text

New forms of carbon as electrodes have open new doors in protein electrochemistry. We have focused on the electrochemistry of insulin using carbon nanotubes as a biosensor, and on the photoelectrochemistry of photosystem I protein complexes, first on carbon nanotubes, but then moving to graphene and reduced graphene oxides.

Direct electrochemical detection of insulin provides sensitivity and rapid analysis times to enable continuous real-time measurements. While previous electrochemical sensors have been used to detect insulin, the limited stability and lifetimes of the electrode films leads to loss of insulin sensitivity. We present an insulin sensor for electrochemical detection in a microfluidic device based on direct oxidation at a MWCNT/Dihydropyran composite film. We have successfully adapted this sensor for the microfluidic chamber of the multianalyte microphysiometer and recorded the response of isolated murine islets to glucose stimulation, as well as nutrient stimulation. The increase in concentration of insulin detected for islets is much higher than the limit of detection and as high as 100 micromolar for the sensor because of the confined volume of the microfluidic chamber and the buildup of insulin molecules during a stop flow period.

Photosystem I (PSI) is one of the primary membrane protein complexes that drive photosynthesis. Our electrochemical interface with graphene electrodes incorporates photosystem I in applied photosynthetic systems. Recently, we developed a completely organic, transparent, conductive electrode using reduced graphene oxide (RGO) on which a multilayer of PSI could be deposited. The resulting photoactive electrode demonstrated current densities significantly higher than a graphene electrode modified with a monolayer film of PSI. We have created the first all carbon based photovoltaic by replacing ITO, semiconductors, and metals with graphene and reduced graphene oxides.

Abstract Text

[i]Painting a Fresco with Giotto #3[/i] (Indianapolis Museum of Art, #2009.466) by contemporary designer Fernando Brizio comprises a white vase pierced with Giotto-brand felt tip markers. The bleeding of the pen inks creates a playful polka dot surface of solid circles or concentric dye rings around each marker. The vase was newly acquired for a 3 venue exhibition, but returned to the museum badly faded, with some of the ink dots having nearly vanished. Conservation scientists were asked to explore the cause of the fading and to prepare future exhibition and handling guidelines based on the object's measured lightfastness.

In-situ microfading testing of the inks revealed that many of the colorants are still prone to rapid color loss. Communication with the manufacturer of the markers confirmed that they are student-grade and not intended to have high lightfastness, but rather to be safe and easily cleanable. The identification of the inks from the pens by Raman microspectroscopy proved challenging. Despite acquiring high quality data from the dried ink, only two dyes could be positively identified based on current spectral databases. Analysis of the inks from new Giotto markers was undertaken using HPLC-PDA-MS. This led to the identification of 8 of 9 dyes detected in the 30 different pens: Acid Violet 17, Brilliant Blue FCF, Acid Red 18, Acid Red 14, Acid Red 52, Food Sunset Yellow, tartrazine, and erythrosine. Genuine examples of these dyes were characterized by Raman spectroscopy, confirming that the dyes in the pens from the vase and the new pens contained the same colorants.

The artist was contacted regarding the fading issue, about which he was already aware. Future interviews will record Brizio's material choices, his thoughts on the status of the IMA piece and whether it still achieves his vision, and how he views the longevity of his work in general. This project highlights the urgency of characterizing the fading rate of potentially fugitive artworks.

Abstract Text

In the 1960s, the LA art scene blossomed, transforming the city into an international art capital. One of the first truly indigenous and original LA art current was the "LA Look". The term refers to loosely affiliated group of Los Angeles artists who used novel materials and processes, often borrowed from different industries, to create a body of work characterized by pristine surfaces, and bright, sensuous colors .

The Getty Conservation Institute has undertaken in recent years a major study into materials and technologies utilized throughout the 1960s and 1970s by artists such as Peter Alexander, Robert Irwin, Craig Kauffman, John McCracken, Helen Pashgian and De Wain Valentine. Because the typically pristine surfaces of the LA look objects often prohibit any sampling, an important part of the project has been the use of a portable ATR instrument with a curved ATR measuring head for rapid, non-invasive, in situ analysis. Although contact with the object is required with this instrumental set up, the force exerted during measurement is minimal and in most cases extremely high quality FTIR spectra were obtained without leaving any mark on these typically delicate surfaces. However, when possible – typically when pre-existing damages were present- sampling was performed and a more traditional array of analytical techniques used, from microscopic observations to Raman microscopy to identify synthetic organic pigments and py-GCMS to obtain detailed information on the chemistry of the organic media used by the artists.

This paper will present the findings of the project to date and detail the use that LA artists made of synthetic materials, in particular automotive paints and polyester and acrylic plastics. It will also briefly introduce the conservation challenges presented by these objects and how science can contribute to build a range of treatment options through ongoing research on adhesives and repair methods for translucent plastics.

Abstract Text

Surfactant migration to acrylic emulsion paint surfaces has been anecdotally and experimentally linked to a wide variety of surface phenomena and conservation challenges on these types of surfaces. Increased soiling, changes in gloss and color, blanching or 'bloom' are often cited as common surface aesthetic effects. But as well, mechanical effects such as changes in elastic modulus and T_g at paint surfaces that have accrued surfactant moieties are also of concern with these types of artist's media. Environmental conditions play a role in surfactant migration and segregation. There appears to be a clear relationship between both temperature and relative humidity (RH) in the ambient environment around acrylic paint films and the accumulation of surfactant at these surfaces. Surfactant hydration and de-hydration under varying temperature and RH conditions appears to affect both the ultimate partitioning of the surfactant at the paint-air interface, as well as the inherent size, aggregation tendencies, and solubility of surfactant in the bulk paint binder. In the present study three-dimensional (3D) microscopy and quartz crystal microbalance with dissipation (QCM-D) were used to add to and reinforce current understanding of the physical and mechanical changes to acrylic paint films with temperature and RH. The migration of surfactant at the film surface was studied using desorption electrospray ionization-mass spectrometry (DESI-MS) and attenuated total reflectance Fourier-transform infrared (ATR-FTIR) microscopy. Electronic speckle pattern interferometry (ESPI), as a method for examining, in virtual real time, the mechanical changes in these paints as a function of the ambient environment around them will also serve to underscore the highly responsive nature of surfactant accumulation on these paint surfaces.

Abstract Text

Although he rejected being categorized as a Minimalist, the American artist Donald Judd (1928-1994) is recognized today as one of the leading figures of the 1960's movement called Minimalism. He created a large body of work that spans the two-dimensional and three-dimensional spatial range, and pioneered the utilization of materials designed for industrial use and had them executed by fabricators of various trades. Judd's artistic approach opened new venues for art, but also presented unusual challenges for conservation science.

More often than not, the pristine, uniform surfaces of Judd's works prohibit customary sampling practiced for traditional art. Collecting the tiniest sample would cause permanent damage to these works, hence the removal of samples for analysis is generally severely limited, or in many cases forbidden. The ability to employ non-invasive and non-destructive analytical methods that can be used *in situ* is essential in the study of such objects and opens new opportunities for the investigation of the materials these works are fashioned from.

This presentation will focus on Judd's three-dimensional works made of metal and their finishes from 1964-1994. Portable instrumentation were utilized in this study, including handheld X-ray fluorescence spectroscopy (hhXRF), attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) and colorimetry. The advances in portable instrumentation have allowed for researchers to study a larger number of works - gaining a fuller understanding of the artist's *oeuvre* - compared to the small number of actual samples that can be taken from the objects. Issues of the challenges and limitations of these portable techniques will also be discussed.

Abstract Text

Daylight fluorescent pigments fade rapidly, accompanied by a chronology of colour change. Multiple organic fluorescent dyes are routinely incorporated into a given daylight fluorescent pigment, to either additively fluoresce or interact through energy transfer. The organic fluorescent dyes employed differ in photo-stability and upon loss of each species of fluorophore an abrupt colour change is observed. The collective result of this fading behaviour is that in a short period of time a daylight fluorescent paint layer will be of a different hue, devoid of luminosity. As consequence it is almost impossible to colour match a faded daylight fluorescent paint layer without the hues diverging asynchronously, or ascertain the original palette of a daylight fluorescent artwork after a protracted period of time. To ensure best practice in the preservation of artworks that contain daylight fluorescent paint here we perform a fluorimetric and chromatographic analysis of the DayGlo daylight fluorescent pigment range at the constituent dye level, prior to and during an accelerated light ageing program. This research finds that the complex dye formulations employed in daylight fluorescent pigment manufacture raise several implications for the display and treatment of this modern palette.

Abstract Text

The past several decades have seen significant effort directed towards the development of compact mass spectrometry systems. However, realization of a mass spectrometer with a handheld form factor has remained elusive. Eliminating the turbomolecular pump typically utilized in transportable instruments significantly reduces the system size, weight, and power (SWAP). Submillimeter scale ion trapping structures have allowed the first demonstration of high-pressure mass spectrometry (HPMS), the generation of mass spectra at pressures exceeding 1 Torr, and a truly handheld mass spectrometry device that can operate for hours using its on-board batteries. Such pressures can be maintained at high gas throughput using small, rugged mechanical pumps, significantly reducing the instrument's form factor and robustness. HPMS has led to the development of a handheld mass spectrometer that promises to be an order of magnitude smaller than currently available field deployable instruments. Moreover, the HPMS system utilizes ambient air as the buffer gas, essentially eliminating reagent logistics. The performance characteristics of these HPMS systems will be discussed.

Abstract Text

The mass resolution of a TOF mass spectrometer is directly proportional to its total flight path length. Thus, the maximum flight path that can be achieved in a typical laboratory instrument is of the order of a few meters. In order to overcome this fundamental problem, it is necessary to store the ions in a closed orbit, and to pass the ions around the same orbit many times. However, if the ion beam diverges in both time and space, then both the mass resolution and the ion transmission are compromised as the number of cycles increases. To avoid this, we need to design an ion optical system that gives 'perfect focusing', where the ions return to their point of origin in the system, in both time and space. We found three ion optical systems that achieve the 'perfect focusing'.

One of these proposed TOF systems, the 'MULTUM Linear plus', was constructed as a laboratory model for the ROSETTA space mission. It consists of four cylindrical electrostatic sectors and 28 electric quadrupole lenses. It was experimentally demonstrated that mass resolution increased according to the number of ion cycles through the ion optical system. A mass resolution of > 350000 was achieved after 500 cycles. Another multi-turn TOF mass spectrometer, the MULTUM II, was also developed in an effort to reduce the number of quadrupole lenses. The new instrument consists of only four toroidal electric sectors. MALDI ion source was attached to the MULTUM II for analysis of biomolecules. A mass resolution of > 100000 was achieved for Angiotensin I.

Recently, we are developing various types of mass spectrometer based on the MULTUM II technology, for example, a tandem TOF mass spectrometer 'MULTUM -TOF/TOF', a stigmatic type imaging mass spectrometer 'MULTUM -IMG', and portable mass spectrometers of high mass resolving power 'MULTUM-S' series.

I will talk about the outline of the multi-turn TOF mass spectrometer and the development history of the MULTUM-series and their applications.

Abstract Text

On the upcoming joint European Space Agency (ESA) – Roscosmos (Russia) ExoMars rover mission, the Mars Organic Molecule Analyzer (MOMA) investigation includes a linear ion trap MS under development with support from NASA. The goal of the ExoMars rover is to seek the signs of past or present life on Mars, and MOMA contributes to this by analyzing organic molecules that may be present in samples acquired by a two-meter deep drill. At such depths any complex organics may be well-protected from the punishing cosmic ray flux on Mars, which easily reaches the surface due to the lack of a global magnetic field. The MOMA investigation, led by Max Planck Institute for Solar System Research (MPS) in Germany, with PI Dr. Fred Goesmann, combines pyrolysis GCMS with Mars-ambient laser desorption MS (LDMS) modes to analyze powder samples from the drill.

The linear ion trap supports both electron ionization (EI) from the GC effluent, injected into the trap from one end of the hyperbolic electrode array; and laser desorption/ionization from the other end, with ions carried through a narrow tube from Mars ambient (5-8 Torr) to low pressure. The laser interface is a new development for space application, however it is based on the discontinuous atmospheric pressure ionization (DAPI) approach pioneered at Purdue University. A new check-ball type valve is used to close off the inlet tube after laser ions are trapped, permitting the analyzer pressure to reduce to below 1 mTorr where the high-voltage detectors can be activated. Another novel feature (and challenge) of the MOMA ion trap is that the residual Mars atmosphere, primarily CO₂, is used as the bath gas in LDMS mode. A separate He tank and regulator is included in the University of Paris-provided GC, which supports pressurized flow and bath gas in the GCMS mode.

Abstract Text

Sensors need good selectivity for accurate measurements on complex samples such as found in the environment. Spectroelectrochemistry offers a means of providing the selectivity to target a single analyte in a sample containing many potential interferences. In one type of spectroelectrochemical sensor the additional selectivity is provided by subjecting the analyte to electrolysis that electrochemically modulates an optical signal such as absorbance or fluorescence. The modulated signal can then be distinguished from the constant signals of the potential interferences, and the analyte quantified by the magnitude of the change in optical signal. This strategy can be implemented with an optically transparent electrode coated with a thin polymer film that preconcentrates the analyte for spectroelectrochemical detection. Spectroelectrochemical sensors using absorbance or fluorescence have been developed for detection of a variety of analytes: metal complexes; heavy metals such as lead, cadmium, copper and zinc; polycyclic aromatic hydrocarbons; and nitrate. Sensors have been demonstrated on complex samples such as radioactive waste from nuclear processing and natural water from the environment.

Abstract Text

Exposure to metals through ingestion of contaminated food and water is well established as a leading exposure route for toxic metals. Exposure through inhalation of particulate phase metals is poorly understood, largely because long sampling times (8-48 hrs) are needed to accumulate enough sample mass for analysis with traditional methods. Furthermore, traditional analytical techniques are expensive, creating a barrier to routine exposure assessment. Electrochemical Paper-Based Analytical Devices (ePADs) provide an alternative, low-cost tool for analysis of metals in particulate matter. ePADs can be both sensitive and selective for different metals when using either anodic or cathodic stripping voltammetry. Here, development of ePADs for analysis of Pb, Cd, and Zn using anodic stripping voltammetry (ASV) and Mn using cathodic stripping voltammetry (CSV) will be presented. Pb and Cd can be readily detected using screen-printed carbon electrodes with ASV. Zinc detection is poor at these electrodes, however, because of the large oxygen reduction background present at the same potential. Electrodes modified by electrospinning using a hybrid polyaniline/graphene film shift the reduction potential of oxygen more negative allowing for detection of Zn. Analysis of particulate samples collected in an industrial work environment were analyzed using this method. Next, analysis of Mn using CSV will be presented. Mn is present in many aerosols, and exposure elevated Mn in particulate matter has been linked with higher mortality rates. To create this system, carbon electrodes were screen-printed from a custom formulation onto thin polyethylene sheets. Benzoquinone was subsequently used as an internal standard and reduced device-to-device variability substantially. Atmospherically relevant detection limits have been achieved and aerosol samples have been characterized using the method.

Abstract Text

Heavy metal analysis is typically made using techniques such as ICP-MS, where solution is taken from the source to the laboratory. However, there is now a move towards direct measurements at the source, with the capabilities for continuous monitoring. Electrochemistry is often touted as an ideal methodology with stripping voltammetry often the technique of choice where metals from solution are electroplated on the electrode (preconcentration) and then stripped from the surface to give a peaked analytical signal. The size of the signal and position of the peak on a potential axis is used to determine concentration and chemical identity. Since liquid mercury has been banned, solid electrodes must be used which complicate the measurement as multiple peaks can be returned for one metal,¹ and alloying of metals on the surface results in peaks in positions which can lead to incorrect interpretation of solution composition. To overcome this problem we recently reported the development of a novel analytical technique, electrochemical X-Ray fluorescence (EC-XRF).² In EC-XRF electrochemical preconcentration of a labile species of interest onto the electrode is achieved by electrodeposition. Unambiguous elemental identification and quantification of metal concentration is made using XRF, improving the limit of detection of energy dispersive XRF by over four orders of magnitude. Initial work focused on ex-situ measurements,² however, work has now moved towards in-situ approaches where EC-XRF measurements are made directly in the fluid of interest. For trace metals which are not electrochemically labile, we also introduce a dual electrode configuration, where an outer or upstream electrode is used to generate known and controllable proton concentrations over the sensing electrode, freeing the complexed metal ion for subsequent electrochemical deposition or detection.

Abstract Text

Excessive levels of metals in urban surface waters are one of primary causes for water quality impairments. As a result, detecting, characterizing, and quantifying metals in these dynamic systems are critically important. Traditional techniques for measuring metals in aqueous samples are time consuming and expensive. In order to achieve sufficient sensitivity, most of the existing techniques used to monitor metals measure total concentrations and generally requires large sample volumes, which greatly reduces the spatial resolution and number of samples it is logistically feasible to collect.

Unfortunately, most metals undergo extensive aqueous complexation and have multiple redox states, both of which control the fate and transport as well as the toxicity of metals. We have recently applied Fast-Scan Cyclic Voltammetry (FSCV) to assess the behavior of metals in the environment. To demonstrate the utility of this novel analytical technique we will show how it was used to assess the complexation of copper with dissolved organic matter (DOM) and the effect of competitive aluminum binding on copper speciation. In another example, we will show how this small electrochemical sensor (200 μ m diameter) can be used *in vivo* to characterize the speciation and transport of arsenic. Finally, we will present emerging applications for this novel electrochemical technique that will help to address critical knowledge gaps in environmental science and engineering.

Abstract Text

Trace metal pollution is critical environmental issue to address. Natural and anthropogenic sources of trace metals can be toxic to plants, animals and humans. There is therefore great interest in reducing their impact. Trace metals often exert their most polluting effects during hydroaulic events (storms), which occur dynamically. To efficiently implement metal mitigation systems, more information is needed about dynamic, aquatic trace metal chemistry. This kind of information can be provided by an in in-situ analytical device that is portable, low-cost, low-energy and submersible while providing a continuous measurement output. Electrochemistry has shown promise for this goal in the past but it has been limited by its temporal resolution and concerns about Hg toxicity. We have recently shown that fast scan cyclic voltammetry (FSCV) at carbon fiber microelectrodes is an ideal analytical tool for real-time trace metal detection. In this work, we describe the fundamental surface mechanisms of FSCV for Cu(II) analysis. We study surface adsorption mechanisms in a variety of ways and derive the thermodynamic adsorption relationships between the carbon fiber surface and solution ligands. Finally we discuss novel methods for modifying carbon fiber surfaces for increased selectivity when analyzing authentic stormwater samples.

Abstract Text

Thermal analysis is the measurement of some physical property of a material as a function of temperature. The properties of interest include heat capacity, heats of transition, mass loss, expansion/contraction, modulus and many others. While not all properties may be measured over all temperatures, the application range of commercial apparatus is -170 to 1600 °C. A brief history of commercial thermal analysis instrumentation is provided along with rationale for development and trends. The Kondratiev Cycle is used to model the growth of the industry to its present maturity along with the Boston Consultation Group model for its present and future. Leading contributions to the art of Robert Stone (Stone Company), Jen Chiu (DuPont Company), Mike O'Neill (Perkin Elmer), Dick Baxter (DuPont Company), Mike Reading (ICI) and others will be recognized.

Abstract Text

The first thermal analysis measurements were made during the 19th century when cooling curves were used to investigate phase transitions. Roberts-Austen created the first differential thermal analysis instrument by adding a second thermocouple to measure the difference in temperature between the sample and an inert reference. This increased the sensitivity of the apparatus. The temperature difference measurement combined with a sample temperature measurement remains the basis for all modern differential thermal analysis and DSC. Vold applied a heat transfer analysis to her differential thermal analysis instrument to obtain sample heats of transformation, thus adding quantitative heat flow rate measurements, i.e. scanning calorimetry to differential thermal analysis. The lumped heat capacity formulation she employed continues to be the basis for obtaining heat flow information from DSC. Boersma described a differential thermal analysis instrument having high thermal conductivity sample and reference holders configured such that the differential temperature measurement was largely independent of the sample thermal conductivity, improving the reproducibility of the differential temperature measurement and hence increased precision of heats of transition. The early 1960s saw the introduction of the first commercial DSCs and the name differential scanning calorimeter was first used. Power compensation DSC was introduced along with heat flow DSC derived directly from differential thermal analysis. Temperature modulated DSC developed by Reading added periodic temperature oscillations to temperature scanning, allowing the resulting heat flow signal to be separated into a heat flow due to the sample heat capacity and a heat flow due to latent effects such as crystallization. Rapid heating and chip DSC have recently been developed that expand heating and cooling rates up to 105 K/min and beyond to facilitate analysis of metastable materials.

Abstract Text

Hyphenated or coupled techniques have been of interest in thermal analysis for decades. Applications of evolved gas analysis (EGA) techniques were a research topic in the late 1980s and early 1990s as analysts realized that techniques like thermogravimetric analysis were much more powerful when the off-gases were precisely identified. Other techniques like spectral DSC or DMA developed as the need for more precise understanding of the thermal transitions or thermo-mechanical changes in a material. Starting with a historical review, we will look at the development and current state of hyphenated techniques including EGA, spectral-thermal, and sample modification methods.

Abstract Text

Thermomechanical Analysis (TMA) is basically measuring physical dimensions as a function of temperature and force. Although the idea that materials generally expand when heated has been well known, it was not until 1948 that the relationship between dimensional changes with temperature were quantified and a technique standardized. This was also when the term "Thermomechanical Analysis" came into use. The first commercial TMA instrument became available in the 1960's. In the 1980's with the advent of Linear Variable Differential Transformers, the precision of TMA instruments greatly improved. Current TMA instruments can measure dimensional changes with a variety of fixtures in compression, penetration, tension, or flexural modes with zero applied force (contact), constant force (stress), or constant strain. In addition to linear dimensional changes, volumetric changes can be measured with special containers. Although TMA basically measures thermal expansion which usually varies linearly over short ranges, the applications are very diverse.

Abstract Text

Over the past 20 years, bisphenol A (BPA) has come to define an entire class of risks to the public from consumer products thanks to extensive media coverage. As such, it has also come to symbolize a broken regulatory system, one that is incapable of responding to new analytic techniques in toxicology and new understandings of endocrinology. Yet a close analysis of the way the media has covered BPA within the context of endocrine disruption and the broad notion chemical risk reveals systemic unbalanced coverage, narrative bias, and a chronic lack of methodological and statistical understanding. The result is that the public has been encouraged to think of BPA as representing the quintessence of chemical risk while regulators have become ever more assured of its safety. How did this happen, and what-if anything-can be done about it?

Abstract Text

Although numerous food regulatory bodies continue to support the safety of bisphenol A (BPA) as a food contact substance, consumers remain wary of products containing BPA. To satisfy consumer demand, can manufacturers and food producers have been developing alternative can coatings to replace epoxy coatings based on BPA. The current FDA Guidance for food contact substances recommends that if the product is retort pasteurized or sterilized, a retort step (121 [degree]C for 2 h) should be performed, followed by a migration test during 10 days at 40 [degree]C. Traditionally, 10 day migration tests at 40 [degree]C have been considered appropriate to simulate migration from packaging into food. However, can coatings can be stored in contact with food for years, and there is very little validated migration data evaluating migration for extended time periods. The scope of this study is to evaluate if the procedures recommended by FDA guidance are appropriate to accurately assess migration for long term storage. To carry out the experiment, four types of can coatings including: Polyester, acrylic-phenolic, epoxy-resins and vinyl coatings were used. After identification of potential migrants, a final set of compounds including monomers and related substances belonging to the coatings were used for tracking migration. Migration times were from 1 day to 1.5 years at 40 [degree]C. Concentrations of the migrants were determined in the different food simulants. For some of the compounds initial data shows an increase in migrant concentration beyond the traditional 10 day time point. These results suggest that migration protocols may need to be modified to address long term storage.

Abstract Text

The quality of food can be positively, and sometimes negatively, affected by its interactions with packaging materials and their environment. Interactions such as migration and sorption with inks, laminates, over-lacquers or seal coatings are often causes for off aromas and flavors in foods. Furthermore, migration can also have positive effects on the quality and safety of food. Use of antioxidants or antimicrobial agents can improve shelf life and microbial safety of products when incorporated into the packaging material. A brief summary of incidents of migration and sorption having negative effects on food will be covered as well as important regulatory considerations. Lastly, development of packaging materials having an intended positive effect will be summarized. This will mainly focus on antimicrobial food packaging research involving incorporation of nisin for reducing microbial growth in ready-to-eat meats.

Abstract Text

Recent technological developments in active food packaging enable exciting new applications. In this work we describe synthesis of a non-migratory active packaging material prepared by photoinitiated surface graft polymerization which is capable of chelating metal ions from packaged food products. Surface analysis of materials was performed using Fourier transform infrared spectroscopy, inductively coupled plasma mass spectrometry, colorimetry, and electron microscopy. Attenuated total reflectance Fourier transform infrared spectroscopy revealed absorbances characteristic of the desired chemistries at each stage of the modification, including grafting of photoinitiator, methacrylic acid monomer, and converted hydroxamic acid moieties (see figure). Polypropylene, polyethylene, and polyethylene terephthalate were successfully surface modified to possess chelating moieties including acrylic acid and hydroxamic acid, grafted via covalent linkages. Utilization of the hydroxamic acid chelating moiety improved retention of chelating properties at pH values as low as 3.0. Our chelating active packaging materials were shown to have wide application, including inhibiting lipid oxidation in emulsions and improving activity of natural antimicrobials such as lysozyme. This work demonstrates the potential for using active food packaging as a means to reduce food additive use, specifically use of metal chelators such as ethylenediamine tetraacetic acid.

Abstract Text

Migration is an important determinant of the potential consumer exposure to nano-components in food contact materials (FCMs). Therefore, characterizing the physico-chemical properties and potential for migration of constituents is an important step in assessing the safety of FCMs. An evaluation of a number of commercially available nano-enabled FCMs purchased domestically within the US and internationally using the current FDA Guidance for evaluating migration, showed the detection of sub-ppb levels of silver in food simulants. The migration trend was characterized by a surface desorption phenomenon, and nanoparticle migration was not observed. Based on the above observations it is important to evaluate the potential for nanoparticle release under conditions that significantly change the exposed surface area of the FCMs. Data from migration analysis performed under stressful use conditions will be presented.

Abstract Text

At temperatures above approximately 7°C, microbial spoilage of some perishable foods can begin within hours. In order to mitigate spoilage during the storage, transportation and handling of perishable foods, use of antimicrobial packaging can be very effective. Ethyl pyruvate is an effective antimicrobial and classified as GRAS (generally recognized as safe) by the U.S. Food and Drug Administration for common use in food applications. In this study, GC/MS was used to evaluate the effective permeability of four film structures for gas phase diffusion of ethyl pyruvate (EP) into the headspace of a food storage bag. The information gained provided insight toward optimized design of a laminate food storage bag which includes unperforated outer and inner layers and an intermediate layer which includes a solventless adhesive mixed with EP. The objective of the study was to determine an effective inner film layer.

Five food packaging films were evaluated: Linear Low Density Polyethylenes (LLDPE, 0.80mil (control) and 1.00mil); Ethylene Vinyl Acetate (EVA, 1.00mil); Low Density Polyethylene (LDPE, 1.00mil); and Metallocene Polyethylene (MPE, 1.25mil). Headspace vials containing microvials with 5uL EP and sealed with the sample films were sampled every 3-4 hours using static and SPME HS. Analysis was performed on an Agilent 6890 GC with DB5-MS column coupled to an Agilent 5973 MSD. The results for static HS are shown in Figure 1. The results show that MPE has a significantly higher permeability than the other films tested, and may be a good candidate for packaging inner layer structure in EP antimicrobial laminate packaging.

Abstract Text

The past decade has seen significant investigation into expanding the use of Dried Blood Spots (DBS) beyond neonatal screening. Most of this research has focused on nucleic acids or small molecule applications. Recently, investigators have reported success with the quantification of proteins from DBS. The work presented by SISCAPA assay technologies is of particular interest to OpAns. Leveraging our current work with the quantification of small molecules in clinical DBS samples and protein/peptide quantification using pull down enrichment, we have investigated the quantification of proteins from DBS using the SISCAPA approach. We will discuss challenges with the methodology, solutions that we found, and the practical applications of the technique in our hands.

Abstract Text

Serum thyroglobulin is measured as follow up assessment for treatment of thyroid cancer. Traditionally, serum thyroglobulin has been measured by immunoassay, which have excellent sensitivity (0.01 ng/mL). However, several studies have pointed out the presences of antibodies to thyroglobulin in about 10% of the population, which cause interferences in an immunoassay. The percentage is even higher in patients with differentiated thyroid carcinoma. Mass spectrometry is a growing tool for clinical diagnostics especially in the quantitation of small molecules, but has had less growth in the quantitation of proteins. The importance of accurately measuring thyroglobulin concentrations in serum and the problems with immunoassays has made it necessary to develop mass spectrometry techniques to solve this problems. This talk will discuss the current status of assays and patents for thyroglobulin quantitation.

Abstract Text

Today's clinical laboratories offer many tests that can be used to detect a number of diseases. In some cases, the quantitative analysis of small-molecule biomarkers in biological fluids can be indicative of a disease state, though it is commonly believed that proteins, especially low abundance proteins and their modifications, are a rich source of biomarkers with greater potential for the detection of disease than small molecules. This paper will examine the current limitations of traditionally employed sample preparation and analysis techniques for protein biomarkers in biological fluids. A novel platform for the extraction and quantitative analysis of protein biomarkers will be discussed, using several model compounds for illustration.

Abstract Text

Objective and Significance

Micro flow LC-MS/MS (MFLC-MS/MS) has been shown to deliver significant sensitivity gains over traditional HPLC-MS/MS, while providing additional benefits such as lower required sample volumes and solvent consumption. At these $\mu\text{L}/\text{minute}$ flow rates, the ESI-MS source can be coupled with the MFLC column ("the column is inside the source") to further improve MS signal and chromatography compared to traditional segregated techniques.

Procedures and Equipment

Organic precipitation was used to prepare samples of human methotrexate (MTX) in plasma for analysis by MFLC-MS/MS. A Eksigent Express HT-Ultra LC[®] system coupled with an ABSCIEX 6500[®] QTRAP mass spectrometer was used for MFLC-MS/MS analysis.

Results

Accuracy and precision for the analysis of MTX from human plasma was better than $\pm 13\%$ at all levels of QC samples (LLOQ to ULOQ). A stable-labeled internal standard was utilized for quantitation. Sensitivity, selectivity, accuracy, and precision were acceptable for routine bioanalysis and compared very well to conventional HPLC-MS/MS results.

Conclusion

Here we have demonstrated a validated, high throughput method for bioanalysis using ESI-MS/MS coupled with the MFLC column. This data, along with the sensitivity and efficiency benefits of MFLC-MS/MS, suggests that the technique has value as a technique in the bioanalytical or clinical laboratory.

Abstract Text

Mass spectrometry (MS) is an efficient, sensitive, and highly specific detector for a wide range of compounds encountered in the the clinical laboratory. The addition of tandem mass spectrometry enables targeted quantitation of both small and large molecule of endogenous and exogenous origin. The sample preparation and introduction method of choice for mass spectrometry has been reverse phase liquid chromatography (RPLC). The peak capacity and resolution of RPLC has been an essential part of the success of MS in the clinical laboratory.

Unfortunately the greatest strength of LC for LC-MS is also its greatest weakness. LC is an inherently analog technology. Considerable effort in method development and technical overhead (operator expertise) is required for success. Much of the down time spent in high throughput laboratories is split between method development followed by downstream support of the LC instrumentation. High quality chemical separations take time, both to develop the method, as well as to achieve each individual separation per sample. Chemical separations occur on the minutes to hours time scale.

In contrast MS is inherently digital. Ions are generated and analyzed at a rapid rate in discrete packets. MS is acquired on the microsecond to millisecond time scale. The LC in LC-MS is limiting the adoption of MS in the clinical environment.

We present an approach to digitize the LC-MS workflow to alleviate these limitations. By segmentation of the LC sample stream into 1- or 2-dimensional microfluidic arrays, , the chromatogram may be moved from an analog environment to a digital workflow. This simple paradigm shift fully decouples the mass spectrometer from the LC. Since the MS is no longer tied to the timescale of LC, it can be applied in totally new ways that would not be economically feasible by traditional LC. Some initial results and possible directions for this new technology platform will be presented in the analytical laboratory.

Abstract Text

Quantifying the ability of a dosed therapeutic to disrupt the interaction between an endogenous protein ligand and its receptor is a complex biological question. To fully address this complexity, the Discovery Bioanalyst must often provide an understanding of the preclinical disease model, demonstrate on-target effect, and accurately quantify target load in the diseased tissue. Complete PK/PD modeling is then possible considering perturbations of biomarkers, ligand, and receptor quantified in both circulation and resident to tissue. Bioanalytical assays to provide this data require exquisite sensitivity due not only to extremely low endogenous levels, but also limited sample amount. Additionally, multiple measurements are often made from a single sample in order to describe various protein-protein interactions proximal to drug action to provide strong proof-of-mechanism. To accomplish these measurements, we incorporate sample preparation using immunoenrichment followed by low flow LC-MS technology. By intelligently designing assays to capture specific protein populations of interest, coupled with selective and sensitive detection of multiple target proteins, we are able to provide critical PD information. In this presentation we highlight key LC-MS technologies and sample preparation approaches that have enabled an unprecedented depth of understanding during the development of biotherapeutics. These understandings could ultimately impact personalized healthcare, providing guidance to patient selection and proper dosing.

Abstract Text

In the manufacturing of pharmaceutical drug substances, it may be necessary to demonstrate that impurities are below an appropriate safety threshold. The threshold is defined by the International Conference of Harmonization (ICH) and determined by the target dose and route of administration. Robust methods are needed to perform impurities testing on the final drug substance as well as starting material, intermediates, and critical control points in a synthesis. This presentation will review case studies involving method development of trace-level impurities in drug substances as well as starting materials and intermediate. Analytical techniques, such as chemical derivatization, HPLC, and MS, which are used in developing methods for the control and monitoring of impurities and degradation products will be discussed.

Abstract Text

A pharmaceutical impurity is any component that is not the chemical entity defined as the drug substance or an excipient in the drug product. The drug impurity can be organic or inorganic impurity, residual solvent and filter aids. The organic impurity may result from the starting materials, process-related impurities, intermediates, API and degradation products. Due to the apparent impact of impurities on pharmaceutical quality, the identification of any impurity >0.1% area in relationship to the API are generally required. The common impurity isolation and identification technologies include LC/MS, LC/HRMS, HPLC, SFC, prep-HPLC and prep-SFC, 1D/2DNMR, re-crystallization and sample degradation. Isolation of low level drug impurity (~0.1-1%) can be very challenge. The deep understanding on the isolation technologies, chromatography, and the theories on the impurity formation/pathways are critical for the success. In this presentation, we will provide a general overview for impurity isolation strategy including various purification technologies, column chromatography, analytical method development for optimizing the resolution as well as the discussions on impurity structure work flow.

Abstract Text

As a drug candidate moves successfully through the development process it becomes increasingly important to identify drug related impurities. Isolation of low-level (0.1-1.0%) drug product degradants for structure identification can prove very cumbersome and time consuming when going directly through the drug product as a sample source. Low level impurities in low dose formulations with limited sample supply will significantly limit the amount of impurity material one can recover. Sample enrichment becomes a critical step to support the structure elucidation process. One can exploit the degradation chemistry "toolbox" by generating targeted screens with a narrow approach in experimental design. Case studies will be presented to highlight sample enrichment and isolation process that ultimately support MS and NMR structure elucidation of targeted low level drug product degradants.

Co-Author(s)

Abstract Text

In many cases, routine 1D NMR methods are sufficient for structure elucidation of relatively simple low molecular weight compounds. However, as the complexity of molecular structure increases, interpretation of 1D NMR spectra becomes challenging. Use of more powerful homonuclear and heteronuclear 2D correlation NMR spectroscopy addresses this challenge for small to medium size molecules. Practical strategies and tactics for establishing structural connectivity using 2D NMR methods will be discussed. Case studies of the structure elucidation of impurities in drug substances will be presented.

Abstract Text

Development of new chemical entities (NCE) with high chemical and chiral purity is a regulatory expectation in new drug development. Today, it is not unusual to have complex molecules with 3 or 4 stereogenic centers which show high affinity for disease targets. For the process development of these “multi-chiral” molecules, numerous analytical methods capable of separating all stereoisomers (enantiomers and diastereomers) must be developed rapidly to assess and control the stereochemistry of raw materials, intermediates and the final active pharmaceutical ingredient (API). Achiral reversed-phase (RP) methods, used to assess the overall chemical purity assays, can typically be developed to monitor the diastereomeric content in a single run. In many cases, these achiral methods often become the primary quality control (QC) and stability-indicating purity assay methods. This paper describes the method development and QC strategies used for these complex multi-chiral drug molecules, which include:

- Adoption of a 3-pronged HPLC method development template approach
 - Development of a single RP method using multi-segment gradients for determination of overall purity and diastereomeric content
 - SFC for rapid initial screening for chiral separations
 - 2-D LC for peak purity determination and achiral/chiral combinational assays
- These strategies will be described with actual examples used during clinical development of several new drug candidates.

Abstract Text

Chromatographic isolation of impurities and minor components in complex mixtures can be extremely challenging. Often times the impurity or minor component to be isolated is structurally very similar to the parent component, making it necessary to perform chromatographic method development in order to establish pure analyte. The use of the isolated trace level compounds range from full characterization via MS-MS and NMR to evaluation of biological activity and toxicity making quantity isolated as important as purity. This presentation will detail the modes of chromatography used for these separations and will highlight modifications made to preparative instrumentation traditionally used in the high-throughput arena to maximize performance for these challenging samples. Characterization data generated for the isolated compounds will be presented to demonstrate the array of information that can be derived from the small sample size with state of the art instrumentation.

Abstract Text

The chromatographic separation and the analysis of polar compounds using HPLC has always been a challenging. It would seem that HPLC analysis would be well suited for the determination of the polar compounds however routine reverse phase HPLC analysis has yielded poor quality results for these types of compounds. The analysis of polar compounds via routine HPLC analysis has been deficient in several main aspects including poor retention, unacceptable low k' values and poor peak shapes. One of few HPLC techniques capable of analyzing polar compounds has been traditional normal phase chromatography (polar stationary phase with a non-polar mobile phase). Unfortunately, normal phase chromatography suffers from several major deficiencies including poor retention time reproducibility, poor column to column reproducibility and very low or no solubility of the target analytes. A number of HPLC stationary phases have introduced to improve the analysis polar compounds. These HPLC stationary phases include high aqueous stable phases, HILIC (hydrophilic interaction chromatography) phases and polar embedded phases all of which utilize various levels of water in the mobile phase. It is the focus of this presentation to compare and contrast the HPLC modes developed for the analysis of polar compounds with a particular focus on HILIC mode. As part of our presentation we will introduce new HILIC stationary phases optimized for the separation of polar compounds. The goal of this work is to present a strategy for the HPLC analysis of polar compounds using HILIC conditions. In addition, the potential limitations of HILIC chromatography will be discussed including dynamic/linear range, retention time reproducibility, mobile phase composition and potential sample matrix effects.

Date: Monday, March 09, 2015 - Afternoon

Time: 01:50 PM

Room: 268

Co-Author(s)

Abstract Text

In this talk I will describe how I ended up at HORIBA and how my career evolved the way it did. My academic work was in solid state physics at the University of Pennsylvania, and from there I moved to the Biophysics Department in the Medical School where I built a Resonance Raman instrument for studying interactions between hemes in functioning mitochondrial membranes. Because I was unable to secure a stable position in that department I accepted a position with ISA (also known as Instruments SA, and then later known as Jobin Yvon and finally HORIBA Scientific) to serve as the interface between potential users of Raman microscopes and the sales group. At the time (1978) the field was wide open, so product acceptance required extensive collaborative efforts to demonstrate the possibilities of the equipment. It was gratifying knowing that some of the measurements that I was making were being done for the first time, certainly in North America, and often in the world. And the best part was that the people who had requested the measurements were almost without exception appreciative, and invited me to publish with them. It is also worth commenting that for sure a large part of my success was due to the "corporate culture" that existed, and continues to exist in the company, which encouraged technical excellence and interpersonal cooperation.

Abstract Text

This talk will reflect upon the career path taken thus far (25+ years) by one women chemist. Many steps - from graduate school to full professor - required taking chances and trusting in one's instincts. Yet until reflecting upon this path, the significant risk taking and serendipity were not necessarily apparent. And the challenges and benefits could not have been predicted at the outset.

Time: 02:30 PM

Room: 268

Co-Author(s)

Abstract Text

None of us were able to get to where we are today without a little help! One way to increase the number of women who pursue science involves actively creating an environment that not only encourages but also supports women. This environment does not have to be created by women alone! Everyone can help in their own way to create such an environment to help inspire more young women to pursue science.

Each of us can encourage women in science through demo events, allowing students to shadow you for a day, or talking to a local class, showing students what science looks like is a valuable part of inspiring women to pursue science.

Highlighting historic and current female scientists can also provide concrete examples of role models. When women see other women with successful science careers, they are more likely to believe that they too can have a successful science career.

An environment that supports women in science involves several components including emotional, verbal, and institutional support. Women are presented with many challenges that do not affect men in the same way, and providing an open ear or access to councilors can help women feel that they are accepted as part of the community. Verbally supporting women to show that women and men are valued equally, is one of the easiest things we can all do, but often forget. Finally, institutional support such as compliance with Title IX, childbirth accommodations, and leave options for both fathers and mothers not only support women, but also help more women continue their careers after having children.

Creating an environment that encourages and supports women in science is not easy, but we can all make small changes in what we do and say to work towards more equality. It's also important to remember that these changes do not have to come from people who are already settled in their careers, young women can help too!

Abstract Text

Career choices in the sciences are often presented as black and white, like do you want to work in a lab or teach in academics or go to medical school? Starting into the workforce teaching high school chemistry and physics, with a goal of teaching at the university level, the analytical instrument business was never on the radar. Yet, the last 15 years in the instrument industry have been an incredibly fun and stimulating journey through roles as product manager, product specialist, and direct sales. Each transition brought growth and an enhanced personal skill set, however, one passion has woven itself through every facet of this exciting ride: an uncontainable love of teaching. Teaching chemistry and physics at the high school level, TAing chemistry in graduate school, and analytical and instrumental courses in a university setting offered traditional and enjoyable years in teaching, but the best was yet to come. This presentation will share personal experiences throughout three decades in analytical chemistry in both academics and the instrument industry with an emphasis on the more unconventional teaching roles, opportunities, and unique skills development that have served as career highlights in the last 15 years in the corporate arena.

Abstract Text

Madame Marie Curie served as my inspiration to become a woman scientist, and along the way I became a spectroscopist. My start began in physics like Marie Curie but evolved into physical chemistry and then a love for spectroscopy that has concluded at the National Institutes of Health in a study of biomedical solutions. To me, spectroscopy is the key to unlocking the many puzzles of science, all disciplines of science. With a physical chemistry degree in spectroscopy, I began my career in a radiochemistry lab working in food science and then quickly moved into spectroscopy of pesticide chemistry and instrument development for metabolites, then into toxicology which evolved into forensic toxicology and spectroscopic research in forensics. After the attacks of 9/11/2001 and the anthrax letters that followed, a lot of government work turned its focus to detection of biologicals that might be used as weapons. This evolved into the research of instrumental development for disease diagnosis and finally to the current position that I hold as Scientific Review Officer at the National Institutes of Health for the Instrumentation and Systems Development study section. In all roles, spectroscopy has played a major part in finding solutions for every different discipline that crossed my path. Along the way, I married (a Spectroscopist), had children (one who also became a woman scientist), led two national Professional Organizations as their elected President, and enjoyed a family life (hobbies will wait for retirement). Women in Spectroscopy can be successful and be women too.

Abstract Text

The d-forms of multiple free amino acids have been found in the central nervous and endocrine systems of both vertebrates and invertebrates. While progress has been made in understanding the significance of some d-amino acids (D-AA) such as D-serine (D-Ser) and D-aspartate (D-Asp), there remains interest in the characterization of less common d-amino acids. Progress has been complicated by the heterogeneous nature of these tissues, low endogenous concentrations, as well as sample volume constraints. Capillary electrophoresis coupled with laser-induced fluorescence (CE-LIF) is well suited for the analysis of low concentration analytes when working with small sample volumes, such as single cell samples. In this work, levels of the well characterized D-Asp and the less understood D-glutamate (D-Glu) in single sensory neurons from *Aplysia californica* are measured via chiral CE-LIF. *A. californica* nervous system was selected as it is an established neurobiological model, where the relationships between the activity of specific neurons and behavior have been linked. The approach used here involves sample pretreatment via methanol extraction, sample reconstitution and derivitization with naphthalene-2,3-dicarboxaldehyde for the measurement of the D-AAs. Additionally, the CE electrolyte included quaternary-ammonium- β -cyclodextrin for chiral resolution as well as employed large-volume sample stacking with an electroosmotic flow pump for sensitivity enhancement. The ability to separate and measure d-amino acids from single neurons appears well-suited for aiding in their characterization in the CNS. This work was funded via NSF CHE-1111705.

Abstract Text

Functional hyperemia is a biological mechanism of maintaining homeostasis in the brain through mediating regional cerebral blood flow (CBF) responses to regional neuronal activity. As a neuron fires, CBF increases provide blood rich with oxygen and glucose to renew locally depleted energy sources. Decoupling this system can result in Alzheimer's or other disease states. Neurotransmitter dysregulation is also prevalent in neuropathies, making the relationship between CBF and neurotransmission important to understand. Excitatory glutamate neurons make up the largest percentage of neurons in the brain, but their behavior is best characterized in the cortex or in slices. We aim to better understand glutamatergic neurovascular influence deeper within an intact brain.

This research explores cell firing and oxygen responses to localized administration of glutamate to make inferences about its role in regulating vascular responses in the nucleus accumbens. Studies linking glutamatergic signaling to drug addiction behavior in the mesolimbic pathway has given more attention to this neurotransmitter in the nucleus accumbens. Measuring oxygen changes following glutamate-elicited neuronal activation serves as an indirect measure of blood flow changes to the area, and the neuronal activation can be measured using electrophysiology. Iontophoresis is used to locally deliver glutamate and drugs in close proximity to a neuron, and local oxygen is monitored using fast-scan cyclic voltammetry. Glutamate and oxygen changes, as well as neuron firing can be investigated using electrochemistry at a single probe. We present the results of iontophoretic application of glutamate and receptor-specific antagonists to cells in the nucleus accumbens.

Abstract Text

Glutathione (GSH) serves as a reductant to maintain an appropriate redox status in cells. Abundant evidence shows that cells can be damaged during oxygen-glucose deprivation followed by reperfusion (ORG/RP). We wish to understand the effects of OGD/RP on neurons and astrocytes and study the intracellular redox status change in term of GSH response.

We have developed an approach using the organotypic hippocampal slice culture (OHSC) and green fluorescent protein (GFP)-based sensors [1] which are selectively sensitive to GSH redox state changes. The GFP probe, excited at 405 and 488 nm, responds in seconds to GSH redox changes (GSH as reduced form, GSSG as oxidized form). The quantity $[GSH]_{[sup]2}/[sup]}/[GSSG]$ (Nernst) can be determined from the fluorescence emission ratio.

Our study focuses on the GSH redox changes in mitochondria and cytoplasm of pyramidal cells and astrocytes in OHSCs. We treated OHSCs with 20 min OGD / 30 min RP, followed by fully oxidizing and reducing them for calibration. We find significant changes in the quantity $[GSH]_{[sup]2}/[sup]}/[GSSG]$ in mitochondria during OGD-reperfusion, but not in cytoplasm. This is the first time that $[GSH]_{[sup]2}/[sup]}/[GSSG]$ has been monitored in real time in tissue non-invasively. Supported by NIH Grant R01 GM066018.

Abstract Title **Mass Spectrometry-Based Quantitation of Exercise Induced Peptide Changes in the Mouse Brain**

Primary Author Sarah E. Dowd
University of Illinois at Urbana-Champaign

Date: Monday, March 09, 2015 - Afternoon

Time: 02:30 PM

Room: 240

Co-Author(s) Elena V. Romanova, Jonathan V. Sweedler, Justin S. Rhodes, Martina L. Mustroph

Abstract Text

Exercise invokes changes in the brain reward pathway similar to those observed with drug use. We are investigating how signaling peptides in the hippocampus of male C57BL/6J mice change with exercise using two mass spectrometry-based quantitation methods. The quantitative approaches are label-free matrix assisted laser desorption/ionization (MALDI) MS and stable isotopic labeling with LC-electrospray ionization (ESI) MS. To create our behavioral groups, half of the animals had access to an exercise wheel for 30 days while the other half remained sedentary. Tissue samples were isolated from the hippocampus of each animal. For MALDI MS analysis, an internal standard was added to tissue extracts prior to analysis. Profiles were collected for individual animals and peak heights were normalized to the internal standard. Seventeen candidate peaks were found to statistically differ between the two behavioral groups. For relative quantitation using isotopic labeling, extracts were pooled in groups of three and labeled with H₄- or D₄-succinic anhydride. Differentially labeled samples were combined and analyzed by LC-ESI-MS to obtain ratios of peaks relating to relative abundance in the two samples. The chromatographic separation of the sample leads to an increase in the observed peptides and so additional candidate peaks have been observed. The two quantitation methods provide complementary measurements and of the seventeen candidate peaks from MALDI MS analysis, six show correlation with isotopic labeling. Current efforts are focused on identifying the peaks of interest from both measurements.

This work is funded through NIH and NIDA award number P30 DA018310.

Abstract Text

Living cells communicate by vesicular delivering of chemical messengers into their environment, a process called exocytosis. Revealing transmitter storage mechanism in sub-vesicular domains is important in order to study neurotransmission and malfunction thereof in disease. As the vesicles are nanometer dimension, this is extremely challenging.

Here we use imaging mass spectrometry to study the neurochemistry in small environments of large dense core vesicles (LDCVs). The major goal is to image transmitters in the protein dense core and halo solution around it, in an attempt to measure the neurotransmitter molecule distribution between these sub-vesicular compartments – a potentially important pharmaceutical target. Our work is focused on mapping individual LDCVs in two cell models, PC12 and chromaffin cells. Cells were treated with ^{13}C enriched L-3,4-dihydroxyphenylalanine (L-DOPA), a metabolic precursor for neurotransmitters dopamine, adrenaline and noradrenaline. ^{13}C isotopically labeled cells were chemically fixed, for transmission electron microscopy (TEM) and following nano-scale imaging measurements. Imaging inside vesicles has been performed with a Cameca NanoSIMS 50L ion microprobe using Cs^+ primary ions with approx. 50 nm spatial resolution. High spatial resolution negative secondary ion images of isotopic ratios $^{14}\text{N}^{13}\text{C}/^{14}\text{N}^{12}\text{C}$ and $^{13}\text{C}^{12}\text{C}/^{12}\text{C}^{12}\text{C}$ were acquired from micrometer-sized cell regions of the corresponding TEM sections. The overlays of isotopic ratio images and TEM images were used to measure the presence of transmitters in the vesicles as well as to reveal possible transmitter vesicular regions.

The use of NanoSIMS opens great possibilities for the study of neurochemistry in single transmitter vesicles and allows us to identify vesicle compartments as well as to relatively quantify transmitters inside them.

Abstract Text

Mass spectrometry imaging (MSI) generates multidimensional datasets that combine spatial and chemical information. In this study, matrix assisted laser desorption / ionization time of flight (MALDI-TOF) MSI is used to investigate peptide distributions within the central nervous system of the planarian [*Schmidtea mediterranea*] at different time points during animal regeneration. The planarian head is removed, and the tail is retained to monitor the regeneration of the animal's head and brain. For MSI sample preparation, planarians at various stages of regeneration were frozen, embedded, sectioned, and rinsed in ammonium acetate buffer and isopropanol before MALDI matrix application. MSI shows many ions that localize to and around the brain in intact and mostly regenerated planarians. Several ions are also observed to localize to and around the regenerating tissue in animals that had not yet regenerated a visible brain. Chemical trends associated with regeneration are highlighted using principal component analysis (PCA). PC 1 shows a clear separation between intact and regenerating animals, and PC 2 appears to reflect animal-to-animal variations in the regeneration process. To identify the detected ions, many of which are localized and detected at low abundance, multiple extraction media were tested on homogenized tissue samples. Extracts were directly profiled via MALDI MS and then subjected to LC-MALDI MS analysis. Alternatively, micro-extractions were conducted on tissue sections to more specifically extract from the regions of interest. Our ultimate goal is to understand the space, time and chemical mosaic of the neuronal regeneration process.

Abstract Text

Polymer electrodes have recently emerged as an alternative to traditional electrode materials like carbon or gold for the measurement of neurotransmitters. These electrodes are easy to fabricate, offer excellent electrochemical properties for the measurement of biogenic amines, and are easily incorporated into microfluidic geometries. Here, we have fabricated the first injection molded polymer microchip for the capture, stimulation, and measurement of exocytosis from single PC-12 cells. This 2-inch device was fabricated by the thermal bonding of two TOPAS cyclic olefin copolymer substrates. The top TOPAS substrate includes luer lock fittings, a serpentine channel for separating clumps of cells, and a straight channel for cell selection. The device also incorporates an auxiliary 3 micron-wide channel where suction is applied to capture and immobilize a PC-12 cell over a PEDOT electrode for stimulation and measurement. The bottom TOPAS substrate contains 500 nm cavities etched via reactive ion etching. In these cavities, a thin film of gold and chromium serves as contact leads to a 3 micron PEDOT band electrode where measurements of exocytosis from single cells or neurons can be made. We characterize the device by measuring ferrocene and dopamine using slow-scan cyclic voltammetry, and demonstrate the use of the device for easily monitoring exocytosis from single PC-12 cells.

Abstract Text

Gathering spatially resolved chemical information is of paramount importance to understand the underlying mechanisms of different systems. As such, elemental mapping of large sample surfaces is critical in various fields, from materials science to biology. Nevertheless, low-throughput limits current techniques for elemental mapping, requiring several hours to tens of hours for obtaining a full map with sufficient pixel density. Therefore, a high-throughput technique that can achieve fast chemical imaging of large area samples is needed. Pulsed glow discharge optical emission spectroscopy (GDOES) has shown the potential to allow elemental mapping when coupled to a spectral imaging system. In this manner, it can yield quantitative-, multi-elemental mapping in seconds. Most preliminary studies have shown GDOES elemental maps of samples with medium size areas (7mm to 30mm diameter). Glow discharge cell that can accept bigger samples are required to harness the technique's potential advantages. The development of a glow discharge chamber to accommodate samples with 100mm diameter will be presented. Furthermore, the coupling of this new GD chamber to a push-broom hyper-spectral imaging system will be discussed. Finally, novel applications enabled by GDOES elemental mapping will be shown.

Abstract Text

Inorganic mercury at low concentrations does not cause significant health risks. However, its conversion to organic methyl mercury by anaerobic bacteria seen commonly in marine environments makes it extremely toxic. Methyl mercury enters the food chain through the absorption by phytoplankton and its concentration increases as we go higher in the aquatic food chain. Consumption of fish having high concentrations of methyl mercury frequently can cause health issues including chromosomal damage, reproductive damage, skin reactions etc. Hence monitoring methyl mercury levels in fish has gained significant interest.

The high demand for analyzing mercury in fish has increased the number of labs looking at direct mercury analysis since it offers significant advantages over multi-step techniques and provides a cost and time savings by eliminating digestion equipment and waste disposal.

However, the direct mercury analyzers available today are designed to analyze total mercury and not methyl mercury. In recent years, methods have been developed that allow chemists to extract the organic methyl mercury from an environmental sample and analyze aliquots of the extracted organic phase for total and speciated methyl mercury using a direct mercury analyzer. This presentation will cover:

- Introduction to direct mercury analysis and its advantages over conventional techniques
- Concept and operating principle of direct mercury analyzers
- Methods to analyze methyl mercury using a direct mercury analyzer
- Data Analysis

Abstract Text

Quantitative analysis in any Optical Emission Spectroscopy starts with a high level of confidence in the spectral line assignment from databases. Nevertheless, the resolution of the spectra is usually degraded by the instrument and/or the line broadening. This low spectral resolution makes it possible that spectral interferences occur for the majority of the lines. Such interference makes the elemental profile uncertain.

This presentation shows the development of a factor to quantify the level of confidence attributed to line assignment in LIBS as an example and its extension to a complete quantitative atomic profiling. This factor is combining a physical understanding of the plasma emission with a statistical analysis of the spectrum.

The possible applications and outcomes of using such a quantitative factor to evaluate line assignment in plasma spectroscopy will be discussed in the context of forensic science.

The work presented is funded by the US National Institute of Justice (2012-DN-BX-K027: "Level of Confidence in Elemental Analysis by LIBS") and the State of Florida.

Abstract Text

Due to its advantages, nanotechnology has been receiving increase attention in the recent literature and at current conferences. In nano, it is widely accepted that size defines properties. While this has been proven to be true on numerous occasions, it is often forgotten that impurities also define properties.

In this presentation, use of an electrothermal, near-torch vaporization sample introduction system for inductively coupled plasma-atomic emission spectrometry that allows direct (i.e., without dissolution) analysis of carbon nanotubes will be presented in detail.

Abstract Text

There is a distinct need for portable, in field elemental analysis when rapid investigation is needed. To be portable analytical instrumentation must be small, rugged, compact, and produce minimal waste. For this purpose our laboratory has developed a liquid sampling-atmospheric pressure glow discharge (LS-APGD) microplasma that performs as an excitation/ionization source for elemental analysis. As an excitation source for analysis of small, discrete liquid samples (i.e. μL) by optical emission spectroscopy (OES), the LS-APGD operates at low solution flow rates ($100\text{-}200\mu\text{L min}^{-1}$) and low power consumption ($<100\text{ W}$) with He sheath gas flow rates of $.6\text{-}.8\text{ L min}^{-1}$ and counter flow gas rates of $.2\text{ L min}^{-1}$. The microplasma is generated in the $1\text{-}1.5\text{ mm}$ gap between an electrode and a fixed co-linear (i.e. 180° geometry) fused silica liquid capillary that delivers an electrolytic solution sheathed in a stainless steel gas capillary delivering helium gas. The LS-APGD has been previously implemented as an ionization source for elemental mass spectrometry and for laser ablation (LA)-introduced solids and in the desorption of organic species from surfaces. The parameters of the LS-APGD have been fine tuned for OES with detection by a five channel, broad wavelength optical spectrometer, Aurora by Applied Spectra. Limits of detection, limits of quantification, robustness, working range, precision, and bias from certified reference materials have been evaluated through studies with multi element solutions. Evaluation of the key operational parameters of the LS-APGD has shown promise towards a portable, in field OES source for elemental analysis.

Abstract Text

As miners strive to extract lower and lower levels of gold from ores (commercial mines operate with gold levels of 1 gram per ton). Fire assay has long been the go-to method for the determination of gold in ores but, as levels of gold decrease, the fire assay technique has undergone modifications in order to deliver accurate results. There is a sense amongst many analysts that the technique no longer deserves the trust it earned. In this presentation, we shall present the results of our investigations into alternative methods for the preparation of samples for the determination of precious metals by ICP optical and ICP mass spectrometry.

Abstract Text

Biofuels are increasingly becoming an important alternative or supplement to traditional petroleum based fuels. With the new sources for producing biofuels come the potential for new contaminants not necessarily found in fossil fuels. In the United States, the production of biodiesel is primarily driven by the use of soy beans. Unfortunately, the competition for this raw material and others for different biofuels has had an adverse effect on the price of food stuffs produced from these crops. The search for alternative and more efficient sources of raw materials for biodiesel production is ongoing. Elemental contaminants in engine fuels such as calcium, magnesium, phosphorus, potassium, sodium, and sulfur may adversely affect the quality of the fuel, engine wear, or emissions. ASTM International has embraced ICP-OES as the approved technique for measuring most of these elemental contaminants as well as providing specifications for the biodiesel that must be met before it can be used as a fuel or blended with traditional petroleum-based diesel to form bioblends.

ICP-OES offers a rapid and multielement solution for the analysis of all 6 elemental contaminants in biodiesel. Sample preparation is quick and simple and involves nothing more than diluting the biodiesel in a solvent such as kerosene. Viscosity effects between biodiesel samples is minimized with dilution and can further be corrected with internal standards added to the solvent prior to sample dilution. With appropriate sized sample introduction hardware and plasma conditions, non-volatile solvents such as biodiesel and kerosene can be analyzed directly without the need for additional sample introduction accessories. The results obtained demonstrate that this technique is very effective and efficient for determination of elemental contaminants regardless of the raw materials used to produce the biodiesel.

Abstract Text

Hair growth promoting agents are in high demand because of psychosocial effects of alopecia on human especially cancer patients undergoing chemotherapy. Plants have been employed since ancient times in traditional medicine for hair growth promotion. In this study, the leaf of Hibiscus rosa-sinensis a common herb in Nigeria acclaimed traditionally for hair growth-promoting potential was studied. The ethanolic extract of the leaves of H. rosa-sinensis was subjected to phytochemical screening using standard methods already adopted. The proximate compositions were determined by the official methods of analysis and the hair growth investigation of the ethanolic extract was carried using established protocols at concentrations of 2.5 mg/ml, 5 mg/ml and 10 mg/ml. Four groups of albino rats were used. The results of the phytochemical screening revealed the presence of alkaloids, flavonoids, tannins, phenols, steroids and terpenoids. The proximate analysis showed that the leaves have high protein (48.57%) content, carbohydrate, ash, moisture, fiber and lipids were also present in descending order. The micro and macro nutrients were determined to be magnesium (91.52 mg/100g), sodium (20.40 mg/100g), iron (12.31 mg/100g), potassium (9.70 mg/100g), manganese (8.90 mg/100g), calcium (7.57 mg/100g), zinc (4.80 mg/100g), and copper (0.23 mg/100g). Complete hair regrowth was observed after 21 days treatment with the 5 mg/ml concentration of the leaf ethanolic extract, petroleum jelly was the control. The result of this study suggests that the leaf of Hibiscus rosa-sinensis has hair growth and probably hair loss prevention potentials.

Abstract Text

Biofilms play a significant role in the emergence and proliferation of multi-antibiotic resistant bacterial strains as they protect cells from rapid exposure to antibiotics, allowing them to react to the attack by mutating at an accelerated rate or going into dormancy. Further, both physical and chemical variables affect the formation and properties of biofilms in complex and, thus far, unpredictable ways, which makes them difficult to analyze. Therefore, we are developing custom micro/nano-fluidic devices that control the formation of biofilms and combining them with surface plasmon resonance imaging (SPRi) to provide label-free, real-time, high-resolution, large-area imaging of biofilm dynamics. By changing the aspect ratio of the fluidic channels, we are able to study mature biofilms in a single plane without the need for confocal imaging.

First, Lysogeny Broth (LB) growth medium containing *Staphylococcus aureus* bacterial cells was loaded into the fluidic device. Next, the effect of flow rate on biofilm formation was investigated by flowing LB through the device at multiple flow rates. For biofilm removal experiments, the bacteria were allowed to grow and form biofilms under stagnant conditions, prior to the start of fluid flow. The entire process was monitored using SPRi. SPRi generates a gray scale image of the 1 sq. cm sensor surface with 10 micrometer resolution every 3 seconds. The brightness of points on the image is proportional to biomass density, allowing visualization of where cells are located on the surface.

This technique can be used for evaluating the attachment and removal of any microbial species, making it very versatile and adaptable for applications ranging from optimization of orthopedic implants to removing biofouling in chemical plants.

Abstract Text

Currently a dual-luciferase reporter is used to confirm multi-miRNA regulation of mRNA. However, this sensor is limited in that it can only inspect two miRNAs at a time and only one color is used to look for both miRNA. This is a signal off type sensor that is generally less sensitive than signal on approaches. Furthermore, this biosensor is only used after a laborious process of altering miRNA expression and looking at changes in downstream products to determine which miRNA are relevant to study. We have investigated development of a mimic-mRNA sensor with a three colors each corresponding to three miRNA-mRNA binding regions. The sensor works by mimicking the sequence of mRNA of interest. Then several quenchers are strategically placed along the backbone of the mimic-mRNA. Partially complementary fluorescent reporters hybridize to the mimic-mRNA near the quenchers. The partial complementary of the reporters will allow for a competition reaction between the miRNA analyte and the reporter for the mRNA binding spot. We will report on the design, selectivity, and sensitivity of the mimic-mRNA sensor to expedite discovery of multi-miRNA regulation of mRNA. A key attribute of this sensor is that precise knowledge of miRNA target sites on the mRNA does not need to be known.

Abstract Text

Image processing algorithms have been developed that extract a single, numerical representation of color from digital images in the form of the hue, or H component, of the HSV color space. This quantifiable analytical parameter has been shown to be quite robust and maintains precision when obtained with different imaging devices, under varied lighting conditions, with different colorimetric indicator concentrations, and with variable sample volumes. Because this parameter is stable, simple to calculate, easily obtained without specialized equipment (images from consumer grade scanners or digital cameras are acceptable), and amenable to high-throughput analysis we have applied it to color changing assays of biological samples. We developed a hue-based pH determination method to analyze a digital image of multiple 100 [micro]l samples in a 384-well plate after addition of a universal pH indicator cocktail. We then used in-solution isoelectric focusing to determine the isoelectric point of several proteins by applying the method to quantify the pH of these small-volume fractions. We have observed a dramatic change in the pKa of some pH indicator molecules in the presence of non-ionic surfactants often used to maintain the solubility of proteins. We have developed calibration techniques and alternate pH indicator mixtures that allow the hue-based method to achieve accurate results and avoid the use of bulky, slow, and expensive pH electrodes whose surfaces can be fouled in the presence of detergents.

Abstract Text

Light coupled into spherical dielectric resonators can exhibit resonances known as whispering gallery modes (WGM). These morphology dependent resonances occur when light traveling around the sphere returns in phase, leading to constructive interference. Efficient confinement of light is achieved when the proper resonant conditions are met which is dependent upon various factors including the effective refractive index. The ability of WGM resonators to be utilized as sensitive refractive index detectors has prompted interest in using WGM platforms for label-free biosensing. To employ WGM resonators as label-free biosensors, biological recognition elements are attached to the sphere surface. The effective refractive index is altered due to an antigen-antibody binding event, which results in a measureable WGM resonance shift. In this study, the high sensitivity, small size and flexibility of WGM microsphere resonators is explored through the development of label-free biosensing platforms. Recently, a multiplexed WGM biosensing platform was demonstrated where WGM resonances were measured through fluorescence imaging. Multiplexed detection of ovarian cancer biomarkers was achieved by imaging a field of microspheres, where the antigen identity was encoded in the resonator size. Current work focuses on taking advantage of the small resonator size by developing small volume, label-free biosensing platforms. Reducing the total volume allows for minimal sample requirements, monitoring real time binding events, and rapid analysis time. Additionally, small microsphere resonators can be easily integrated as sensitive refractive index detectors for novel imaging modalities. Progress on the development of these WGM label-free biosensing platforms will be presented.

Abstract Text

MicroRNA (miRNA) are short, non-coding RNA strands that are involved in a wide variety of processes, such as cell-to-cell communication, gene expression and gene silencing. The under- or over-expression of various miRNA could result in a variety of abnormal states, such as cancer. As a result, being able to quantitate miRNA levels is essential to early-stage disease detection. However, a single miRNA strand could be involved in several gene expression pathways. Probing multiple strands simultaneously is needed to proper diagnosis of abnormalities. In addition, the perceived ranges of healthy miRNA levels can span several orders of magnitude, making early stage detection difficult. If the levels of miRNA bound to a particular carrier could be quantified, it could be possible to narrow the healthy range for a particular strand, and allow for earlier and more accurate diagnostics.

Asymmetrical flow field-flow fractionation, being a purely size based separation technique, is well suited to localizing miRNA to particular carriers (protein, lipoprotein complexes, vesicular) without disturbing the miRNA-macromolecular complex. A method was devised to fractionate pure serum into several fractions for miRNA localization. After extraction and quantitation, the profile of four miRNAs (associated with breast cancer) across the fractions was compared between healthy and diseased patients. The expression levels of miRNA were as expected between healthy patients and patients with breast cancer. Differences in the miRNA profile across the six fractions made it possible to determine which fractions may be most important for a particular miRNA strand.

Abstract Text

Bacterial and viral infections are among the top 10 most common reasons for hospital visits [1] yet are often misdiagnosed [2]. There is a need for analytical tools which can distinguish between bacterial and viral infections as their misdiagnosis has high costs on human health. Recently, the CDC named antibiotic resistance as an immediate threat to human health and among other actions prescribed improvement of antibiotic use [3]. We report here a carbon nanotube field-effect transistor/chemiresistor for the quick, cost-effective and accurate detection of bacteria. Carbon nanotubes were immobilized through a drop-cast method onto gold-patterned Si/SiO₂ substrates and functionalized with different lectins, sugar binding proteins, targeting carbohydrates present in the outer membrane of the bacteria for capture. This allows for diagnosis of infection on a broader scale. A change in device resistance indicates successful bacteria capture. Devices incubated with virus do not show a change in resistance. On the other hand, devices incubated with E. coli K12 bacteria resulted in a linear response with logarithmic cell concentration. Development of such biosensors which can distinguish between bacterial and viral infections are beneficial to decreasing the number of misdiagnosed infections and antibiotic misuse by providing an empirical test to determine infection type and screen antibiotics for efficacy.

Abstract Text

The demand for a rapid and sensitive detection method of bacteria is growing significantly in biological, biomedical and clinical fields. Due to their shorter detection time and higher sensitivity over the conventional methods, impedimetric sensors modified with biorecognition molecules have been used for detection and quantification of bacteria. This presentation will describe the design and development of an antimicrobial peptides (AMP) based impedimetric sensor for the detection and quantification of bacteria. The sensor showed different impedimetric responses to various bacterial strains, which may relate to different affinities of the synthesized peptides for various strains. The detection limit of the sensor is 10^2 CFU/mL for the four strains. Scanning electron microscopy (SEM) was used to further examine the binding mechanism and the morphology of the AMP modified substrate surface. The relationship between the AMP immobilization process as well as orientation of the peptides and the sensor performances will be discussed. This presentation will demonstrate the potential use of synthesized AMP in impedimetric sensors for bacteria detection.

Abstract Text

A phospholipid nanogel additive was used to aid in the separation, detection and species determination of various *Aspergillus* species from PCR amplified clinical isolates in a rapid and portable device. Conventional methods for detection of an *Aspergillus* infection are cell cultures, antibody assays, imaging procedures and biopsies, which can be time consuming and may not offer species identification [1]. *Aspergillus* infections have a 90% mortality rate of immunocompromised or critically ill patients; therefore, accurate identification is important [2, 3]. Use of phospholipid nanogels with traditional benchtop capillary electrophoresis has determined 7 species of *Aspergillus* with 2 base pair resolution [3]. In a microfluidic device these additives can control valves and have been used in the separation of mannose sugars samples [4]. This unique phospholipid nanogel is thermally actuated, easily entering the channel as a liquid at 19 °C and forming a gel in-channel at 29 °C [4]. Unlike traditional polymer gels, this allows for quick removal and replacement at 19 °C, and the creation of a temperature gradient of the separation matrix in the microfluidic channel [5]. Once heated in the channel the phospholipid nanogel acts as a pre-concentrator, stacking injected sample at the buffer – nanogel interface. The use of phospholipid nanogel in a microfluidic chip allows for a rapid and portable method for detection *Aspergillus* species with internal DNA standards, generating 550,000 theoretical plates per meter. This presentation discusses the advancement and application of nanogels for stacking, separating and determining of *Aspergillus* species.

Abstract Text

Capillary electrophoresis (CE) is an excellent analytical separation method with promising features such as small sample volume ([micro]L to pL), fast analysis time (s), high selectivity and efficiency, and excellent compatibility with biological samples. However, the inability of conventional CE detectors to sense biologically active compounds that are optically and electrochemically inactive limits their use for drug screening. We have developed a highly stable electrophysiological detection platform consisting of ion channel (IC) reconstituted in synthetic bilayer membrane or BLM across a functionalized microaperture to be coupled to a high resolution capillary separation channel. Further, the BLM platform was enhanced by > 5 fold using photopolymerizable monomers partitioned into the lipid membranes. Additionally, we have developed ion channel coupled receptor fusion protein towards wide range of ligand detection in BLM sensor platforms. The pharmacology of IC functionalized with muscarinic acetyl choline and dopamine receptors using cell based assay by patch clamp electrophysiology showed activation by acetylcholine and dopamine. Thus this platform holds a great promise as the next-generation integrated analysis system for rapid screening of biologically active compounds (eg. glucagon) in complex matrix such as whole blood and urine for the diagnosis and management of chronic disease such as diabetes.

Abstract Text

Adipose tissue is traditionally thought to be used for storage of triglycerides, but recent discoveries suggest that adipocytes contain chemical messengers important to the endocrine system. Amino acids are thought to serve as messenger molecules in adipose tissue, much like neurotransmitters in the brain. Of particular interest are the branched chain amino acids (BCAAs): isoleucine, leucine, and valine, because evidence suggests they are highly regulated in adipose tissue. The dysregulation of these amino acids, often seen in obesity, has been correlated to the development of diabetes and other metabolic disorders. We have developed a high-speed online microdialysis assay for analyzing secretion and uptake of amino acids in adipocytes. Currently there are no adequate methods to measure these dynamics. Human pre-adipocytes, as well as 3T3-L1 cells, have been cultured and differentiated into mature adipocytes and their relative extracellular BCAA concentrations have been analyzed. Secreted amino acids are sampled using microdialysis and labeled with 4-fluoro-7-nitro-2, 1, 3-benzoxadiazole (NBD-F) in an online reaction. Microdialysis is coupled, online, to high speed capillary electrophoresis (MD-CE) and detected using laser induced fluorescence (LIF) at 488 nm, which allows for analysis of cellular secretions with a temporal resolution of less than twenty seconds. Separation conditions have been optimized for the separation of the BCAAs. The method presented allows for the detection of cellular response in response to other extracellular signaling molecules, such as glucose or insulin.

This project is funded by National Institutes of Health Grant R01-GM063533-10.

Abstract Text

Characterized by late clinical presentation, significant co-morbidity and poor long-term survival, epithelial ovarian cancer (EOC) remains a serious medical concern to women. We have used three variants of the aptamer selection (SELEX) process to identify new functional oligonucleotides that recognize ovarian cancer biomarkers. Cell-SELEX has been used to select aptamers for cell-associated mesothelin and MUC16, two proteins implicated in metastasis and immune suppression. CE-SELEX was used to select aptamers for HE4, an informative serum marker. Finally, we have developed a novel "one-pot" selection method in which the gold standard ovarian cancer biomarker, CA25, is the target. In each case, the selection process concluded with the interrogation of the selected DNA pool by high-throughput sequencing. This sequencing process yields significantly more insight on the selection process than the conventional sequencing that has traditionally been used at the end of the SELEX process. We have developed a set of bioinformatics tools that enable the most enriched aptamer candidates to be identified. Affinity probe capillary electrophoresis, fluorescence anisotropy and label-free immunoassay platforms are currently being used to assess the affinity of the selected aptamers for their targets. We acknowledge support from the National Cancer Institute.

Abstract Text

Given the clinical importance of tyrosine kinases (TKs) as drug targets in a host of human diseases, demand is high for new and improved TK assays in primary samples. Heterogeneous TK activity within populations of primary cells, and thus heterogeneous response to clinical TK inhibitors, requires direct assays of TK activity at the single cell level. We present a direct chemical cytometry assay for Epidermal Growth Factor Receptor (EGFR) TK activity and demonstrate its application in single A431 epidermoid carcinoma cells. The foundation of this assay is a short synthetic peptide substrate Htc-tide, whose phosphorylation by EGFR in single cells is quantified by single cell capillary electrophoresis with LIF detection. Htc-tide differs from traditional TK peptide substrates in the introduction of conformational constraint of the peptide backbone at the phosphorylation site. The conformational constraint is well tolerated by EGFR, but discourages assay interference by many off-target enzyme activities including protein tyrosine phosphatases and cytosolic peptidases. Dephosphorylation of phosphorylated Htc-tide by tyrosine phosphatases is significantly less efficient compared to the native tyrosine analog Tyr-tide ($k_{cat}/K_M = 2.3$ vs. 3500 for PTP1B), resulting in a major reduction of PTP assay interference. We apply the Htc-tide-based assay to directly quantify EGFR activity in single intact A431 cells and show the ability to detect fewer than 10^{-20} mol of phosphorylated reporter in individual cells.

Abstract Text

Enzymes are used to determine the sequence of glycans. Studying glycans sequence is important because change in glycosylation pattern of glycans is the hallmark of cancer and analyzing the glycan composition is essential to therapeutics [1,2]. Neuraminidase an important enzyme used to evaluate and control sialic acid content. Traditional methods of enzyme characterization use milliliters of enzyme which require several hours for the reaction to be completed. By using capillary electrophoresis, the amount of enzyme required for analysis is reduced to nanoliter levels and enzymatic processing is complete in minutes. Phospholipid additives DMPC and DHPC were used to perform complex glycan separations [1-3]. These phospholipids self- assemble to form a thermally reversible pseudogel. Furthermore, these preparation have fluid like properties at lower temperatures and becomes viscous gel at higher temperatures [4]. Fluorophore labeling is done for the oligosaccharides to increase the charge-to-size ratio for faster separation. Neuraminidase catalytically cleaves the sialic acid from the non-reducing end of the oligosaccharide. Currently the neuraminidase being studied preferentially cleaves α 2,3 and α 2,6 bonds. The goal of the present study is to utilize enzyme specificity and to evaluate the catalytic efficiency of different neuraminidases.

Abstract Text

Sub-micron silica colloidal crystals form uniform packing on a planar system. Eddy diffusion is greatly reduced in such uniformly-packed bed. Band broadening caused by slow mass transfer is reduced by using non-porous particles. Thus, fast and efficient electrophoresis can be achieved in silica colloidal crystals. This technique can be further improved by using label free detection. This can be achieved by in-gel protein immobilization, followed by on-column western blotting.

Abstract Text

Subcellular liver fractions (“microsomes”) act as an excellent in vitro system to study drug and xenobiotic metabolism. Hence, developing microsomes-based green bioreactors to synthesize drug metabolites for pharmacokinetic evaluation, and microsomal biosensors for pollutant screening possess enormous significance in human health and environment. In order to achieve efficient electrocatalytic properties of microsomes, electrons should be injected to the metabolic enzymes (e.g. cytochrome P450) present in microsomes. Our goal is to drive the metabolic reactions of microsomes electrochemically by simple application of potential without requiring expensive NADPH cofactors. Our prior work identified that polished high purity graphite and edge plane pyrolytic graphite electrodes featuring high surface defects were suitable to directly adsorb microsomes with good electronic connectivity and bioactivity. In the present study, our objectives are to achieve high density immobilization of microsomal fractions to enhance product yields in the electrocatalytic conversion of drugs, and additionally offer highly sensitive biosensors. For this, we are investigating two strategies: In the first one, microsomes are bound to conductive, large surface area carbon nanostructures; in the second approach, microsomes are attached to magnetic nanomaterials and immobilized on electrodes. Direct electrochemical and electrocatalytic properties of these microsomal systems combined with nanomaterials will be discussed.

Abstract Text

We work with tethered membranes which are planar supported phospholipid bilayers held above a gold electrode by a set of hydrophilic polyethylene glycol (PEG) chains covalently bonded to the gold surface by organic disulfide anchors. A lipophilic alkane phytanyl group is bonded to the top of some (typically 1 – 10%) of the PEG chains (these are the tethers) which then act as a scaffold around which the membrane lipids spontaneously cluster, eventually forming a continuous layer.

These tethered systems have been found to be good models for the study of natural cell membranes. They can accommodate both small ionophores and large ion channel proteins, and thus provide a controlled system for the study of the transmembrane ion transport. In particular it is easy to add just one type of ionophore, or protein to the system so that it is clear that results come from a single type of molecule.

We have been using an EIS (electrochemical impedance spectroscopy) method to determine membrane conductivity values. These values are particularly sensitive to the nature and concentration of ion channel or ionophore added, as well as to the presence of other membrane active species such as cholesterol.

Several case studies will be presented to highlight the versatility of the system and the insights that the EIS measurements can provide.

Abstract Text

Genotoxic impurities (GIs) cost the pharmaceutical industry billions of dollars a year, are carcinogenic, highly toxic and are often difficult and expensive to detect and remove from active pharmaceutical ingredients (APIs). It is imperative that new multidisciplinary approaches for detection and removal be adopted as current techniques such as mass spectrometry and high pressure liquid chromatography are labor intensive and suffer from long analysis times. In this work, a flow injection analysis approach with electrochemical detection is utilized for hydrazine quantitation in the presence of excess electrochemically active APIs. It is possible to screen out the interfering effects from APIs via functionalization of a polycrystalline boron doped diamond microband electrode with metallic nanoparticles as shown in Figure 1.¹ Coupling of this electrode with FIA produces a tuneable sensor with high signal to noise ratio, fast data acquisition and small sample requirement. Our results demonstrate hydrazine quantitation down to 64.5 nM (274 ppb) in the presence of excess acetaminophen (50 mM), surpassing the limits of detection required by pharmaceutical guidelines,² without the need for excessive sample preparation or derivatization.

Figure 1. Voltammetric response of GI (hydrazine, black) and API (promazine, red) on Au/Pt nanoparticle functionalized polycrystalline boron doped diamond.

Abstract Text

According to the 2012 statistics from the American Diabetes Association, 9.3% of the population in the United States suffer from diabetes. This metabolic disorder arises either from insulin deficiency (Type-1, insulin dependent) or insulin resistance (Type-2, insulin non-dependent). Insulin, a polypeptide hormone, maintains glucose homeostasis and its concentration levels (picomolar) in the body fluids can help in diagnosing the type of diabetes. Our objective is to develop a sensitive, simple electrochemical quartz crystal immunosensor for detecting insulin levels in clinical samples. We have devised magnetic nanoparticle-antibody-antigen bioconjugates to accomplish direct diabetes relevant picomolar insulin detection in whole blood by a sandwich immunoassay. The sensor outputs are based on changes in oscillation frequency and double layer capacitance. The designed immunosensor enabling dual mode measurements adds good sensitivity and reproducibility for detection of insulin in a complex biological fluid and thus presents a promising platform for clinical applications.

Abstract Text

Nitrogen-doped carbon nanotubes (N-CNTs) provide an excellent platform for the electrochemical detection of enzymatically generated hydrogen peroxide. Glassy carbon electrodes were modified with 7.4 wt% N-CNTs and used to immobilize glucose oxidase (GOx) through spontaneous adsorption; the enzyme's catalytic rate was then detected through amperometric oxidation of the enzyme catalyzed H_2O_2 byproduct. Inhibition of GOx by heavy metals ions such as Ag^+ was detected by percent decrease in amperometric current down to a 0.19 ± 0.04 ppb limit of detection (± 3) in phosphate buffer solution. The Ag^+ sensor displayed a sensitivity of $2.00 \times 10^8 \pm 0.06 \text{ M}^{-1}$ at a low operating potential of 0.05 V (vs. Hg/HgSO₄), a linear range of 20 - 200 nM, and sample recovery at $101 \pm 2\%$. Interestingly, the sensor experienced no loss in sensitivity with continued use; due to the inhibition based detection scheme, the loss of enzyme with each use is inconsequential. Cu^{2+} and Cd^{2+} were found to be much less inhibitory with sensitivities of $1.45 \times 10^6 \pm 0.05 \text{ M}^{-1}$ and $2.69 \times 10^3 \pm 0.07 \text{ M}^{-1}$, respectively. The inhibition constants (K_i) and modes of inhibition were determined for both Ag^+ and Cu^{2+} , and a strong correlation between K_i and sensor sensitivity was found.

Abstract Text

Nanomaterials have received much attention for their outstanding catalytic activity, large surface area, and excellent photonic and electronic features. These characteristic properties have been used to improve the sensitivity and the specificity of biosensors. In our work, we used advanced nanomaterials such as graphene, quantum dots and gold nanoparticles to assemble on the surface to construct new biosensors for the determination of biomolecules and tumor cells. Based on the above principles, a new electrochemical assay strategy was proposed based on the specific recognition of folate receptors on a cell surface to folic acids CdSe/ZnS quantum dots (QDs)-labeled folic acids (FAs) can couple with the folate receptors (FRs) on the KB cells, which can overexpress FRs. By square wave stripping voltammetry (SWSV), the developed electrochemical assay showed an excellent analytical performance for the sensitive detection of KB. We also proposed a novel and sensitive label-free aptasensor has been developed based on direct electrodeposition of gold nanoparticles (AuNPs) on NH₂-graphene modified glass carbon electrode for the determination of adenosine triphosphate (ATP). These deposited AuNPs produced a sharp electrochemical current peak, which can be used as probes for the detection of ATP. The graphene/AuNPs based-aptasensor is sensitive, selective and stable and has a wide linear range from 10 pM to 100 nM, with the detection limit of 10 pM. These proposed sensing strategies should offer a new way for directing the development of an electroanalytical chemistry and will have the potential applications in clinical diagnostics and biotechnology.

Abstract Text

The multifaceted environs in which cells interact are highly differentiated, and susceptible to extreme changes that require cellular survival, division, differentiation, or death. These responses are not limited to only one cell, but are usually a group response, dictated by the change in signal molecule concentration. Therefore extracellular molecular signaling is paramount to the survival and destruction of cellular organisms. Yet, there is a shortage of methods for the direct, in vitro correlation between observed changes in cell behavior and proliferation to extracellular molecular signal (ECMS) concentration. This is subsequently due to the lack of small scale culture methods needed to confine cells to isolated small volumes (pL- μ L) to explore spatial and populations/density relationships within/between cellular colonies, and the low detection limits required for valid results.

Efforts toward quantification of ECMS concentration relative to observed cell behavioral changes within microenvironments via electrochemistry are described. The electrode material is a carbon based optically transparent electrode made from pyrolyzed photoresist film (PPF). The strategies discussed include using a laser based technique to photocrosslink a protein fabrication solution into μ 3D-protein hydrogel structures around cells, confining cells within 3D volumes on the electrode surface, and micropatterning the electrode to improve detection limits for ECMS target molecules. The electrode will be used to make in vitro voltammetric and amperometric measurements of cell colonies isolated within 3D structures. Fluctuations of the electrochemical signal combined with optical microscopy could link the electrochemical signal generated from a specific signal molecule to observed cellular behavior in real time. Target molecules discussed include nitric oxide, NADH, hydrogen peroxide, and oxygen.

Abstract Text

Certain virulence factors, produced by bacteria, can be sensed via electrochemical detection. Detection of these factors can be used for rapid differential diagnosis of bacterial infections, leading to the application of targeted antibiotics. Here we report the selective and sensitive detection of pyocyanin, uniquely produced and excreted by the opportunistic pathogen *Pseudomonas aeruginosa*, using unmodified carbon electrodes embedded in Kings A agar. Compared to visual inspection, which usually requires 24-72 hours for identification, electrochemical sensing allows conclusive identification, starting from as few as 100 cells, in less than 18 hours. The identification time can be reduced further by optimizing the plate geometry and improving electrochemical sensitivity.

Disposable screen printed electrodes were embedded into culture plates, by pouring sterilized King's A agar over them. King's A agar is known to increase the production of pyocyanin. Square wave voltammetry (SWV) scans of the virulent *P. aeruginosa* strain PA14 were taken every hour. Optical images of the cultures were collected to determine when *P. aeruginosa* could first be detected visually.

In the potential range from -0.5 to 0 volts, no molecules other than pyocyanin (in *P. aeruginosa* cultures only) were detected. To confirm selectivity, SWV scans were obtained from *Staphylococcus aureus*, one of the most common pathogens. Temperature dependent production of pyocyanin was observed, with the highest production rates and earliest detection times for *P. aeruginosa* at temperatures above 37 degrees Celsius. The results indicate the potential for sensitive and selective electrochemical determination of *P. aeruginosa* infection directly from patient samples. By integrating detection with a commonly accepted format, we hope that this technique will be rapidly adopted and utilized by the healthcare industry.

Abstract Text

Pharmaceuticals and personal care products (PPCPs) are used for a wide variety of applications. U.S. Geological Survey published a screening study results in water in 2002. Detectable PPCPs were found in 110 out of 139 susceptible streams in 30 states in USA. Due to large amount of PPCPs that may have been transported to natural water resources, the removal of PPCPs in source water and drinking water becomes important.

An Ultra-fast and sensitive UFLC-MS/MS method was developed for the detection of 6 selected PPCPs, including azithromycin, cephapirin, enrofloxacin, ciprofloxacin, diphenhydramine and cotinine. Different powdered activated carbons (PACs) including Super activated carbon nano powders (raw material coconut) Aqua Nuchar (AN) and Hydrodarco B (HB) were used to remove the selected PPCPs. Different pHs water matrices, dosing concentrations, and contact times were evaluated. HB at the dosage 2 mg/L removed over 60% of azithromycin, cephapirin, enrofloxacin, ciprofloxacin and diphenhydramine have over 60% removal after 4 hours contact time. For AN, the removal trend of the PPCPs was the same for most of the selected PPCPs but with higher removal efficiency except cephapirin compare with HB. Cotinine could not be removed by any of the tested PACs under the experimental conditions in this study. The detailed experimental conditions, interferences, and results will be presented at the conference.

This research was supported by Missouri Department of Natural Resources.

Abstract Text

Disinfection byproduct anions, such as chlorite, bromate, and chlorate are predominantly produced from chemical disinfectants used to treat potable water systems. Bromate is a byproduct from the ozonation of waters containing bromide. The U.S. EPA listed bromate as a probable human carcinogen at low ppb concentrations. Based on available toxicology data, the U.S. EPA has specified a maximum contaminant level (MCL) of 10 ppb for bromate and 1000 ppb for chlorite. In a previous study, we demonstrated the advantages of use a hydroxide-selective anion exchange column for the determination of bromate and other oxyhalides, such as a lower background, lower noise, and therefore lower detection limits relative to using a carbonate eluent that is described in U.S. EPA Method 300.1 (B). Additional improvements in column and suppressor technologies over the last several years has enabled even lower detection limits and better resolution of oxyhalides and bromide in drinking water samples. In this report, we demonstrate this determination using a recently developed hydroxide-selective column combined with electrolytically regenerated suppressed conductivity detection. The calculated method detection limits for chlorite, bromate, chlorate, and bromide in this study were determined to be 0.1, 0.12, 0.14, and 0.21 ppb, respectively. To determine the accuracy of the methods, drinking water samples were spiked with known concentrations of oxyhalides and bromide, which produced recoveries ranging from 83-92%, 93-108%, 93-101%, and 91-100% for chlorite, bromate, chlorate, and bromide, respectively. The linearity, accuracy, and precision for the determination of oxyhalides and bromide will be discussed further in this report.

Abstract Text

The photoionization detector (PID) is a very sensitive GC detector for sulfur compounds with pg detection limits for hydrogen sulfide. This compound can be efficiently collected in the field in an impinger with a basic solution (0.01M NaOH) at a known period of time and flow rate. The solution should be kept out of sunlight. Back in the lab, since the pKa for H₂S is 6.9, the addition of 0.1 M acid will convert the sulfide (collected) to H₂S which can be swept out of a vessel with an inlet, exhaust and septum (for addition of acid {H⁺}). Once the H⁺ is added, the solution is stirred for several minutes, then the nitrogen is turned on at 15 cc/min/ and the H₂S is swept into the sample loop of the six port GC injection valve. The H₂S is separated on a porous polymer column and detected by the PID. A 10ng/L sample (permeation tube) of H₂S collected for 10 minutes indicated a detection limit (3 sigma) of 0.9 ppb. The coefficient of variation at 25 ppb was 16.3% for 5 successive runs. The PID has a dynamic range > 10⁷ so a high level stack sample (200 ppm) would still be in the linear range with a slightly shorter sampling time.

Abstract Text

In indoor air measurements, volatile organic compounds (VOCs) are major hazardous pollutants originating from emission of building materials. An important group is the semi-VOCs (SVOCs). These components, such as the phthalates, have boiling points between 240-260°C to 380-400°C (ISO 16000-61) and low vapour pressure. To guarantee the Quality Assurance and Quality Control (QA/QC) and therefore the accuracy of their measurement, gas standards in the form of transfer reference materials are necessary.

This presentation gives an overview of the recent developments and challenges in the preparation of a selection of VOC and SVOCs gas standards at trace levels (few ppb levels) and their loading into sorbent tubes. In addition, details of their analysis by will be showed.

The preparation consists of dynamic blending of vapours of VOCs and SVOCs with clean air followed by pumped sampling of know volumes of this gas mixture into thermal desorption type tubes. During the study, the loading levels varied from 30 to 500 ng of respectively styrene, n-hexadecane, dibutyl phthalate, dimethyl phthalate, 2-ethyl-1-hexanol, 1-methyl-2-pyrrolidone. The method of analysis of the standards tubes consisted of thermal desorption followed by GC-FID analysis.

The results of the study show that it is possible to obtain SI traceable gas standards at trace levels with an expanded uncertainty between 3 and 5 %. This research was part of the MACPoll project under the European Metrology Research Programme.

Abstract Text

People with chronic kidney disease suffer from the uremic toxins which accumulate in their bodies. Detection and quantification of the uremic toxins helps diagnose kidney problems and start patient care. The aim of this research was to achieve trace level detection and separation of uremic toxins in water and urine. Some uremic toxins contain guanidino groups, which in neutral aqueous environments are protonated. To detect and quantify the guanidino containing uremic toxins, new stationary phases for ion chromatograph (IC) columns were prepared. The separation materials were based on glutamic acid functionalized resorcinarenes (GAU) bound to a 4.6 μm divinylbenzene macroporous resin packed in a 3 \times 150 mm PEEK column. Two different packing methods, one using sonication and the other using grinding, afforded fast and efficient separation of the five compounds: guanidineacetic acid (GAA), guanidine (G), methylguanidine (MG), creatinine (CRN), and guanidinobenzoic acid (GBA). Isocratic and gradient elutions with methanesulfonic acid (MSA) solution as eluent resulted in fast separation of guanidino compounds on packed GAU column. The column efficiencies, reported as the number of theoretical plates which shows significant plates number for our designed IC column. The peak resolutions at room temperature and elevated temperatures were calculated and reported. Trace levels of analyte were detected directly by electrochemical detection with a gold working electrode in urine sample. Quantitative calibration showed linear curves for the gold working electrode in water, urine and elevated temperature. Pulsed amperometric detection method successfully measured analyte concentration from 30 to 158 ppb in water and 93 to 591 ppb in urine at room temperature.

Abstract Text

The toxicity, microbial resistance, and unforeseen adverse effects in the environment, induced by pharmaceuticals, necessitate a comprehensive study of abatement, degradation pathways, and toxicity changes of each target pollutant during advanced oxidation processes (AOPs). The selected AOPs included UV-based and O₃-based (e.g. UV, UV/H₂O₂, and O₃/H₂O₂) technologies, which have shown great potential for effectively removing pharmaceuticals from sewage effluent. Six frequently detected pharmaceuticals in sewage effluent, including sulfadiazine (SDZ), norfloxacin (NOR), trimethoprim (TMP), metoprolol (MET), roxithromycin (ROX), and caffeine (CAF), were selected for this study. The removal efficiency and degradation kinetic studies were conducted using liquid chromatography tandem mass spectrometry (LC-MS/MS). The abatement and degradation byproducts of these pharmaceuticals by the selected AOPs were studied using liquid chromatography time-of-flight mass spectrometry (LC/Q-TOF-MS) to propose degradation pathways. In addition, this project has evaluated the pollutant removal efficiency, energy consumption, and operation factors of the different AOPs and determined the most applicable method. This research was supported by National Science Foundation East Asia Pacific Summer Institutes (Grant #1414954) in collaboration with the Chinese Ministry of Science and Technology, and the National Natural Science Foundation of China (Grant #51221892).

Abstract Text

The increase in U.S. natural gas production can be largely attributed to the extensive use of hydraulic fracturing (also known as fracking). This process extracts natural gas and oil by drilling into bedrock (primarily shale) several thousand feet below the surface and then injecting fluid under high pressure causing cracks to form. As a result, trapped oil and gas is released that can then be recovered. Hydraulic fracturing requires large quantities of water, putting stress on local sources, and produces large amounts of wastewaters, which must be either disposed of or reused. Treatment and reuse has significantly reduced the water and disposal requirements of this process. Knowing the composition of ions in wastewater can be used to develop effective treatment strategies and optimize fracturing fluids that are created from this water. Additionally, this information can be used to meet stringent local reporting requirements for fracturing activity. This presentation describes the use of ion chromatography (IC) to determine anions and cations in produced water from three different hydraulic fracturing sites. Considerable variation in ion concentration was found, which was attributed to differences in the geology of the locations from which samples were obtained.

Abstract Text

This research presents the use of a low detection limit μ GC for field investigation of individual VOC time-dependent concentration trends in residential areas near a petrochemical industrial park at central Taiwan. The prototype μ GC is previously developed in our group which equips a multi-stage mini-preconcentrator with amplification factor > 10,000, a capillary column with at-column heater configuration, and a photo-ionization detector (PID). An in-lab calibration shows that detection limit of μ GC is 0.02 ppb for benzene. A tablet computer was embedded inside the μ GC which enables the system to be remotely controlled and read out by a cell phone via wireless internet. The μ GC weights less than 3 kg and consumes only 15 W on average during analysis. The field study data was obtained by using the μ GC continuous analysis (24 hr) at two different sites (school and residence) located approximately 3 km away from a petroleum chemical industrial area. Side-by-side canister/GC-MS was used to provide qualitative reference. Six VOCs including acetone, chloromethane, methyl t-butyl ether, hexane, toluene, m/p-xylene were found at first site. Three VOCs including, acetone, 1,3-pentadiene, toluene were found at second site. The concentration range varied from 0.5 to 4.8 ppb for most VOCs. The chemicals resulted from either traffic sources or industrial area can be seen with different time patterns. This newly developed μ GC enables continuous and near-real-time VOC analysis at sub-ppb level with very low cost per analysis which can be useful for tracking time-dependent trends for individual pollutants.

Abstract Text

Between July 9 – 12, 1997, at least 400 tonnes of polyvinyl chloride (PVC) were consumed in a fire at the Plastimet Inc. plastics recycling facility in Hamilton, Ontario, Canada. This led to the release of contaminants, including highly toxic polychlorinated dibenzo-p-dioxins (PCDD) and dibenzofurans (PCDF). This study re-examines a composite soil sample collected shortly after the fire using state-of-the-art FT-ICR (Fourier transform ion cyclotron resonance) and GC×GC-TOF (comprehensive two dimensional gas chromatography-time of flight) mass spectrometry. The FT-ICR experiments led to the identification of approximately 150 molecular formulae, corresponding to chlorinated and mixed chloro/bromo compounds. The majority of these are halogenated polycyclic aromatic hydrocarbons (halo-PAHs), including highly substituted (e.g. C₁₄HCl₉ and C₁₆HCl₉) and high molecular weight (e.g. C₂₈H₁₂Cl₄) Cl-PAHs that have not been reported previously in environmental samples. Complementary GC×GC-TOF experiments resolved individual halo-PAHs, some of which were confirmed with available standards. The concentrations of the most abundant halo-PAH groups, C₁₄H₈Cl₂ (22 µg/g) and C₁₆H₈Cl₂ (20 µg/g) are much higher than reported dioxin values and comparable to the corresponding PAH groups C₁₄H₁₀ (12 µg/g) and C₁₆H₁₀ (19 µg/g). The high abundance of the halo-PAHs identified in this study highlights the need for further investigation into their environmental occurrence and risk.[sup][sub]

Abstract Text

The objective of this research is to develop an analytical method for the identification of emerging contaminants of concern, such as bio-terrorism analytes, illicit drugs and metabolites and other toxic compounds. Due to the wide range of compounds of interest, the methodology of analysis must be able to successfully characterize compounds in a complex sample. In order to achieve this level of sensitivity and selectivity, both Comprehensive Gas Chromatography coupled with Time-Of-Flight Mass Spectrometry (GC x GC-TOFMS) and High Performance Liquid Chromatography couple with Time-Of-Flight Mass Spectrometry (HPLC-TOFMS) were utilized to analyze wastewater samples obtained from the Pennsylvania State University wastewater treatment facility (WWTF). The ultimate goal is to determine emerging contaminants and define temporal and spatial characteristics of usage at the community level.

In addition to the development of a method for the identification of contaminants, the environmental transport and fate of identified contaminants was investigated to determine the potential implications of identified compounds. Plant and soil samples from the Pennsylvania State University agricultural fields, which use an open-loop water system, were collected to refine analytical methodology.

Multiple water samples were gathered from different stages throughout the Penn State WWTF and treated with USEPA method 3510c, which uses a liquid-liquid process and Kuderna-Danish to concentrate samples to 1 mL. The normalized background developed in earlier stages was used to identify any new contaminants emerging in the wastewater samples.

Abstract Text

Forensic investigation of hazardous substances is essential for effective response to chemical spill emergencies or other accidents. Rapid and accurate identification of unknown emergency samples is always a challenge because there is usually little background information available to select the appropriate sample preparation and analytical methodology. In addition, the samples are often chemically complex and have been altered by the environment, and particularly, the potential target compounds are often co-eluted with interfering substances during an instrumental analysis. At present, the identification of the organic substances is mainly based on information from analyses by gas or liquid chromatography coupled with mass spectrometry (GC/MS). However normal low resolution single quadrupole MS typically provides less conclusive information. At the same time, time-consuming extraction and cleanup are not suitable for the rapid analysis of emergency samples.

This work presents our studies on the application of the latest chromatographic and spectral technology in identifying unknown hazardous substances. The Agilent 7200 gas chromatography coupled to an accurate-mass quadrupole time-of-flight (GC/Q-TOF) mass spectrometer inherits both advantages of powerful separation of GC and rapid and accurate TOF detection. GC/Q-TOF simultaneously provides a good tool for solving complex analytical problems, resolving structural elucidation of unknowns, and confirmation of non-target compounds. Preliminary results demonstrate that accurate mass information not only enables a rapid and efficient screening of target and non-target compounds and increases detection selectivity, but also improves the quantitation confidence by eliminating those interferences presented with nominal mass chromatograms.

Abstract Text

There are several Environmental Protection Agency (EPA) volatile methods. The sample introductory technique specified by the EPA is Purge and Trap (P & T). This presentation will focus on enhancements to these methods utilizing new P & T techniques and advancements in Gas Chromatography/Mass Spectrometry (GC/MS) technology.

In addition to providing improved productivity for the industry, the results attained using alternative carrier gases such as hydrogen and nitrogen will be compared to helium. This is advantageous due to the difficulty of obtaining helium, and the exorbitant price of helium, the current carrier gas, used for this method.

Improvements to analytical parameters, in addition to comparing results from alternate carrier gases, will be discussed.

Abstract Text

In the summer of 2009, the FDA obtained authority to regulate the manufacturing, distribution, and marketing of cigarettes and smokeless tobacco products. The Family Smoking Prevention and Tobacco Control Act was passed to reduce the trend of new users forming an addiction to tobacco before they were of the age to have an understanding of the toxic and even deadly consequences. However, other tobacco products, such as hookah apparatuses, water pipe tobacco, e-cigarettes, and other tobacco or tobacco free alternatives were not controlled until very recently, April 24th, 2014, when the FDA announced they were in the beginning phases of supervising the new alternative cigarette niche. Shisha Steam Stones are one alternative tobacco product the CDC currently admits to having no available research. These small pebble-like rocks are coated in a viscous flavored formulation, consisting mostly of glycerin, which is placed in a hookah head as an alternative to hookah tobacco. In order to analyze for the volatile organic compounds in hookah tobacco smoke, solid phase micro extraction (SPME) was used in tandem with gas chromatography mass spectrometry (GCMS). A smoking machine was constructed to mimic a hookah apparatus, where the smoke passed into miniature cold vacuum trap suspended in a dry ice + acetonitrile cold bath at -40°C and collected in NMR vials cut to a length of 2 centimeters. The VOCs found in tobacco and steam stone smoke differed substantially, specifically with the absence of nicotine and other toxic compounds in the steam stone smoke.

Abstract Text

[b]Significance of the Research[/b]: Ambient air is polluted by many VOCs coming from Petrochemical Industry. PAMS, Oxygenated or Halogenated VOCs can be found in many ranges of concentration between background and site fence line. These compounds are precursors of ozone and Industrial bodies need to identify them to be in compliance with the authorized limits and to improve their process.

[b]Objectives[/b]: Chromatotec is developing a system capable of measuring on line and in field conditions a large number of VOCs from ppt to ppm. The device is required to identify automatically potential coeluted compounds by MS technology adapted to industrial context.

☐

[b]Solution adopted[/b]: The coupling of two different FID GCs to a Quadrupole MS allowed by an elaborated multiplexer system is the originality of the project: one TDGC for light compounds and one TDGC for heavy compounds with specific trapping conditions and variable sampling volumes.

[b]Results[/b]: A measurement campaign in petrochemical new site shows the concentration of around 100 compounds at different steps of the commissioning. Variations during specific hours are detected. Potential coeluted compounds as terpenes or organochlorinated are identified and monitored at ppt level.

[b]Conclusion of the project[/b]: The ability of coupling in continuous two different GCs to a unique MS and the automatic identification is a new advance in the technology of industrial GC-MS. The big advantage is the possibility to play with two different trapping and thermodesorption techniques linked to one MS. This fully automatic system allows non-specialist operators to access to expertise level results.

Abstract Text

Benzene, toluene, ethylbenzene, xylenes, and styrene (BTEXS) are volatile organic compounds (VOCs) associated with adverse health effects that include damage to the kidneys and central nervous system, and are known carcinogens and mutagens. The presence of these compounds in blood can result from exposure to consumer products, polymers, paints, adhesives, fuel, emissions, and smoke. Concerns about BTEXS exposure from predominant sources (fossil fuel products and cigarette smoke) have led to regional and national biomonitoring studies that characterize exposure levels. The ability to distinguish BTEXS exposure from various sources is not only important for identifying unsuspected sources, characterizing remediation efforts, and understanding public health, but also important for accurate quantification of various sample matrices as BTEXS are prevalent in common laboratory supplies (e.g., butyl rubber, helium, and acetylene). In this method, whole blood samples are collected in specially cleaned, VOC-free blood collection tubes and prepared by homogenization with isotopically labeled analog internal standards to compensate for loss biases and competition effects. Blood samples are quantified down to low ppt levels using passive headspace sampling by SPME followed by GC/MS-SIM configured with cryofocusing. Once laboratory biases are controlled, it is possible to distinguish and accurately quantify exposure levels from other different sources. In this work we compare inter-laboratory results that are biased by differences in laboratory materials used, and describe how to distinguish exposure sources among different regional and national biomonitoring studies.

Abstract Text

Negative impact of aromatic amines and amides to the health of general population led to a ban of some of them in cosmetology, textile industry and agriculture. Therefore there is a demand in the development of rapid and reliable methods for the detection of aromatic amines and amides in the environment. GCMS methods are the most efficient in structure elucidation of these chemicals when examined as chemical modification products. We have undertaken a task of developing dependable GCMS methods for their structure elucidation. The objects of the study were isomeric hydroxyl-, mercapto- and amino-anilines, various diphenyl and triphenyl-amines, phenyl-naphthyl-amines and amides of benzoic acids.

General dissociation directions for N-alkyl, -trifluoroacetyl, -chlorodifluoroacetyl, -pentafluoropropionyl, -heptafluorobutyryl and -trimethylsilyl derivatives of aryl-amines and -amides will be presented. This will include comparative analysis of spectra for various derivatives. Emphasis will be made on the specific fragmentation pathways useful for structure determination by GCMS: in the series of mono-perfluoroacyl amines para-isomers show dramatically different fragmentation directions that allows their reliable detection; di-substituted perfluoroacylamines can be successfully used for differentiation of [i]ortho[/i]-isomers from their [i]meta[/i]- and [i]para[/i]-analogs; mixed derivatives, such as N-methyl-N-acyl, are good for differentiation of aryl moieties and the positions of amino functions. Hydrogen and oxygen rearrangement processes in the case of perfluoroacylarylamines are recognized and the fragmentation mechanisms are established.

As a result, diagnostically important ions for differentiation of isomers are identified and an effective approach for the detection of aromatic amines has been developed.

Abstract Text

The major shortcoming and Achilles Heel of GC-MS is its inability to analyze relatively non-volatile and thermally labile compounds. We found that the GC elution temperatures can be significantly lowered upon the reduction of the column length, increase of carrier gas flow rate, reduction of capillary column adsorption film thickness and lowering the temperature programming rate. Over 200 degrees lower elution temperatures were achieved with our GC-MS which is equipped with a supersonic molecular beams (SMB) (also named GC-MS with Cold EI) system. Furthermore, via using high column flow rate during the injection, lower injector temperatures can be used and sample degradation at the Cold EI fly-through ion source is inherently eliminated.

The resulting lower elution temperatures in various analyses is further complemented via the feature of enhanced molecular ions obtained with GC-MS with Cold EI combined with the elimination of ion source related peak tailing and degradation. Thus, the reduced GC separation power involved in the analysis of thermally labile and low volatility compounds is compensated by increased MS separation power.

The extension of the range of compounds amenable for GC-MS analysis will be demonstrated with the 5975-SMB GC-MS with Cold EI in the analysis of large hydrocarbons up to C₇₄H₁₅₀, large polar drugs such as Reserpine, thermally labile explosives such as TATP, PETN, Tetryl and HMX, thermally labile carbamate pesticides such as methomyl, aldicarb, aldicarbsulfone and oxamyl and a range of free fatty acids. Consequently, GC-MS with Cold EI bridges the gap with LC-MS.

Abstract Text

Utilization of alternative ion sources for GCMS which generate primarily the molecular or quasi molecular ion, commonly known as soft ionization, has seen increased interest in the past few years. The combination of soft ionization and high resolution MS allows nearly unambiguous molecular formula identification; information that is extremely valuable when performing unknown compound identification.

In this work we use a vacuum ultraviolet (VUV) lamp and a dopant compound to generate a plasma within our ion source. Once this plasma is formed, ionization of organic compounds can take place in a variety of pathways generating primarily molecular or quasi molecular ions. We have used this ion source to couple a GC to an ultra high resolution TOFMS with mass spectral resolving power in excess of 50,000@FWHM. This source provides soft ionization relative to an EI source, conventionally used for GCMS. The advantage of soft ionization is that molecular ion information is retained and, when coupled with ultra high resolution TOFMS, high mass accuracy is achieved which can be a powerful tool for compound identification. High resolution also assists in retaining isotopic fine structure when multiple ionization pathways are present, further assisting in compound identification. In addition, rapidly pulsed post source fragmentation can be done enabling quasi-simultaneous collection of precursor ion spectra and fragment ion spectra across the entire chromatogram. Results demonstrating this capability will be shown for a variety of compounds.

Abstract Text

The possibility of converting various biomass feed stocks directly to biofuels or value-added specialty chemicals using catalytic pyrolysis has precipitated a demand for a fast, reliable method to characterize newly developed catalysts. Catalytic pyrolysis is a three-step process: (1) the feedstock is first pyrolyzed (often referred to as “fast pyrolysis”), (2) the pyrolyzates flow through a catalyst bed and (3) the ‘products’ are identified and quantitated. The Tandem Micro-Reactor GC/MS system integrates these three processes into a single instrument.

The Tandem Micro-Reactor is designed for the rapid evaluation and characterization of catalysts in various atmospheres, at different temperatures (up to 900°C) and under different pressures (up to 3.5 MPa [500 psi]). The system consists of an upper micro-reactor and lower micro-reactor each with independent temperature and reaction gas controls. The first micro-reactor vaporizes liquid samples, or pyrolyzes solid samples. Vapors formed in the first reactor flow through the catalyst in the second reactor. The Tandem Micro-Reactor is designed to allow a quick change of the catalyst bed. Adding a cryo-trap and a selective sampler extend the capabilities of the system to include heart-cutting experiments. Batch or continuous experiments can be performed with this system to evaluate both catalyst performance and to characterize products formed on the catalyst surface. Provisions are also designed into the system to allow catalyst regeneration and evaluation. The catalytic pyrolysis of lignin, cellulose and Jatropha “press cake” will be used to illustrate the utility of the Tandem Micro-Reactor. The analysis of lignin in Hydrogen (at high pressure) using Heart-cut EGA-MS analysis will also be discussed.

Abstract Text

The global helium shortage and price increase often force analytical laboratories running multiple gas chromatographs to reconsider their helium consumptions.

Migrating to another carrier gas like hydrogen is probably the most common choice, even if its adoption brings to some obvious safety concerns.

Despite hydrogen's well known behavior of allowing the best separation per unit time, thus allowing laboratories to increase their throughput, some analytical considerations must be done as well, which can affect both the injection port as well as the detection technique used.

An innovative solution will be presented in this paper, consisting on the use of a dedicated GC injector, which allows the high separation efficiency of hydrogen carrier gas without incurring into its the negative aspects.

Drastically reducing the amount of hydrogen carrier used, but still allowing its excellent chromatographic separation and rapid GC or GCMS method implementations, this injector provides hydrogen-using gas chromatograph systems with an increased margin of safety over that provided with prior art hydrogen equipped chromatographs. This allows in principle GCs to be using hydrogen carrier gas without the need of hydrogen sensors installed.

Data will be presented to discuss the impact of such an injector on reducing the total amount of hydrogen used and the chemical reactivity sometimes observed towards unsaturated analytes; we will also demonstrate that the adoption of this innovative injector extends the applicability of thermal conductivity detectors, whose sensitivity and performance are known to be affected by carrier gas switching during the run.

Abstract Text

Fast pyrolysis is one of the techniques being used to convert biomass to biofuels or bio-based intermediates. However, initial work with fast pyrolysis underscored the difficulty of converting biomass to transportation fuels in a single step. Catalytic pyrolysis has emerged as a means for improving the quality of the bio-oil produced from pyrolysis. Catalytic pyrolysis is often done in Hydrogen, usually at elevated pressure. Most of the high pressure, catalytic pyrolysis studies are conducted in room-size reactor systems, which often limits the scope of the study. The introduction of a table-top, high pressure Tandem Micro-Reactor system overcomes this limitation.

A tandem reactor consists of two reactors in series; additional capability can be added via a series of accessories. The atmosphere and temperature (up to 900°C) of each reactor are independently controlled. The system is designed to be operated up to 3.5 MPa (500 psi). Reactor pressure is controlled using a unique back pressure regulator, which has the advantage of being downstream of the reactors. Only the portion of the sample being split flows through the regulator. A small portion of the sample vapors flows directly to the column. A second back pressure regulator maintains a constant pressure on the column, so that retention data is constant and independent of the reactor pressure.

Heart-cut EGA GC/MS analysis of lignin under high pressure in a hydrogen atmosphere will illustrate how the Tandem Micro-Reactor GC/MS is used to investigate the potential of various feedstocks and novel catalyst. The products formed after pyrolysis and catalytic conversion of cellulose will be used to highlight the various operating modes of the tandem reactor.

Abstract Text

Sample identification by GC-MS is typically performed with library search among available electron ionization (EI) mass spectra via the availability of fragments, automatically providing compound names and identification probabilities. Significantly improved methods of sample identification were explored using the Aviv Analytical 5975-SMB GC-MS with Cold EI, an instrument based on the use of supersonic molecular beams (SMB) for interfacing the GC with MS and EI of vibrationally cold sample compounds in SMB with a fly-through ion source.

The following sample identification aspects were improved:

- A) The use of short columns with high column flow rates enables significant extension of the range of compounds amenable for GC-MS analysis, while the fly-through ion source ensure their ionization without ion source degradation, thereby bridging the gap with LC-MS.
- B) Enhanced molecular ions significantly improve library search and confidence in identification.
- C) The combined availability of enhanced molecular ions and Tal-Aviv Molecule Identifier (TAMI) software based on isotope abundance analysis serves to confirm or reject NIST results.
- D) The TAMI software further provides elemental formula based on the combination of isotope abundances and increased mass accuracy measurement of the molecular ions masses with single quad MS.
- E) The combination of enhanced molecular ions and high mass fragments provides extended structural and isomer information.

GC-MS with Cold EI and TAMI software is superior to GC-HR-TOF in sample identification since greater range of compounds can be eluted and exhibit trustworthy molecular ion with it, while the TAMI software provides elemental formula.

Abstract Text

Acquisition of quality mass spectra of analytical derivatives for important chemicals is essential for the improvement of the NIST/NIH/EPA Mass Spectral Library. Thermally and catalytically labile compounds, compounds with poor gas chromatography properties, and compounds containing insufficient characteristic ions and structural information in their mass spectra are on the top of our priority list. The presentation will describe derivatization methods used in the GC/MS leading to (a) locating centers of unsaturation, branching and positions of functional groups, and (b) determining cycle ring size and positions of substituents. Advantages and disadvantages of a particular derivative for a specific compound will be assessed. Special attention will be paid to procedures for preparation of chemical derivatization products with two or more different functional groups; recommendations for their synthesis will be given. The fragmentation pathways of compounds of interest and their derivatives, as well as characteristic ions in their mass spectra will be discussed. Furthermore, evaluation methods of newly acquired mass spectral data of analytical derivatives for the addition to the NIST/NIH/EPA mass spectral library will be described.

Abstract Text

Circulating tumor cells (CTCs) open up the opportunity to examine and study cancer progress with a more non-invasive manner (blood drawing). However, to better understand CTCs and its relation with disease progression still calls for new methods that are able to purify the extremely rare CTCs from blood sample. In recent years, separation of cells using acoustic forces has drawn increasingly amount of attentions due to the advantages of flexibility, contact-less, and high bio-compatibility. However, isolating CTCs from blood sample has not been possible using acoustic based methods due to the insufficient throughput or separation stability. In this work, we increase the separation distance and throughput between cancer cells and leukocytes by optimizing the configuration of standing wave field in a microfluidic channel. As a result, isolation of CTCs from blood with reasonable throughput and efficiency becomes possible. The device achieved >80% separation efficiency with as few as 60 cells/mL. The current single device is able to process 1.2 mL of blood per hour, and cells are still viable after separation and can be cultured for one week.

Abstract Text

Multiplexed protein detection methods for molecular diagnostics have struggled to enter into a clinical setting in part due to the lack of convenient analytical tools. Microring resonator arrays are a class of silicon photonic biosensors that are well suited for multiplexed protein measurements in complex matrices following a similar workflow to conventional sandwich immunoassay methods. The platform consists of individually addressable rings arrayed across a silicon surface with current generation chips capable of up to 32-plex analysis. The assay is highly automated with integrated, programmable fluidic control with rapid data acquisition (<2 h) and picomolar limits of detection. Herein, we demonstrate the application of the microring resonator platform for simultaneous analysis of 12 phosphoprotein targets in model cancer cell lines and tumor tissue homogenate. The assay is able to discriminate heterogeneities between model cell lines as well as monitor alterations in the proteomic profiles in response to environmental changes. Applications of the phosphoprotein expression profiling include monitoring disease progression, detection of emerging resistance mechanisms, correlating protein modifications with oncogenes, and additional categorization of cancers into clinically actionable sub-groups.

Abstract Text

Gliomas are the most frequent primary brain tumours in adults, with these intracranial neoplasms accounting for 70% of adult malignant brain tumours [1]. The current diagnostic regime is subjective, invasive, and may require the patient to undergo unnecessary surgery.

Studies have shown the potential of ATR-FTIR spectroscopy for diagnostic applications when collecting spectral measurements of human serum to discriminate between healthy and diseased states; studies involve cardiology [2], ovarian cancer [3-4] and our previous studies on brain cancer [5-6], to name but a few.

We used ATR-FTIR spectroscopy combined with a Radial Based Function Kernel Support Vector Machine (RBF-SVM) to diagnose high-grade gliomas (e.g. Glioblastoma multiforme), low-grade gliomas (e.g. oligoendroglioma) and non-cancerous samples using serum volumes of 1 μ l. Optimum sensitivities and specificities of 93.75 and 96.53% respectively, were achieved when analysing whole serum samples. We built upon our existing spectral dataset to construct 5 models; (1) cancer vs. non-cancer, (2) metastatic brain cancer vs. brain cancer vs. non-cancer, (3) organ of tumour origin, (4) high grade glioma vs. low grade glioma vs. meningioma, (5) subtype of brain cancer. In total our latest research includes 433 patients demonstrating a rapid stratified serum diagnostic process using minimal sample.

We present a rapid, robust and reproducible methodology that can be used to diagnose and distinguish between cancer, organ origin and tumour severity from non-cancer with a 1 μ l volume of human serum with high sensitivity and specificity.

Abstract Text

Development of technically simple, inexpensive devices for cancer detection has the potential to enable early detection and personalized medicine. Paper has attracted interest as a cheap, versatile material for development of clinical diagnostic measurement tools for analytes in urine and blood. Paper analytical devices (PADs) have the potential for rapid testing of biological samples to offer real time disease diagnostic tests to assist physicians in delivering personalized treatment and improve prognoses for patients. A low cost, high throughput and disposable paper analytical pad with 64 analytical wells was fabricated using wax patterned filter paper. The PAD interfaced with capture antibodies decorated magnetic microbeads and chemiluminescence reagents was used to detect cancer biomarker proteins prostate specific antigen (PSA) in undiluted serum at pg mL^{-1} levels. Capture antibodies for PSA was first immobilized onto magnetic beads and a sandwich type immunoassay involving antigen (standards or patient samples), biotinylated antibodies, and streptavidin-polyHRP was carried out. The chemiluminescence output was measured with a charge-coupled device (CCD) camera and total assay time from antigen immobilization to qualitative results were completed in ~ 20 mins for all 64 analytical spot. Detection limits of 2 pg mL^{-1} for PSA were obtained in undiluted serum and a clinical relevant dynamic range of 4 logarithmic orders was achieved. These disposable low cost PAD presents an ideal candidate for rapid, high throughput diagnostic tool for serum proteins.

Abstract Text

DNA nanotechnology has explored its universal application by constructing various functional nanostructures. As a rising star applied in biomedical field, DNA nanostructures have been used as anticancer drug carriers to decrease the systemic toxicity resulting from nonspecific drug distribution and enhance drug delivery efficiency. Here, we report an aptamer-based DNA dendritic nanostructure as a multifunctional vehicle for targeted cancer cell imaging and drug delivery. The multifunctional DNA dendrimer is constructed by functional Y-shaped building blocks with predesigned base pairing hybridization including fluorophores, targeting DNA aptamers and intercalated anticancer drugs. With the controllable step-by-step self-assembly, this programmable DNA dendrimer has appealing features such as facile modular design, excellent bio-stability, good biocompatibility, high selectivity, strong binding affinity, efficient cell internalization property, and large drug loading capacity. Due to the unique structural features of DNA dendrimers, multiple copies of aptamers can be conjugated in each one dendrimer, generating a multivalent aptamer-tethered nanostructure with enhanced binding affinity. The high content of drug-binding double-strand DNA structures in these dendrimers enabled them with high drug payload capacity. A model chemotherapeutic anticancer drug, doxorubicin (Dox), was delivered via these aptamer-based DNA dendrimers and exerted a potent toxicity for target cancer cell with low side effects for the non-target cells. Therefore, this controllable aptamer-based DNA dendrimer presents a promising candidate for biomedical applications.

Abstract Text

Pancreatic cancer is highly lethal cancers, with a 5% 5-year survival rate [1,2]. In recent work by our collaborator, it has been shown that at the time of diagnosis most patients are metastatic [1, 3-6]. Thus, there is both a great need for early diagnosis and an opportunity, due to the early presence of circulating tumor cells (CTCs) [7, 8]. The detection of CTCs from blood poses a technical problem, due to their extreme scarcity (1 in 10E9 blood cells) and the lack of any biomarker that can be used to identify 100% of the CTCs. Microfluidic approaches have been used to isolate CTCs, but limited by biased sorting (missing non-epithelial CTCs), reliance on downstream analysis that can cause cell loss and impractically slow throughput for clinical application [9].

To address these issues, we developed a platform that can sort CTCs from the vast background of blood cells, and screen each cell individually using on chip in-situ RNA analysis. We sort white blood cells using negative immunomagnetic selection. Our chip uses a novel track-etched magnetic micropore (TEMPO) filter based microfluidic geometry. By using magnetic micropores, magnetically labeled blood cells can be removed directly from unprocessed whole blood at high flow rates (≈ 10 mL/hr). The TEMPO consists of a thick (1.25 micron) electroplated NiFe layer (Fig 1a), 30 micron diameter pores with density of 4×10^5 pores/cm², creating strong magnetophoric forces while minimizing flow velocity and clogging. To sort the rare CTCs, we demonstrated extremely low loss (Fig 1b) and exponentially improved sorting efficiency by stacking TEMPO filters in series (Fig 1c). Downstream of the TEMPO, potential tumor cells are trapped on a size-based filter for fluorescence in situ hybridization (FISH) that could resolve a single molecule of RNA in individual cells (Fig 1d), with the specificity to resolve a single point mutation. We are applying this technique to clinical and murine mouse models for pancreatic cancer.

Abstract Text

Online analyte preconcentration is a preferred method to increase the limited detection sensitivity of miniaturized capillary electrophoresis (CE) resulting from its small sample injection volume. We have developed a microfluidic platform that employs a pneumatic microvalve for controlled sample injection for CE. A pneumatic microvalve, created using multilayer soft lithography, aligned at a T-junction on PDMS chip can serve as a semipermeable membrane under an applied potential, enabling current to pass through while blocking the passage of charged analytes. For sample preconcentration, analytes are focused at the closed valve. Once analytes are concentrated, the valve is briefly opened and the stacked sample is injected onto an integrated microchip or capillary column. Preconcentration and injection of cationic and anionic species has been demonstrated using crystal violet and fluorescein, respectively. Fluorescein was enriched by a factor of ~70 to 190 μM in just 8 s as determined using a calibration curve and the concentrated analyte was injected as a 1 nL plug onto the CE channel. Compared to existing preconcentration approaches, our method enables both rapid analyte concentration and controlled injection volume for high sensitivity and high resolution CE. Additionally, this may present a promising method for coupling two-dimensional separations, such as liquid chromatography coupled to CE.

Abstract Text

Improved monitoring of cellular systems can be achieved with microfluidics. Flow over cells on-chip provides a continuous source of nutrients and allows real time sampling of secreted metabolites. Using lab-on-chip techniques, we have integrated a dual enzyme assays system on a chip with a cell perfusion chamber to create an automated, multiplexed, and miniaturized platform for cellular monitoring. Adipocytes secrete non-esterified fatty acids (NEFAs) and glycerol through a metabolic pathway known as lipolysis. Measuring both products allows assessment of metabolic function and NEFA recycling, which refers to re-esterification of NEFAs after lipolysis within a cell. Measuring secretion can provide insight into the physiological conditions of the cells. For example, an imbalance of lipolysis and NEFA recycling is often associated with type 2 diabetes and various other disorders. A novel, multilayer polydimethylsiloxane (PDMS) chip has been developed to detect both NEFAs and glycerol secreted from a group of adipocytes in near real time to better understand NEFA recycling. The reversibly-sealed chip integrated a valve, cell chamber and parallel NEFA and glycerol enzyme assay reaction channels. Using the system, 3T3-L1 adipocytes were continuously perfused in the chamber, and the on-chip assays were optimized to allow detection of the secreted metabolites and changes in recycling as a function of age and drug treatments. To provide more detail on the chemical identity of NEFAs that are secreted, we have also coupled the chip to solid-phase extraction with ESI-MS for lower temporal resolution monitoring. This system provides simple coupling of microfluidics to MS for cellular assessment.

Abstract Text

Recent advances in proteomics are facilitating the study of increasingly complex systems. However, traditional one-dimensional separation methods are capable of analyzing only a few dozen analytes, which is nowhere near the thousands of components typically present in a biological sample. Multi-dimensional separations offer an advantage since separations can be done based on multiple properties. Much interest has been placed in the field of comprehensive on-line two-dimensional separations, where two columns which provide orthogonal separation methods are directly connected. One of the main limitations to this technique is that the rate at which the first dimension is sampled is dependent upon the time it takes to fully run and re-equilibrate the second dimension. For the first time, micro free-flow electrophoresis (μ FFE) has been directly coupled with nano-liquid chromatography (nLC) for amino acid and peptide separations. μ FFE is a continuous separation technique where samples are introduced to the top of a separation chamber and are driven by pressure flow. The flow rate and capillary size for samples are comparable to that found in nLC, making it ideal for coupling. An electric field is applied laterally, and the analyte streams begin to move and separate according to their electrophoretic mobilities. Because the separation is continuous, the sampling rate becomes dependent only on the time required for detection, typically 100 msec. The research presented demonstrates the orthogonality and separation capabilities of nLC- μ FFE by separating a 25 amino acid mixture and tryptic peptides of BSA using reversed-phase LC and various μ FFE conditions. By implementing a near zero dead volume interface between the nLC instrument and μ FFE microfluidic device peak capacities of over 2300 have been achieved in a 10 minute separation window for peptides, and near 100 for amino acids in 75 seconds.

Abstract Text

It is well established in drug discovery that in vitro tools capable of dynamic in vivo processes are lacking. Conventional polydimethylsiloxane (PDMS) based thrombosis models, while able to recreate in vivo dimensions, suffer from a lengthy fabrication process, final devices are often not reusable, and to date fail to enable localized injury to an endothelium triggering the thrombosis pathway. A polyjet 3D-printer is used to fabricate a reusable, transparent fluidic device featuring threaded inlets for sample and removable electrode introduction, and a 1000 μm wide x 800 μm high channel. Channels are coated with either PDMS or polystyrene (PS), well characterized substrates that are amenable to cell adhesion and growth. These coatings decrease the internal channel dimensions, 3-100 μm (PDMS) and >100 μm (PS) as confirmed with scanning electron microscopy, but have limited effect on device transparency. Collagen encompassing the internal channel provides the extracellular matrix component and aids in endothelial cell immobilization. Injury to the endothelium is performed in a site-specific manner by electrically lysing cells via potential application to electrodes inserted into the base of the device, providing the basis for thrombosis formation. Electrical lysis facilitates injury without introducing any foreign circulation components, expediting the process by foregoing the need to prep the channel before sample introduction. Whole blood is introduced to the device after electrically-induced injury to form the blood clot, which can be imaged using microscopy techniques or used to assess anti-thrombotic or thrombolytic drugs.

Abstract Text

High-throughput screening (HTS) using multiwell plates and fluorescence assays is a powerful tool for drug discovery by allowing tens of thousands of assays to be completed per day. While this method has been successful, typically only one analyte is detected and indicator reactions can lead to false results. We have developed a novel method using droplet microfluidics to couple multiwell plate-based assays to microchip electrophoresis (MCE) for screening. Samples contained in multiwell plates are reformatted in to nanoliter volume plugs segmented by an immiscible oil. The segmented flow sample streams are coupled to a hybrid polydimethylsiloxane-glass microfluidic device capable of selectively extracting the aqueous samples from the droplet stream and rapidly analyzing by MCE with laser-induced fluorescence detection.

To validate this new method, a test library containing 140 small molecules were screened for inhibitors of protein kinase A (PKA). Each sample was reformatted as two droplets allowing at least 6 MCE injections per sample. Sub-second separation of three analytes – rhodamine, substrate peptide, and product peptide – was achieved in 5 mm using an applied electric field of 2000 V/cm with an efficiency of 16,000 plates/second. Using 700 injections total, 96 samples were analyzed in 12 minutes (0.13 Hz) and several small molecule inhibitors of PKA were identified and verified through dose-response experiments. While this method has been applied to screening applications, the device layout and operation is amenable to many applications including coupling 2D separations and chemical sensing. This work was supported by funding from the National Institutes of Health.

Abstract Text

In recent years, microfluidic paper-based analytical devices (µPADS) have drawn much interest as platforms for analysis in a variety of complex biological and environmental systems. µPADS have many benefits due to the unique properties of paper including capillary action, reagent compatibility, widespread availability, and low cost. Common fabrication methods include photolithography, wax printing/dipping, and inkjet printing; all suffer drawbacks including high cost, difficult post processing, unstable hydrophobic agents, limited applications, and non-biodegradability.

Polycaprolactone (PCL) is a biodegradable polyester with a melting point of 60°C that can address many of the current issues. PCL is commonly used for manufacturing specialty polyurethanes and for coating extended release tablets. In the present study, PCL is used as both a hydrophobic barrier and adhesive agent in the fabrication of single, and multilayer microfluidic devices. µPADS were prepared by airbrushing PCL solutions onto masked substrates. Hybrid microfluidic devices comprising both open channels and paper wicking regions were prepared by impregnating filter paper with PCL solutions followed by drying, cutting, and assembly. In both methods, CAD software was used to generate designs, which were then transferred to prepared substrates with a cutting plotter. Multilayer devices were then laminated to create three-dimensional structures.

We employed this fabrication process to produce colorimetric diagnostic assays for clinically relevant biomarkers including glucose, albumin, bilirubin, and creatinine. Assay results were initially analyzed off-line using commercially available software. In order to maximize portability, a smartphone application was developed allowing for quantitative and statistical analysis of colorimetric assays without the need for a computer.

Abstract Text

Deficiencies on essential metal ions such as copper, zinc and iron could lead to various diseases that are detrimental to human health. Therefore, it is important to quantitatively monitor the concentrations of these metal ions in a simple, cost-effective, point-of-care and reliable fashion. Here, we present a fully inkjet-printed microfluidic paper-based analytical device ([micro]PAD) with pre-treatment and ion sensing functions on a filter paper material for the simultaneous color image analysis of Cu²⁺, Zn²⁺ and Fe²⁺ ions. Microliter order of sample containing metal ions was dropped on a single sample compartment that instantaneously flowed into the 3 different pre-treatment area then into the ion sensor. The printed pre-treatment reagents on the [micro]PAD were mainly composed of either buffers with specific pH or a mixture of reductant and masking agent, which aided for more selective measurements. As for the ion sensing, Zincon dye was used to measure both the Cu²⁺ and Zn²⁺ ions and Ferene S dye for the Fe²⁺ ion. These dyes were printed on cellulose-anchored cationic polymer nanoparticles (~100nm) via electrostatic interaction that resulted to a more reliable measurement. The normal serum level of each cations were well within the calibration standard obtained by the [micro]PAD. Moreover, simultaneous analysis of each metal ions were successfully demonstrated. This simple and cost-effective fully inkjet-printed [micro]PAD could be implemented for clinic and field applications.

Abstract Text

Point-of-care testing (POCT) with the advantages of speed, simplicity, and low cost, as well as no need for instrumentation is of great importance to improve healthcare, ensure environmental safety, and guarantee food quality, especially in a variety of environments that lack access to laboratory infrastructure, such as in less-industrialized countries, in emergency situations, or in home healthcare settings. While qualitative POC assays are widely available, quantitative POC assays pose significant challenges. Here we describe a novel method that integrates an Au core/Pt shell nanoparticle (Au@PtNP) encapsulated aptamer-crosslinked hydrogel with a volumetric bar-chart chip readout (HV-Chip) for sensitive, selective, and quantitative POCT with naked eyes. Upon target introduction, the formation of target/aptamer complex destroys the hydrogel crosslinks, leading to the dissolution of the hydrogel to release Au@PtNPs. The resulting nanoparticles can efficiently catalyze the decomposition of H₂O₂ to generate a large volume of O₂ to push the movement of an ink bar in the V-Chip. The concentration of target introduced can be visually quantified by reading the travel distance of the ink bar. By changing the aptamer sequences, the HV-Chip method allows for inexpensive, rapid, portable, and quantitative visual detection of a wide range of targets without any external electronic devices, which has the great potential to be used for quantitative POCT by local communities in developing regions to improve healthcare, environmental safety, food quality, etc.

Abstract Text

Ion chromatography (IC) based methods are appearing in greater number in the United States Pharmacopeia National Formulary (USP-NF). In addition to the counter ion analysis assays commonly performed at pharmaceutical companies, there are now IC assays of drug substances and drug products, and methods to determine related substances and impurities in drug substances and drug products. Most IC assays feature an ion-exchange separation followed by suppressed conductivity, pulsed electrochemical, or UV absorbance detection. This presentation will describe four recently developed IC assays for active pharmaceutical ingredients (APIs) as well as impurities. Some of these methods are part of an ongoing effort of monograph modernization (e.g. the determination of ammonia in bicarbonate). Lithium carbonate will be used as an example of an API assay as well as for an assay of sodium and calcium impurities. In this example one IC method replaces three separate methods in the monograph. The other two application examples will feature anion-exchange IC. The discussion of all four application examples will emphasize the column, mobile phase, and detection choices made during the development of each method.

Abstract Text

Analytical characterization of monoclonal antibodies is required during the manufacturing process and clinical studies. Structural heterogeneity such as intra-molecular disulfide scrambling can be induced during all aspects of the manufacturing process. For IgG2, disulfide scrambling is especially a problem due to the four disulfide bonds in the hinge region. RPLC has been used to partially resolve four peaks for IgG2, corresponding to three disulfide isomers. It is unclear about the cause of the extra peak. In this study, SEC results prove that aggregates can be induced from the mobile phase used in RPLC. The percentage of aggregates formed is related to sample concentration. Only the separation at low concentration can reflect the real composition of disulfide isomers in the original sample. The separation efficiency can be improved by using submicron nonporous particles. The higher separation efficiency, together with optimized bonded stationary phase allows for higher resolution separation of IgG2 disulfide isomers.

Abstract Text

When core-type particles are available with the desired phase chemistry, there are compelling reasons to include them during HPLC and UHPLC method development. Because core-type particles typically generate more theoretical plates than porous particles for a given diameter, one option is to choose the same core-type particle size and generate higher efficiency and resolution at the same operating pressure. Another option is to select a larger core-type particle size and achieve equivalent efficiency and resolution at lower pressure. This efficiency/pressure advantage can be an attractive tool when methods may be used by multiple analysts on instruments with different performance capabilities. The core-type efficiency advantage typically increases at high flow velocities, which is critically important for any method that has greater separation speed as an objective. A second important advantage for core-type columns is that they have been reported to be more rugged in use compared to porous columns, especially with smaller particles inside. This makes them ideal for unattended runs during column switching and screening or for multi-sample assays where loss of column performance during the run can be very costly. The efficiency/pressure and ruggedness advantages become even more important in UHPLC methods because operating pressures may become limiting and column performance losses at high pressure may decrease resolution and accuracy. Because core-type and porous particles have similar retention factors, they may be screened together to gain experience with both column types. Since their introduction in 2007, core-type particles have become widely available for HPLC and UHPLC with a variety of column geometries and phases that should make development of rugged methods faster and easier.

Abstract Text

The use of superficially porous particles (SPP) and sub 2- μm fully porous particles (FPP) in achiral applications has rapidly grown in the past decade and has allowed for extremely fast and efficient achiral separations. However, chiral separations have yet to follow the trend. Chiral separation are notorious for low efficiency due to required strong interaction between the analytes and the stationary phase. In this work, HPLC columns packed with bonded, brush-type chiral selector were produced using 2.7- μm SPPs and 1.9- μm mono-dispersed FPPs. These new, highly efficient chiral stationary phases are used to rapidly separate a wide range of chiral analytes in less than 60 seconds. These high efficiency columns can be used for fast separation of chiral analytes in pharmaceuticals for increased throughput and for use in multidimensional (2-D) separations. Short columns packed with these particles can also be used for rapid screening of large number of analytes in a very short time frame.

Abstract Text

Degradation products such as aggregates and fragments pose a critical problem in monoclonal antibody (mAb) drug development. Reduced therapeutic efficacy and immunogenic responses in patients have been associated with these drug impurities. Conventional reversed phase stationary phases such as porous and core shell packing can currently separate intact mAb fragments but are still limited in the separation of aggregates. Capillaries packed with submicron nonporous silica particles have been used to successfully separate mAb aggregates using reversed-phase chromatography with baseline resolution at room temperature. Since stainless steel RPLC columns are more widely used as an analytical tool for mAb separations in the pharmaceutical industry, it is desirable to translate this efficient separation in capillaries to a form that is amenable with commercial UHPLC instrumentation. This work examines the progress being made in using nonporous submicron silica particles packed in stainless steel columns for both mAb fragments and aggregate characterization. Preliminary results show that stainless steel columns packed with submicron nonporous silica particles separated mAb fragments and aggregates simultaneously from its monomer with better resolution than leading commercial RPLC columns.

Abstract Text

The separation of chiral compounds continues to be the center of significant interest not only in the development of pharmaceutical drugs and therapeutics but also in agricultural industry (herbicides and pesticides) as well as biomarkers.

Capillary electrophoresis (CE) is a highly effective technique for chiral separation, which is superior to gas chromatography (GC) for analyzing non-volatile chiral compounds and has some advantages over high performance liquid chromatography (HPLC) in terms of the cost, sample consumption and etc.

The combination of CE to mass spectrometry (MS), a hyphenated technique, largely improves the limit of detection of CE to analyze both small and large molecules by mass difference. However, most of the small molecular weight chiral selectors conventionally used in CE suppress the MS detection to a large extent. Therefore, identifying novel chiral selectors which provide high separation selectivity and are MS compatible has become a major effort in developing CE-MS approaches.

According to the literature, sugar based surfactants unpolymerized micelles have low critical micelle concentrations of about 0.5 mM and have been successfully used as pseudostationary in MEKC for the separation of enantiomers. Based on this report, a new series of molecular micelles, the sugar based surfactants with vinyl terminated group have been synthesized and been used to separate some ephedrine alkaloids, β -blockers, and binaphthyl derivatives in MEKC-MS.

Abstract Text

Efficient peptide separation is essential for proteomic research and therapeutic peptide development in pharmaceutical industry. By using submicron nonporous particles, higher efficiency can be achieved due to better-ordered stationary phase, reduced mass transfer and slip flow enhancement. In this work, 500 nm silica particles were packed into a 150 μ m i.d. capillary to form C18 bonded stationary phase, with a pulled tip to couple to mass spectrometer. Using bovine serum albumin tryptic digest as a standard sample, a peak capacity of over 300 was achieved in a 17 min gradient. High sensitivity of peptides was observed in the mass spectrum. Various percentages of formic acid and trifluoroacetic acid in mobile phase were applied to study the influence of different solvent conditions. Human B cell tryptic digest was used to test the ability of proteomics sample separation. In a 10 min gradient, a peak capacity of over 200 was obtained. Thus, our capillary shows great potential for highly efficient peptide separation in proteomics study and pharmaceutical application.

Abstract Text

Glibenclamide, a second generation sulfonylurea is a diabetic drug which functions by stimulating insulin secretion. Calliandra portoricensis is used in the treatment of snakebite, antiulcer effects and as abortifacient. The pharmacokinetic interaction of glibenclamide and calliandra portoricensis (CP) was therefore investigated in rats.

Twenty four Wistar rats of both sexes weighing 150 ± 15 g, received a dose of glibenclamide, 0.6mg/kg body weight and two weeks later, they were administered 500mg/kg of calliandra portoricensis single-oral doses for days 1-5 and also received 0.6mg/kg glibenclamide single-oral doses 15 minutes post-administration on the fifth day. Blood samples were withdrawn by retro- orbital puncture using capillary tubes over a 48 h period on both occasions and the quantity of glibenclamide in the plasma at each time was determined by HPLC.

The observed decrease in the elimination half-life, $t_{1/2}$ and maximum plasma concentration, C_{max} , as well as increase in time to reach maximum plasma concentration, T_{max} and volume of distribution, V_d were not significant when glibenclamide was co administered with calliandra portoricensis. The lower C_{max} and longer T_{max} observed could be an indication of reduced rate of drug absorption. This was shown by the reduction in AUC. Drug elimination was slower on administration of ciprofloxacin with calliandra portoricensis as there was a decrease in the elimination half-life, $t_{1/2}$ and increase in volume of distribution, V_d . These findings suggested a drug – drug interaction between ciprofloxacin and calliandra portoricensis. Thus, the implication of the concomitant administration of these two should not be overlooked.

Abstract Text

Selective extraction, solvent fractionation, subsequent chromatographic separation are eliminated in favor of total lipid extraction followed by tandem mass spectrometric analysis. The total lipid extract is applied directly via electrospray ionization, followed by neutral loss scanning to enable ion selection for lipids in the desired mass/charge range based on the offset of either one (monogalactosyldiglycerides) or two (digalactosyldiglycerides) galactose groups after fragmentation. This reveals the acyl group population that appears for the glycolipid and subsequent quantitation.

Abstract Text

Dried blood spot (DBS) analysis is becoming the avenue of choice for many pharmaceutical, toxicological, and forensic studies. Aside from economic benefits of shipping DBS cards rather than vials of blood, this method allows for smaller volumes of blood to be collected, which is advantageous in pediatric and geriatric studies. The traditional method of analyzing DBS is liquid chromatography-tandem mass spectrometry (LC-MSⁿ), which requires extracting the blood and any analytes from the paper substrate. This process is time-consuming, difficult to automate, and can dilute the sample. For these reasons, direct analysis techniques have become of interest, as they offer the potential for more rapid analysis. Paper spray ionization tandem mass spectrometry (PS-MSⁿ) by 3-D ion trap and matrix-assisted laser desorption/ionization tandem mass spectrometry (MALDI-MSⁿ) by linear ion trap are compared in this research for application to DBS analysis.

In addition, quantification of compounds in blood has been a focus of many studies. However, quantification by MALDI-MS is challenging due to non-homogenous crystal formation and laser shot-to-shot variations, which lead to irreproducible signal intensities. To overcome these challenges, an internal standard (IS) is added to help improve signal stability. Wide-isolation MALDI-MSⁿ, in which the analyte and internal standard signals are analyzed in a single isolation window, reduces the signal variability and allows for quantification. Quantification by additional direct analysis methods have also been explored.

Abstract Text

The reduction in column diameter from traditional 2.1 mm i.d. to column i.d. of < 300 um has been historically employed due to its attribute of delivering greater sensitivity with a lower sample volume requirement when coupled with mass spectrometry. However, in the 20 years that these types of separations have been made widely available, they have predominantly been applied to proteomics analysis in conjunction with high resolution mass spectrometry (HRMS). In contrast to the fused silica columns that are typically utilized for these analysis, intergraded microfluidic devices (MFD) offer the ability to operate at elevated pressures, increased resolution, and in a more robust manner.

In the work presented here we show data for a variety of biofluid samples analyzed with the incorporation of MFD in conjunction with HRMS. Robustness testing utilizing samples prepared from plasma, urine, bile and microsomal incubations were carried out utilizing typical bioanalytical sample preparation techniques. The quantitative data produced with the MFD/HRMS approach produced equivalent s/n values for probe pharmaceutical compounds when compared to analysis under standard analytical UHPLC coupled with tandem quadrupole mass spectrometry. Analytical methods utilizing this approach were capable of obtaining low pg/mL sensitivity with calibration curve linearity of 3 orders of magnitude or better. We also explore the use of the MFD coupled with HRMS to obtain better quality simultaneous Qual/Quan data for bioanalytical studies.

Abstract Text

How proteins interact with one another and assemble on a structural basis in addition to the identification of their function(s) is key to understanding biological processes. Native mass spectrometry (MS) has been used successfully to characterize intact protein complexes, providing stoichiometry and structural information that is complementary to conventional structural biology techniques. In this study, native top-down MS/MS approaches, including ISD, CAD, IRMPD, and ECD, using ultra-high resolution Fourier transform ion cyclotron resonance (FT-ICR) MS with nano-electrospray ionization (nano-ESI) were established to characterize the structures of soluble protein assemblies to beyond 800 kDa, and then further extended to a more challenging system —membrane protein complexes in nanodiscs.

The results demonstrate that with the superior high resolving power, accurate mass accuracy, and the versatile fragmentation techniques of FT-ICR MS, rich information, including the molecular weights of the protein complexes (and thereby stoichiometry), amino acid sequence, metal/ligand binding sites, and PTMs can be accomplished in a single native top-down FT-ICR MS experiment for soluble protein complexes. Nanodiscs consist of membrane scaffold proteins that wrap around a hydrophobic core of lipids. Although nanodiscs provide a native-like environment for membrane proteins, the inherent lipid heterogeneity poses a great challenge for MS analysis. With the hyphenation of various fragmentation techniques, not only can membrane protein complexes be released from nanodiscs, but the levels of phospholipid incorporation into the nanodiscs can be revealed. Therefore, native top-down MS/MS can be used to gain structural insights of protein complex topologies.

Abstract Text

This paper describes new developments in miniature deep UV Raman and fluorescence instruments for detection of trace chemical, biological, and explosives (CBE) material on surfaces. Instrument examples include the newly selected Mars rover arm mounted SHERLOC (Scanning Habitable Environments with Raman and Luminescence for Organics and Chemicals) instrument to be flown to Mars in 2020, and the DOD Biological Reconnaissance & Analysis using Non-Contact Emission-spectroscopy (BRANE) sensor under development with the U.S. Army.

Detecting Raman signatures of CBE materials on natural surfaces is difficult. Making this detection in complex natural environments where fluorescence from analytes or surroundings in the Raman spectral region, or ambient light backgrounds are potential interferents or obscurants, is additionally difficult. One of the solutions is to perform excitation sufficiently far in the ultraviolet to avoid fluorescence within the Raman region or from ambient lighting and limit penetration depth to spatially separate analytes from substrates. This introduces a different set of problems due to the limitations of deep UV lasers and increases in sample damage.

To enable these measurements to be practical in a hand-held or robot-mounted sensor, significant improvement of the excitation and detection efficiency and miniature deep UV lasers has been necessary. We have improved the excitation and detection efficiency by over 1000x compared to traditional Raman systems. We will show results in which good signal-to-noise Raman spectra of a wide range of materials are achieved using only a few mJ of excitation energy. In addition, we will describe progress in the development of new, miniature (400 gram) lasers with output over 1 W at 248.6 nm and linewidth less than 0.5 pm. These lasers have been tested over a temperature range from -135°C to +70°C and three times the shock and vibrations specifications for a Mars mission, without failure.

Abstract Text

We report on the development of novel state-of-the-art deep UV Raman instrumentation and methodology for stand-off detection of energetic molecules. UV Raman spectra excited below 230 nm are free from fluorescence background. Deep UV Raman spectra of high explosive materials are resonantly enhanced. This enables explosives trace detection at a distance. We used recently developed a high power deep UV laser that produce ~100 mW of 213 nm light. This is solid state Nd:YVO₄ pump laser designed and manufactured by UVisIR Inc. This laser utilize novel technology to improve 5th harmonic BBO crystal durability. The laser head is compact in size and weights ~ 20 lbs. We designed a new high throughput, high dispersion UV Raman spectrometer. This spectrometer consists of high-efficiency filtering stage monochromator and high-dispersion Echelle spectrograph. High spectrometer throughput enables ultrahigh signal-to-noise ratio deep UV Raman spectra. We used this novel spectrometer to measure UV Resonance Raman spectra of PETN, TNT, NaClO₄ and NH₄NO₃ at a stand-off distances > 2 m. We discuss the explosives stand-off detection limits and factors affecting them.

Abstract Text

Raman hyperspectral imaging reveals both the chemical identity and spatial distribution of chemical domains within a sample. Conventionally, Raman imaging has been performed using point mapping, line-scanning or wide-field imaging modalities. Raman is an inherently inefficient scattering method, however, and Raman imaging techniques often require long detector integration times and high laser powers to obtain suitably useful signal-to-noise ratios. Increasing the spatial resolution across a fixed region of interest can often lead to impractically long acquisition times. In the work presented here, we have developed a multi-megapixel digital micromirror device (DMD) based Raman imaging system that takes advantage of spatial multiplexing to provide improved signal to noise ratios at comparably shorter acquisition times. The method utilizes simplex encoding matrices to generate binary DMD masks and Gaussian elimination to reconstruct Raman images of the sample at each wavelength band. The encoded light is detected using a conventional imaging spectrograph, enabling all wavelength bands within the spectral range to be recorded in a single acquisition for each spatial mask. Because noise and other artifacts that lead to intensity-based errors can be distributed across all image pixels during data recovery, validation of the Raman DMD imaging system is important and has been performed on model samples using the point-mapping modality. In addition to the instrument design and performance metrics, several Raman image datasets from both model and complex real-world samples are presented.

Abstract Text

Fast, quantitative analysis of bulk mixtures has become increasingly important in regulating pharmaceutical manufacturing processes. Raman spectroscopy is an attractive method for confirming concentrations of these materials as it can offer quick, non-destructive and highly selective quantification without the need for time consuming sample preparation.

Transmission Raman spectroscopy (TRS) presents significant benefits over the more common backscattering Raman Spectroscopy by providing an average through the entire sample, offering fast and effective analysis of content uniformity. In this work we introduce a novel technique utilising TRS and Renishaw's high speed encoded stage to enable the analysis of bulk mixtures far larger than conventional single point TRS configurations (analysing tens of cm³).

Analysis can be configured to provide fast average information or a chemical image revealing mixture distribution (spatial transmission mapping) over this massive area in just a few minutes.

The analysis of very large mixtures is critical to ensure uniformity and relative amounts are accurately quantified and optimised. Achieving this provides less variation when, for example, formulations are subsequently manufactured. This potentially could reduce issues with regulatory dosage testing of batches, where amounts and distribution are not accurately known until final analysis. At this point significant material write-off or damaging regulatory non-compliance could be avoided.

Both single and mapped TRS measurements of powder mixes with differing concentrations will be reported to demonstrate the benefit of analysing such large volumes on short timescales.

Abstract Text

An assay has been developed using highly specific fluorescently labelled monoclonal antibodies which are conjugated to silver nanoparticles for the direct detection of small molecules using surface enhanced Raman scattering (SERS). SERS produces a unique 'fingerprint' spectrum in which the peaks are narrow, this has advantages for multiplexing, allowing for the detection of multiple target analytes. An antibody which has a high affinity for a target analyte is an attractive capture probe as it will specifically bind. Therefore, silver nanoparticles were functionalised with antibodies which, upon binding of the target analyte, allow for a specific SERS spectrum to be obtained due to the analyte being brought close to the nanoparticles' surface. Proof of concept was demonstrated by using TNT and RDX.

TNT and RDX are small nitroaromatic molecules which are commonly used as concealed explosives. Therefore, a simple and rapid test for explosives which has an unambiguous result, is affordable and can be widely deployed is highly desirable. We have developed a direct SERS detection assay which is quantitative, fast, simple, highly specific and selective towards targeting molecules. This assay has resulted in an observed limit of detection of 10 nM of TNT and 600 pM of RDX. Furthermore, with the use of multivariate analysis, we can also detect and distinguish both targets from within a complex matrix. This approach demonstrates the use of sensors for fast, sensitive and direct detection of small target analytes.

Abstract Text

We developed novel wide-field Raman hyperspectral imaging spectrometers that utilize crystalline colloidal array photonic crystals to select narrow wavelength spectral regions for detection and imaging. Our photonic crystals are comprised of highly charged, monodisperse silica or polystyrene nanospheres that self-assemble in solution to form face centered cubic crystalline arrays. The photonic crystals diffract a narrow wavelength spectral interval governed by Bragg's Law whose wavelength can be tuned by changing the incident angle of collimated light. We reduced the bandwidth of the diffracted spectral region by using recent advances in silica nanosphere synthesis to create smaller nanospheres with increased monodispersity. Directing a collimated beam of Raman scattered light onto our photonic crystal allows us to select a narrow wavelength spectral region for detection. Focusing this light onto a CCD chip produces a Raman image which spectrally details the chemical composition of the sample. We utilized our wide-field Raman imaging spectrometers to produce visible and deep UV Raman images.

Abstract Text

Handheld Raman is a powerful technique for material identification. It has applications in the pharmaceutical, cosmetics, and dietary supplements industries and others areas and is used by safety and security professionals. The primary advantage of using handheld Raman is to take the analysis to the sample rather than bringing samples to an analytical laboratory, improving turnaround time and efficiency. Measurements performed at a decision point outside a formal testing laboratory can reduce analysis time and cost. However, doing analysis at the sample is only viable if the handheld Raman analyzer can make reliable measurements.

We have investigated and implemented a variety of different ways to improve material identification using an advanced handheld Raman instrument. Improvements to material identification can be made by the careful selection of excitation wavelength, using advanced spectral search algorithms and improvements in spectral quality such as higher resolution, improved signal-to-noise and a broader spectral range. Examples showing improved material identification from different application areas will be discussed.

Abstract Text

A new Ultra-fast Raman Chemical Analyzer, AcuScan2000 has been developed for molecules identification and quantification of organic as well as inorganic substances. The AcuScan2000 is designed with the integration of robotic control of the whole processes in sample preparation, sample injection, laser positioning and detection, Raman maximum signal intensity optimization, spectrum collection, and spectra data comparison to more than 16,000 Raman spectra library data for material identification. With a proprietary spectra deconvolution technique in conjunction with the highly reproducible spectra intensity data and calibration relationship between spectra intensity and concentration of the measured substance, the system presents highly reproducible quantitative results to between 0.1 to 0.5% RSD for polystyrene, lipstick, EDTA, 10% aqueous sucrose solution, etc.

The Raman chemical analyzer can also become an on-line detection system for HPLC to obtain molecules identification and quantification for sample components eluted from HPLC column.

Applications of the AcuScan2000 for plasticiser, environmental contaminants, Food contaminants, etc. will be reported.

Abstract Text

Two biginelli compounds (1 and 2) were synthesized and further used for developing fluorescent organic nanoparticles (FON's) using reprecipitation method. Compound 1 is derived from urea while compound 2 is derived from thiourea. Characterization techniques like NMR and MASS were used to characterize the compounds. The FONs were characterized using techniques like TEM and DLS. The FONs were checked for their sensing properties using fluorescent spectroscopy technique. Nano-aggregates of compound 1 did not show any sensor activity. On the other hand, nano-aggregates of compound 2 showed selectivity for mercury by showing enhancement in the monomer peaks of pyrene moiety after the addition of mercury. Moreover, the complex of nano-aggregates of 2 and mercury recognised the iodide ion by showing quenching in monomer and excimer emission. Mercury can be detected at a lowest concentration of 21 nM by nano-aggregates of 2. Also, detection limit of 2.Hg(II) for iodide is 4 μ M.

Abstract Text

Polystyrene-core silica-shell nanoparticles (nPs) were developed for scintillation proximity assay (SPA) applications with [beta]-particle emitting radionuclides in physiological samples and biological systems, where due to the high surface area and small volume, polystyrene-core silica-shell nP assays could have greater utility than other SPA designs. [beta]-particle emitting radionuclides are frequently used as signal transducers in biological assays because unlike fluorophores or fluorescent protein tags, radionuclides do not significantly increase the size or mass of the labeled component, and therefore have minimal effects on binding, conformational changes, diffusion, and active transport. In addition, lower background signals are typically obtained for radioassays compared to fluorescence assays. For convenient quantitation, aqueous samples are usually dispersed in scintillation cocktails, which are mixtures of energy-absorbing aromatic hydrocarbons, surfactants, and scintillant fluors, and are consequently incompatible with most biological samples. SPA is a derivative of solid scintillation counting, wherein specific binding of radiolabeled analyte to a solid scintillator surface increases the probability of energy absorption by the scintillant. SPA is particularly useful for [beta]-emitters with low penetration depths and results in an increased number of emitted photons upon analyte binding. SPA also eliminates the need to separate bound from unbound radiolabeled analytes, markedly enhancing the throughput and simplicity of assays. Furthermore, the entrapped scintillant fluors can be selected for photon emission at characteristic wavelengths. The addition of 15-25 nm thick silica shells to 150-200 nm diameter fluor-doped polystyrene core particles makes the particles hydrophilic and facilitates the covalent attachment of binding ligands to the exterior nP surfaces.

Abstract Text

Plasmonic coupling, occurring between two metallic nanoparticles in close proximity, can produce “hot spots” and further enhance the local electromagnetic field. This phenomenon provides a great opportunity for fluorescence enhancement if a fluorophore is located within the intensified electric field. Few literatures have reported this effect between an anisotropic metallic array and a fluorophore. Here, to achieve desired plasmonic coupling, we demonstrated controlled gold nanorod (AuNR) assembly with well-defined surface plasmon pattern on a hydrophilic-hydrophobic substrate surface. Then, we investigated the distance-dependent fluorescence enhancement by introducing fluorescence-labeled DNA of different lengths to the assembled AuNRs. The maximum enhancement was observed at a specific distance between 0 and 30 nm for a given AuNR size. Besides the distance, the fluorescence intensity of a dye absorbed to AuNRs was strongly dependent on the overlap between LSPR of AuNR and the spectral properties of the dye. It is noted that the maximum fluorescence from a dye occurred when the LSPR of AuNRs was overlapped with both excitation and emission spectrum of the fluorophore. This plasmonic enhanced fluorescence is very promising in multiplex DNA detection. As fluorescence labeled DNA sequences hybridize with their complimentary sequences conjugated to AuNR assembly on substrate, the enhanced fluorescence renders a more sensitive detection than traditional micro-array.

Abstract Text

Current techniques, such as MRI and microelectrodes, have elucidated much about brain morphology and function. However, it is still difficult to quantify the spatio-temporal fluctuations of neurotransmitter release in the synaptic cleft. One limitation is working in the tight architecture of the brain. We report on a novel DNA-dendrimer nanosensor to detect acetylcholine transmission in neural tissue slices. The advantage of using DNA enables us to design tailored dendrimer architectures, which efficiently assemble and support maximal co-localization of recognition and reporter elements. To detect acetylcholine, the design utilizes butyrylcholinesterase as a recognition element and a pH sensitive fluorescent reporter held with close proximity of one another. The DNA-architectures highly control and organize the spacing of these two moieties, which leads to increased sensitivity and brighter signal with a lower limit of detection of 200 μ M. The diameter of the nanosensors was observed to be 130 \pm 24 nm by transmission electron microscopy and the structure of the DNA architectures was confirmed by atomic force microscopy. The nanosensors responded dynamically and reversibly to acetylcholine in cells and brain slices. We show the nanosensor components and architecture report acetylcholine concentrations with high spatio-temporal fidelity and are sensitive and selective to acetylcholine in the neurophysiological range. We anticipate this work will further analytical capabilities of physiological processes in physically constrained environments.

Abstract Text

Surface enhanced Raman spectroscopy (SERS) offers considerable advantages as a transduction method for many types of optical sensors, due to its sensitivity and potential identification of multiple target species simultaneously. Over the years, SERS substrates have been developed to be capable of extreme sensitivities, with even single molecule detection having been achieved at randomly located hot-spots of colloidal aggregates. However, such architectures suffer from significant irreproducibility, due to the randomness of the aggregation. Alternatively, strategies such as ordered 2D arrays or enhancements based on single probes (e.g. immuno-nanosensors, nanostars) have high reproducibilities, but are generally limited in their signal enhancements.

To bridge this gap, we have developed a widely applicable enhancing geometry based on metal thin films interleaved with dielectric spacers that takes advantage of a third dimension (perpendicular to the surface) to enhance the signal independently from the underlying structure. Preliminary evidence into the mechanism of this enhancement has shown that the dielectric spacer material and thickness play a key role in the magnitude of the resulting additional enhancement. In this paper we investigate the material and thickness dependence of multilayer enhancement using substrates obtained with ultrathin oxide spacers generated by atomic layer deposition. The SERS sensitivity obtained with substrates fabricated from semiconductor materials as well as dielectric materials have been characterized in order to better understand which properties influence the multilayer enhancement the greatest. In addition a model to describe the mechanism by which the spacer properties influence the multilayer enhancement will also be discussed.

Abstract Text

We developed novel air-stable 2D polymerized photonic crystal (2DPC) sensing materials for visual detection of the vapor phase analytes water and ammonia by incorporating a new ionic liquid, ethylguanidine perchlorate (EGP) as the dispersing medium. 2D arrays of polystyrene nanospheres were embedded in poly(hydroxyethyl methacrylate) (pHEMA)-based polymer networks dispersed in EGP. The bright 2D photonic crystal diffraction depends sensitively on the 2D array particle spacing. The particle spacing change reports on the volume phase transition response of the polymer to the analytes. Water absorbed by EGP increases the polymer-solvent interaction parameter, so that at equilibrium the polymer is smaller. We discuss a novel transient volume phase transition that is observed at smaller time scales, where the polymer network swells in the first 20 minutes before relaxing to the equilibrium state. The process is reversible and the transient volume phase transition is observed for both increasing and decreasing water concentrations. Ammonia absorbed by EGP deprotonates the carboxyl group of the pHEMA-Acrylic Acid polymer, swelling the polymer and causing a redshift in the diffracted light. This ammonia sensor acts as a dosimeter since the volume phase transition is not reversible. We discuss the particle spacing rate of change that is associated with exposure to different concentrations of ammonia gas. This work was funded by the Defense Threat Reduction Agency (DTRA) grant no. 1-10-1-0044.

Abstract Text

Development of analytical methods for highly sensitive, selective and fast detection of cancer cells and biomarkers is of great significance to early diagnosis and therapeutic assessment of cancers. In this paper, a highly selective and sensitive electrogenerated chemiluminescence (ECL) biosensor for the detection of prostate PC-3 cancer cells was developed using a prostate specific antibody as a capture probe and ruthenium complex-labelled wheat germ agglutinin as a signal probe. The ECL biosensor was fabricated by covalently immobilising the capture probe on a graphene oxide-coated glassy carbon electrode. Target PC-3 cells were selectively captured on the surface of the biosensor, and then the signal probe was bound with the captured PC-3 cells to form a sandwich. The ruthenium complex (Ru1)-labelled wheat germ agglutinin (WGA) employed as a signal probe was synthesised and characterised by UV-Vis absorption spectrometry and ECL method. Confocal laser scanning microscopy suggests that Ru1-WGA is attached to the receptors of WGA on the cell surfaces. The conditions of the biosensor fabrication and the capture probe concentration and the incubation times were optimized. The results showed that the ECL intensity of the sandwich biosensor was logarithmically directly proportion to the concentration of PC-3 cells over a range from 700 to 30000 cells/ mL with a detection limit of 260 cells/mL. The ECL biosensor was also applied to detect prostate specific antigen with a detection limit of 0.1 ng/mL. The high selectivity of the biosensor was demonstrated in comparison with that using the ECL fabricated by wheat germ agglutinin as a capture probe and ruthenium complex-labelled wheat germ agglutinin as a signal probe. The strategy developed may be a promising approach and could be extended to the design of ECL biosensors for highly sensitive and selective detection of other cancer-related cells or cancer biomarkers using different probes.

Abstract Text

We have been investigating the Surface Plasmon Resonance (SPR) sensing system. The angle-fixed typed SPR showed remarkably high sensitivity as the mass transducer. The achieved LOD was 30 pg cm^{-2} . However, the sensitivity for clenbuterol by using direct immunoassay was only 500 ppb (ng mL^{-1}), although the requirement was 100 ppt (pg mL^{-1}). Thus, the indirect competitive inhibition immunoassay was used for detection of clenbuterol. By this immunoassay, the sensitivity became 8 ppt (pg mL^{-1}). Kinetics study could explain the reason of this improvement. Moreover, kinetics also predicted the further improvement by using secondary antibody. Aiming to further signal amplification by not only the mass change effect but also localized surface Plasmon resonance (LSPR), Au nanoparticle was attached to the secondary antibody. As a result, the sensitivity at the secondary immunoassay became a thousand times greater than that of the first immunoassay. It was lower than ppq order (fg mL^{-1}).

The sensor surface structure was characterized by electrochemical measurement (Cyclic voltammetry), FT-IR RAS, X-ray photoelectron spectroscopy, and Scanning tunneling microscope. We will discuss that the orientation of antigen (clenbuterol) highly affected on the sensitivity in the immunoassay format of indirect competitive inhibition based on kinetics study.

Abstract Title **Short Chain Fatty Acid Headspace Analysis for GC Using In-Vial Alcohol Esterification**

Primary Author Mark Waksmonski
Shimadzu Scientific Instruments

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s)

Abstract Text

Short chain fatty acids can be difficult to analyze by GC due to their highly polar nature affecting activity within the GC system, as well as affinity for polar solvents when performing headspace analysis. Additionally, if FID detection is used, acids like formic acid give exhibit low sensitivity due to the low number of C-H bonds. Esterification is often a technique used to derivatize fatty acids to esters using an alcohol to reduce polarity, eliminate activity, and increase sensitivity. Headspace analysis with in-vial derivatization provides an easy way to analyze fatty acids with minimal sample preparation. Within this technique there are several options in selecting the appropriate alcohol and ester to optimize analysis of the compounds of interest for different applications. Several alcohol / fatty acid combinations will be analyzed with this method to show suitability for headspace analysis.

Abstract Text

Elemental analyzer with a thermal conductivity detector for Nitrogen and Carbon determination uses as typical Helium carrier gas due the optimum sensitivity. However in the last years the possible worldwide shortage and high cost increasing of Helium, led it to try an alternative gas. Argon gas, readily available with a reduced cost, is the alternative.

The FLASH 2000 Analyzer, based on the dynamic flash combustion of the sample, copes effortlessly with the wide array of laboratory requirements such as accuracy, day to day reproducibility and stability. The instrument was tested with Argon as carrier gas in comparison to Helium using the same Eager Xperience OEA dedicated software for the quantification of the Nitrogen and Carbon content.

This paper presents data on Nitrogen and Carbon determination of pure organic compounds in a large range of concentration in order to demonstrate the performance of the instrument using Argon gas in terms of stability, linearity, accuracy and repeatability.

Abstract Text

GCxGC is one of the fastest growing areas in analytical chemistry due to its ability to resolve a large number of compounds, even in the most complex samples. It employs two columns in series, separated by a modulator. One key to the successful operation of GCxGC is that the two columns must have orthogonal selectivity, that is, they must utilize different retention mechanisms. Column selection strategies to achieve orthogonal selectivity include:

1. Non-polar to polar strategy. Analytes are separated on a non-polar column in the first dimension, and on a polar, highly polar, or extremely polar column in the second dimension.
2. Polar to non-polar strategy. Analytes are separated on a polar, highly polar, or extremely polar column in the first dimension, and on a non-polar column in the second dimension.
3. High resolution polar to non-polar strategy. Analytes are separated on a long (100 m) highly polar or extremely polar column in the first dimension, and on a non-polar column in the second dimension.

Details, benefits, and GCxGC plots for each of these three column selection strategies are presented.

Abstract Text

A scanning, microfluidic platform was developed for use with a flow-based biosensor, affinity-based separations and monolithic columns containing composite nanohybrid materials. The system could be used with HPLC or syringe pumps for the application of mobile phases, reagents and samples, and included a programmable x-y-z platform for detection in three dimensions on devices that included microcolumns, disks, and microfluidic chips. A variety of detection formats were used with this platform, including a scanning near-infrared fluorescence microscope and fiber optic probes for fluorescence or absorbance detection. This system was used for detecting several model target analytes within the channels of microfluidic devices or on the surfaces of modified support materials. This system was also employed for affinity separations in which serum transport proteins were immobilized as binding agents within small monolithic columns, as well as use of similar proteins in flow-based biosensors for the detection of drugs in environmental or clinical applications.

Abstract Text

Gas chromatography has many positive attributes as an analytical tool, however its incompatibility with active compounds is certainly one of the biggest weaknesses and has not been fully overcome yet. The internal surface of a fused silica capillary tubing is chemically active and if not deactivated prior to making a GC column, it can cause solute adsorption and subsequent peak tailing. Therefore, the column making processes generally involve surface deactivation of capillary tubing prior to coating a stationary phase. Substantial progress has been made to make inert GC columns. Until recently, a Grob test mixture referred to here as a column performance test mixture (CPM) consisting of representative acidic, basic, aromatic, ester and hydrocarbon probe compounds was used to evaluate the column performance for inertness. In the current investigation, we have developed various deactivation processes to develop inert columns. Newly developed inert columns were tested using Grob CPM and also, more demanding strong probes "Über One" CPM. It is observed that an excellent performance of a column for Grob CPM does not necessarily provide the best column inertness when compared to the column performance using strong probes Über One CPM. A comparison of the inertness of columns made using various deactivation techniques is illustrated using Grob and Über One CPMs.

Abstract Text

The Pulsed discharge ionization detector utilizes a pulsed DC discharge in helium as an ionization source. The PDD is a universal, non-destructive, high sensitivity detector particularly suited for the analysis of permanent gases. These compounds can be detected up to the low ppb with an excellent linearity range. A criticality in the analysis of gases is the introduction of the sample into the gas chromatographic system, the most reliable and wide-spread technique to inject a gas or a vapor is the injection through a sampling valve.

In this poster the benefits of the adoption of a modular gas chromatograph that offers a flexible and easily installable solution for gases analysis will be presented. Both the PDD detector and the gas sampling valve are comprised into two, user-installable, fully integrated modules that include the detector body or the sampling valve body along with the pneumatic circuits and the electronics necessary for their operation and control.

This modular design allows a new level of instrument flexibility, where inlets and/or detectors selection is based on the application in use, and can be changed in a matter of few minutes by the operator when a new analytical need or application requires different injector and/or detectors without affecting the analytical performances. This poster will discuss the excellent performance of such a system showing the data obtained on gas samples analysis.

Moreover, without adding further hardware complexity, the gas sampling valve module chosen can be easily set to backflush to vent the undesired part of samples, therefore offering an easy and integrated set-up for more complex analysis, without affecting the PDD response. Data showing performance of this solution will be illustrated and discussed.

Abstract Text

Characterization of chromatographic separations is dependent on many factors, including the detector chosen to monitor the separation. A single detector may not be suitable for analysis; it is often useful to combine orthogonal detection. It can be challenging to use detectors based on different physical properties in the same separation: the different detectors seldom have the same sensitivity or linear dynamic range. Also, it can be difficult to find a mobile phase that is suited to work with the mechanism of detection for both detectors. The mass spectrometry and photodiode array detectors give very different information about a sample component. The concentration required for the PDA analysis is usually at a higher intensity than the MS linear response. We have developed a split-and-dilute system to address these challenges. The use of this device is illustrated with a combination of MS and PDA detection. A passive splitter is used to sample a fraction of the flow from the column effluent. The bulk of the flow continues to the optical detector while a portion is then mixed with a makeup liquid that carries the diluted sample to the MS. Using a passive split ratio ensures that both detectors provide and maintain a linear response. The makeup flow can be used to provide more MS compliant conditions for optimum detection. For example, MS signal intensity can be suppressed by ion pairing additives in the mobile phase. We will show elimination of the suppression caused by such modifiers while retaining the desired chromatographic behavior.

Abstract Text

Although reversed-phase columns (e.g. C18) are most commonly used in broad range of applications, they often fail to retain highly hydrophilic molecules (e.g. counterions), and offer limited selectivities. Mixed-mode chromatography provides a viable solution to these challenges by combining both reversed phase and ion-exchange retention mechanisms. One major advantage of this approach is that column selectivity can easily be modified for optimal selectivity by adjusting mobile phase ionic strength, pH and/or organic solvent concentration. As a result, not only is the selectivity of a mixed-mode column complementary to that of reversed-phase columns, but it also allows for the development of multiple complementary selectivities on the same column under different appropriate conditions. Mixed-mode chromatography is well-suited to retaining ionic analytes, whether hydrophobic (e.g. Naproxen) or hydrophilic (e.g. Na⁺ and Cl⁻ ions), and requires no ion-pairing agents in the method, significantly improving the MS compatibility. Most importantly, mixed-mode chromatography column chemistry can be customized to a desired selectivity during stationary phase design. This presentation will give an overview on the latest mixed-mode chromatography technology, describe unique chromatographic properties of mixed-mode columns, and discuss analytical challenges that have been addressed by mixed-mode chromatography approach. Examples include determination of pharmaceutical counterions, simultaneous separation of anionic, cationic, nonionic and amphoteric surfactants, high resolution and fast LC-MS analysis of paraquat and diquat, and analysis of glycans from proteins and human IgG.

Abstract Text

A gaseous amine introduction device, placed after a conventional suppressed conductivity detector in a anion chromatography system based on hydroxide eluent, converts the suppressed elutes from the acid form to an ammonium salt ($\text{NR}_3 + \text{HX} \rightarrow \text{NR}_3\text{H}^+ + \text{X}^-$). Diethylamine is chosen as the amine source due to its low pK_b value (pK_b 2.91) and high vapor pressure. A conventional suppressed anion chromatography system produces a poor response for very weak acids ($\text{pK}_a > 7$), if at all, because HX is hardly ionized. A second conductivity detector then measures the conductivity again. The elutes are thus detected against a low diethylamine background (typically 20-30 $[\mu\text{S}/\text{cm}]$) as negative peaks, because the equivalent conductance of OH^- is greater than X^- . The performances of the amine introduction device were evaluated with respect to induced dispersion and background noise. The introduction of diethylamine in the vapor phase directly through a permeable membrane actually is superior to solution phase NaOH introduction. Relative to a microelectrodialytic NaOH introduction previously reported, the amine introduction device is simpler to build and use. The availability of such a device is expected to facilitate the use of 2-D detection.

Abstract Text

Significance of the research :

Injection is one of the most critical functions for the performance of gas analysis systems based on gas chromatography. The aim of this study was to assess the performance of different gas injection Valves for portable and fast GC application. Mechanical Valves from two different constructors, with internal and external Volume were tested and compared to a silicon injector valve.

Experimental procedures :

The work presented here compares the efficiency of each valve determined with GCAP, a fast and portable GC analyzer based on silicon technology, developed by APIX Analytics. GCAP awarded the coveted Bronze Award for 'Best New Product' at Pittcon 2013 in Philadelphia. It is equipped with a silicon injector and two sensors: a μ TCD and a NEMS (Nano Electro Mechanical System) connected in series. The peak's shape and width will be compared, as well as the plug & play feasibility, the size and the lifetime of each injector type.

Results and conclusions:

Results will demonstrate the importance of injection on the performance of gas analysis systems. High efficiency of silicon injector, resulting in faster throughput, smaller sampling size, higher sensitivity, and easier maintenance, totally confirms the advantage of using silicon technology for fast and portable GC systems. This study conducted in collaboration with Air Liquide, show in particular the advantage of this technology for the calculation of BTU in natural gas application.

Abstract Text

A novel on-column gas detector capable of measuring the transient partition coefficient is developed based on a dual-Fabry-Pérot-cavity structure for micro gas chromatography. The detector is fabricated by inserting an optical fiber coated with a layer of gas sensitive polymer on its endface into a hole drilled on the top of a microfluidic channel which is formed by anodic bonding a glass slide incurred with a line of square groove onto a silicon wafer. The hole is sealed afterwards to prevent any sample loss. The light coupled into the optical fiber is partially reflected at three interfaces of fiber endface-polymer, polymer-air and air-silicon wafer, respectively. The first and second interfaces, and second and third interfaces generate two sets of interference spectra, corresponding to a polymer and an air Fabry-Pérot (FP) cavity. When it is injected into the channel and travels through the detection point, the analyte will be distributed into both of the two FP cavities, resulting in the change of their optical paths and thus the shift of their interference spectra. Therefore, by monitoring their interference spectra shift, the transient amount of the analyte distributed in both FP cavities can be measured, which can be directly used to calculate the transient partition coefficient of the analyte.

Abstract Text

A number of natural materials that possess significant properties (e.g., low cost, easily manipulation for ligand attachment, etc.) have been used for biochromatography¹. Among them, pumice has extra properties such as more stability and large surface area². In this study, chromatographic performance of Cu²⁺-attached pumice particles embedded to monolithic cryogels (Cu²⁺-APPsEMC) for human serum albumin (HSA) was investigated. Monolithic composite cryogels (MCCs) were prepared by means of the polymerization of gel-forming precursors at subzero temperatures. Poly(2-hydroxyethyl methacrylate) (PHEMA) and N,N'-methylene-bis-acrylamide (MBAAm) were used as monomer and cross-linker, respectively. The chemical composition of pumice was determined by XRF. Surface morphology of the composite cryogels was investigated by SEM. Embedded particles (15 mg) in cryogel column were used in the adsorption/desorption of HSA from aqueous solutions. The effects of pH, ionic strength, initial HSA concentration, temperature and flow rate on adsorption were investigated. The maximum HSA adsorption was observed as 549.5 mg/g pumice at pH 8.0 phosphate buffer with initial HSA solution of 3 mg/ml. The efficiency of HSA adsorption from human serum, before and after albumin adsorption was also investigated with SDS-PAGE analyses.

Abstract Text

Chitin is the second most abundant biopolymer in nature after cellulose¹. Problems related to dissolving chitosan in neutral or basic media restricts its usage in many fields. To enhance the solubility of chitosan in aqueous solutions, water-soluble chitosan derivatives are synthesized via the reactive hydroxyl and amino groups that are already present on the chitosan polymer^{2,3}.

In this study, for the purpose of eliminating the solubility problem of chitosan, and thereby extending its usability firstly, a water-soluble O-carboxymethyl chitosan and its copper complexes were synthesized. Then, monolithic composite cryogels of poly(2-hydroxyethyl methacrylate) (PHEMA) and water-soluble chitosan complexes were prepared in a plastic syringe. And these Ni²⁺-attached composite cryogels were used for lysozyme adsorption from aqueous solutions. Optimum conditions of adsorption experiments in aqueous solution were performed at pH 8.0 as 129 mg/g composite. It was observed that lysozyme could be repeatedly adsorbed and desorbed with this composite cryogel without significant loss of adsorption capacity.

Abstract Text

For the purification of large molecules, cryogels are an alternative stationary phase to particle-based media¹. But, due to the drawbacks of cryogels (i.e., low surface area) and particle sorbents (i.e., pressure drop in fixed beds), in recent years, the use of hybrid cryogels has greatly increased².

In this study, a novel hybrid cryogel column was synthesized for the purification of α -amylase from aqueous solutions. Firstly, poly(2-hydroxyethyl methacrylate) beads (2 μ m size) were prepared, and after iminodiacetic acid (IDA) immobilization, Cu²⁺ ions were attached via the IDA chelating groups. These arranged Cu²⁺-attached PHEMA beads (Cu²⁺-ABs) were located into PHEMA based cryogel in order to prepare Cu²⁺-ABs embedded supermacroporous hybrid cryogel (Cu²⁺-ABsEHC) column. The specific surface area of the hybrid cryogel was found as 95 m²/g by using BET. The amount of IDA on beads was found as 875 μ mol IDA/g. It was approached to the optimum adsorption levels at initial α -amylase concentration of 5 mg/mL and pH 5.0 in Tris-Base buffer as 107.1 mg/g beads. It is demonstrated that this column is a potential separation medium for purification of in α -amylase.

Abstract Text

A convenient, energy efficient continuous flow extractor is described. As the latent heat of vaporization is equal to the latent heat of condensation, these basic physical processes are combined in a unique heat exchanger. A compressor reduces the gas pressure within the evaporator allowing the solvent to vaporize and separate from solution and return to the condenser side compressed and be converted back into solvent. This enables the collection of the desired extract, solvent free and permits the continuous flow the regenerated solvent to continuously extract the desired sample. This extraction process requires no heat or cooling input and recycles all solvent. The only energy requirement is power for the compressor.

Abstract Text

One-dimensional gas chromatographic (GC) analysis suffers from limited peak resolution for complex, compound-rich (100+) mixtures. Thus, addition of a second-dimension (2D) separation is often required for an additional separation mechanism. Conversion of 2D data to qualitative or semi-quantitative concentration results requires complex mathematical analysis which is difficult to maintain when chromatographic retention time shifts occur.

MAX™ is a new detection technology for GC which overcomes the qualitative and quantitative limitations of GCxGC. The novel optical detection system employed in the GC-MAX™ technology has proven calibration stability of better than 5% and < 1% RSD on repeat measurements. Once the MAX™ technology is calibrated for a compound, that calibration can be used for the life of the system or any similarly configured MAX™ technology system.

In addition to being fully quantitative, peak identification is also easily performed on co-eluting compounds by a novel spectral analysis algorithm based on chromatographic retention indices. The capabilities of this new technology will be demonstrated with ASTM D5501 Test Method for the Determination of Ethanol Content of Denatured Fuel Ethanol and ASTM D4815 Test Method for the Determination of MTBE, ETBE, TAME, DIPE, t-Amyl Alcohol and C1-C5 Alcohols in Gasoline. Here the advantages of the MAX™ technology to both quantify the high concentration ethanol concentration along with the low level oxygenates in a single analysis without the use of a second-dimension separation to remove hydrocarbon interferences/co-elutions will be discussed.

Abstract Text

Matheson as a company is always striving for continuous improvement and development of new capabilities. Since customers demand the highest quality of materials readily available to them, there are many different ways to steadily improve. One method includes but is not limited to, the use of a measurement capability assessment (MCA) study. MCA studies encompass the measurement of attributes that are important to instrument capabilities. Data is obtained to demonstrate accuracy, static repeatability, linearity, as well as a Gage R&R study. Static repeatability is based primarily on measurement to measurement variation. The linearity study is used to determine the recovery range of the system in question which is done by using a set of standards which cover a concentration range of interest from high to low concentration. Static repeatability is a measure of the short term instrument variation. A gage R&R study measures total process variation and is performed by two operators who perform multiple trials on multiple standards over multiple days. These multiple trials estimate repeatability while the multiple operators are needed to estimate reproducibility. Multiple standards are needed to provide an estimate the variation. This MCA study involved the use of low percent level oxygen balanced helium as the material with the main subject of interest being a target concentration of 0.5%. Other standard concentrations included 0.2%, 0.32%, 0.75%, and 1% oxygen/helium mixes. The results from these studies will be presented and will be compared against the criteria for this type of mixture.

Abstract Text

Method Capability Assessment, or MCA, is a series of studies to determine if an instrument is suitable for a particular analysis and in this case is suitable for the measurement of a gas mixture at a given concentration, or a range of concentrations. A MCA study includes linearity testing, static repeatability, accuracy testing, and Gage R&R. A comparison study was also completed in this investigation to validate the concentration of the mixtures. The instrument used for the MCA was a Varian CP4900 Micro Gas Chromatograph equipped with a Thermal Conductivity Detector (TCD). The TCD detector was selected because of its simplicity in terms of response and wide diversity of concentration ranges that can be measured. A method was developed for the analysis of low percent level nitrogen mixtures in helium, and was validated using these MCA studies. The MCA study concluded the instrument was linear in the range of concentrations analyzed, repeatable and accurate, and the data could be reproduced over a range of concentrations, days, and operators.

Abstract Text

Metrological traceability of mixed standard solution for calibration is required to sustain QA, QC and laboratory accreditation. This traceability to the international system of unit (SI) is described by combination of the unit of amount of substance (mole) and the unit of mass. Those SI base units are managed by National Metrology Institute (NMI). Mole is realized by NMI to assign specific value (concentration with uncertainty) to the pure substances. Number of pure substances assigned by NMI are limited, thus the supply of the SI-traceable Primary Reference Material (PRM) are not enough to satisfy the requirement of the quantitative analysis. We developed new standard materials calibration system with National Metrology Institute of Japan (NMIJ). The user of this system can expand SI-traceable standard mixture (gas or liquid) by calibration using gas chromatograph (GC) with PRM. By the conventional way, it is required to match the calibration components and the analyte. The point of this new system is that it does not need matching to the calibration substances and the analyte.

In particular, standard mixture (PRM) prepared by the gravimetric method from more than three pure substances (PRM) which assigned specific value by NMIJ is used for calibration on this system. This system equips the reactor between separation column and flame ionization detector (FID) on GC. After separation, each substance of this PRM is converted to CO_2 and then reduced to CH_4 . Each substance is detected as CH_4 on FID so that calibration curve for atomic concentration of carbon as CH_4 is obtained. The conversion efficiency of the reactor is checked if this calibration curve is drawn straight and goes through the origin. When unknown substances are measured in the same way and assigned specific value by this calibration curve, they can be assured SI-traceability.

We will show the way to expand SI-traceable standard mixture by this system.

Abstract Text

Computational simulations of equi-potential contours and ion beam shapes in planar drift tubes were used to examine the influences of field strength on beam broadening in air at ambient pressure from 15 to 45 V/mm. Beams were shaped with a slit aperture placed in the drift tube cross section. Results from computational simulations with SIMION 8 demonstrate that beam broadening is decreased in y-axis with increased electric field in the drift region. While much of this control can be attributed to ion residence time in the drift region, shape of beams in non-linear fields suggests some focusing of ion beams with convex equi-potential contours. A planar drift tube was used to bend ion beams 90 degrees in a 14.3 mm radius in three beams passing center, outer and inner tracks of the bend. Differences in electric field with each track and additional time of travel could account for y-axis broadening of the beams. Images of the ion beams inside the planar drift tube were obtained with IonCCD array detector to support the simulations.

Abstract Text

Response in an ion mobility spectrometer equipped with a beta emitter as the ion source originates in positive polarity through an ion-dipole or ion-induced dipole association between a neutral vapor analyte and a hydrated proton in a purified air atmosphere. This reaction forms product ions derived from the analyte and such ions appear as peaks in a mobility spectrum provide the product ions have lifetimes which exceed the time of residence in the drift tube. Existing understandings of quantitative response in IMS arise significantly from results of API MS studies. These suggest that quantitative response in an IMS drift tube at ambient pressure will be affected by moisture in the supporting gas atmosphere and that increases in moisture will cause decreases in absolute response across the range of dipole strengths. Most commercial hand-held or benchtop IMS analyzers contain sieve packs or membrane inlets to reduce and control moisture though effects have never been quantitatively established. Response factors obtained over a concentration range from limits of detection to source saturation are shown for molecules of carbon number from three to eleven for alcohols, aldehydes, esters, ketones, amines, and organophosphorous compounds. Effects are compared to computationally derived values of hydrate numbers for the reactant ion, a hydrated proton, at temperatures from 100 to 250°C. Implications for inter-comparison of quantitative response for IMS analyzers will be discussed.

Abstract Text

The capabilities of modern Wavelength Dispersive X-ray fluorescence (WDXRF) systems are rapidly advancing to meet the analytical demands in research areas from geological to biological. XRF is a non-destructive technique, and having the ability to characterize samples after elemental determination is essential for various research areas.

WDXRF has the ability to utilize multiple measurement techniques for elemental determination depending on sample type. The use of empirical calibrations using reference standards or standardless analysis where in most cases reference standards are not available for XRF, are options to meet qualitative or quantitative needs. Additionally, the WDXRF incorporates unique tools such as sectored inserts to accommodate low sample volume and 2D/3D imaging through Mapping/Spotting techniques.

Samples from research areas including geological, biological, process control, cosmetics and reclamation were analyzed for elemental composition and in some instances mapping was performed to determine elemental distribution across the sample. Each research area presented a unique sample type where extraction or digestion would be difficult to achieve, costly, and time consuming. The sample preparation for WDXRF analysis on these samples was minimal and cost effective.

Results demonstrate the power and flexibility of a modern WDXRF across diverse sample types. The 2D/3D imaging feature displays elemental distribution across a sample, which is beneficial for applications such as reclamation and biological analysis. For certain samples, comparative techniques (ICP-MS, ICP-OES, and XRD) were performed.

In conclusion, a calibrated analytical routine is the typical approach to many applications, standardless analysis methods can provide both valuable and accurate information where reference standards simply do not exist. The ability to examine and even quantify small and irregular samples or samples in-situ has also proven beneficial in many fields.

Abstract Title **Characterization of Aged Varnishes in Art Conservation: A Raman Study of Decomposition Processes**

Primary Author Veronica M. Alvarez
University of Wisconsin Milwaukee

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Anahit M. Campbell, Joseph H. Aldstadt, Lisa K. Kendhammer, Sarah K. Patch

Abstract Text

We will describe a method for characterizing varnishes that may be applied to the more accurate restoration of artistic objects. In the first part of this study, a method based upon Raman Spectroscopy was used to develop a database of spectra for common varnishes, their degradation products, as well as a set of carboxylic acids and fatty acids that are typically found in aged varnish samples. A pattern recognition method based upon Singular Value Decomposition (SVD) was developed to determine how well the database represented the unknown varnish samples. SVD applied to the database yielded seven singular values that were then used to identify unknowns – Linseed Oil, Chinawood Oil, Dammar, and Mastic. The relative root-mean square (RMS) error for the unknowns was 1.7%, 1.7%, 4.9%, and 6.4%, respectively. In the second part of this study, the Raman method was applied to the products created in an accelerated aging chamber as a means to better understand the decomposition processes that occur in varnishes. An ageing chamber was designed and fabricated to allow for the precise control of temperature, light, and atmosphere. Time course studies of Linseed Oil and Chinawood Oil samples were performed over a range of thermal and photochemical conditions. Thermal studies were conducted from 25 °C to 210 °C over periods ranging from 2 to 170 hr. A direct correlation was found between the changes in the vibrational bands that were observed in the Raman spectra and the observation of overt physical changes in the samples. Based upon these data, several reaction mechanisms for the decomposition of the varnishes will be proposed.

Abstract Text

Compared with other elemental analysis techniques, energy-dispersive X-ray fluorescence (EDXRF) is more suitable as a non-destructive method for precious museum objects. Recently, the research has been focused on portable HHXRF due to its convenience. In this study, Particle-induced X-ray Emission (PIXE), Bench top XRF and handheld XRF are applied on the analysis of ancient Chinese ceramics. The instrumentation capability and the analytical performance were systematically evaluated in this study.

Abstract Text

Portable X-ray fluorescence (pXRF) offers an opportunity bring the lab to the sample. As a non-destructive analysis tool that is also portable, it can be used to study the deteriorated 18th century frescoes of the Alamo in great detail. The objective is to digitally recreate the once-elaborate designs of these frescoes and reimagine a cornerstone of Texas history. Select areas of interest are analyzed with the pXRF, which identifies elements based on characteristic differences in energy emissions. We are particularly interested in identifying elements that are characteristic of pigments used in 18th century. Trace levels of copper, iron, lead, and mercury are particularly informative, indicating the possible use of verdigris, red and yellow ochres, lead whites, and vermilion pigments respectively. The presence of elevated counts of these elements, supported by multispectral imaging, and analysis of physical samples with scanning electron microscopy, provides a means of digital reconstruction of the original appearance of the Alamo. Thus far, several designs in the former mission's sacristy have been well characterized and mapped, including a chalice-like shape now nearly invisible to the eye. In addition, multiple leaf and stem-like patterns that are only visible under ultra violet light have been confirmed with pXRF. This research has revealed repeated design elements and elaborate detail on the frescoes in the Alamo sacristy, moving us closer to a recreation of these nearly 300 year-old pieces of art history.

Abstract Text

Raman spectroscopy is a valuable tool in the arsenal of the art conservationist. Through the acquisition of a vibrational spectrum of the surface of a sample, various types of important information can be gleaned. Of particular interest are chemical composition of colorants (inorganic vs. organic), potential origin of the minerals used in pigments, and what weathering or environmental damage has occurred, for example. Additionally, this information helps to establish authenticity and provenance of paint and pigment substances. This poster will focus on our efforts to develop more effective measurement methods for the challenging pigments that are encountered in older artifacts, especially those with green and blue-green mineral pigments, which have been found in the past to have a forbidding amount of native fluorescence.

The samples that will be of chief interest will be pigments on fresco samples from the Coriglia archaeological site near Castel Viscardo, Umbria (Italy). Data will be collected at 785 nm and background corrected to remove fluorescence commonly associated with Raman measurements of pigment materials. The resultant spectra will be compared with pigment and mineral databases, as well as mineral pigments purchased from art supply dealers.

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Alex Sutton

Abstract Text

A variety of demonstrated ethylene antagonists and agonists were modeled using Spartan'10 (Wavefunction, Inc) to develop a systematic theoretical basis for the identification of potential novel ethylene antagonists. It was found that known antagonists yielded HOMO energies at or above the calculated value for ethylene. It was also found that the known antagonists have LUMO energies lower than ethylene. Subsequently a variety of 1-substituted cyclopropenes were modeled and their orbital energies calculated. It was observed that as the electron donating ability at the 1-position increased, so did the HOMO energy. Strongly electron withdrawing 1-substituents had HOMO energies greater than ethylene and as such are predicted to exhibit ethylene antagonist behavior. This comparison of the empirical and theoretical data suggests a relatively simple methodology for predicting the antagonistic behavior of novel candidate compounds.

Abstract Title **A Theoretical Investigation of Trends in the HOMO to LUMO Transition Energies of Tris(2,2'-bipyridyl)ruthenium(II) Complexes Containing Various Substituted Ligands**

Primary Author Jon Gold
East Stroudsburg University

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Christopher Wisniewski, Joseph Sluzevich

Abstract Text

A theoretical investigation of various modified forms of substituted forms of tris(2,2'-bipyridyl)ruthenium(II) were performed using PM3 (semi-empirical) and ab-initio levels of calculation. Selected molecules included single and multiple substitutions at one, two and three bipyridine moieties. The effects on HOMO and LUMO orbital energies differences were studied as a function of substitution. Substitutions included varying the numbers and types of halogens on the bipyridines. In addition the effect of the addition of conjugated propenes to the bipyridine was investigated and compared to changes observed by the addition of saturated chains. A complex behavior attributed to both inductive and conjugation effects was observed for these modelled complexes. Substitution of hydrogen by fluorine was particularly anomalous. However, the substitutions did not affect the HOMO or LUMO orbitals' essential ligand-based π^* character.

Abstract Text

Beta radiation is an attractive ionization technique e.g. for Ion Mobility Spectrometry due to its reliability, well known ionization mechanisms and its independence from external power supply. A main drawback is that beta radiation sources are subject to different national and international regulations. Thus, the use of alternative ionization methods is desirable not only to add new detection options, but also to circumvent the strict regulations that apply for radioactive material.

The new non radioactive ion source consist of an electron gun operated under ultra-high vacuum (UHV). The generated electrons can be accelerated to a kinetic energy in a range from 1keV to 15keV. The resulting beam has enough energy to trespass a thin membrane, which separates the UHV region from the reaction region under atmospheric pressure where the ionization takes place. As an option the electron beam can be guided through the membrane into a chamber filled with a noble gas where so called excimer are generated and during the decay process Vacuum Ultra-Violet (VUV) photons of an energy characteristic for the composition of the excimer are emitted. In this way a dual ion source, electron impact and soft ionization is possible.

Monte Carlo calculations were conducted to simulate the electron transmission through the membrane. Electron distribution and the transmission efficiency in dependence of the initial kinetic energy of the electron beam was computed. The energy deposition in the thin membrane was evaluated.

The total energy deposition serves as input for the thermo-mechanical simulation of the thin membrane. In addition the load due to the pressure differences are considered.

As a result threshold values were calculated at which a mechanical destruction of the membrane will occur. The results are in good agreement with experimental observations. Also optimal operating parameters for the non radioactive ion source were determined.

Abstract Title **The Potential of Internalization and Self-Reliance of Brazilian Pharmaceutical Products**

Primary Author Ana Paula P. Nascimento
IFRJ

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Simone Alves

Abstract Text

The Brazilian chemistry industry trade balance is very alarming, as it presents increasing and persistent trade deficits since the 1990 decade. It reaches a new record in 2013, when it totaled US\$ 32.0 billion with a 13.6% increase compared to 2012 (Abiquim, 2014).

Pharmaceutical products - which provide a more inelastic demand to Gross Domestic product (GDP) - most strongly impact this deficit. However, Brazil's pharmaceutical industry is still currently dependent on imports and registered a deficit increasing of 15.3% between 2012 and 2013, jumping from US\$ 6,637 billion to US\$ 7,658 billion in 2013 (Abiquim, 2014).

The research was based on universe of 625 chemical products classified as pharmaceuticals (APIs) and medicines for human use, selected from the PRODLIST-Indústria 2010 (Ibge, 2011) for which it was collected the trade balance statistics (exports and imports) from AliceWeb System (<http://aliceweb.desenvolvimento.gov.br>) from 2009 to March, 2014.

The results points to a data base of 521 products - 228 drugs and 293 Active Pharmaceutical Ingredients (APIs). Figure 1 shows the trade balance evolution in this period which shows negative results over the years as the small export growth is not enough to reduce the deficit caused by a growing on imports.

Table 1 details TOP 5 values (in US\$ FOB) trade deficit in 2013, split by APIs and medicines for human use segments. The initial exploratory results points to future definitions of strategic medicines and APIs in order to revert the Brazilian dependency on imports in medium and long term. These findings should be investigated in the continuity of the present study, incorporating data from production capacity and planned investments in the sector.

Abstract Text

Film uptake, electrochemistry and spectroelectrochemistry of various rhenium complexes are investigated. The rhenium complex $[\text{Re}(\text{CO})_3(\text{H}_2\text{O})_3]^+$ is converted into the optically emissive complex $[\text{Re}(\text{CO})_3(\text{L-L})]^+$, where the ligand comprises of various bi-dentate ligands. Uptake is observed electrochemically using a selective polymer thin-film on an optically transparent electrode (OTE). Preconcentration of the complexes is observed optically by luminescence modulation. Optimization of the polymer film, electrochemical, and optical components allows for the modulation of complexes with various charges.

Abstract Text

Glassy carbon electrode was modified by drop-coating technique with aza-15-crown-5 for determination of Cu(II) by square wave anodic stripping voltammetric (SWASV). The new electrode exhibit an increase of sensivity due the complexing capabilities of aza crown ether with metals cations. Best result were obtained with aza-15-crown-5 0,031 mmol L⁻¹; pH 4,0; deposition potential -0,7 V and deposition time 80 s. A detecion limit was 0,021[micro] L⁻¹, and linear range was 10-50 [micro]L⁻¹. Interference from metal ions like Fe(II), Pb(II)y Cd(II)was also studied. The method is sensitive, selective and simple with a relative standard desviation of 11 %.

Abstract Title **Differentiation of Adenosine From Histamine With Fast-Scan Cyclic Voltammetry Using Alternative Waveforms**

Primary Author Scott T. Lee
University of Virginia

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) B Jill Venton

Abstract Text

Adenosine plays a major neuromodulatory role in the brain, impacting processes such as neurotransmission and blood flow. Spontaneous, transient adenosine release has been characterized in the rat brain using fast-scan cyclic voltammetry (FSCV) at carbon fiber microelectrodes. Unfortunately, several other analytes, such as histamine, ATP, and H₂O₂, have cyclic voltammograms that can appear similar to that of adenosine. Waveform manipulation has become an appealing route as it requires no additional materials and is simple to test in vitro. Recently, it was found that a sawhorse waveform could differentiate adenosine from ATP and H₂O₂ due to the presence of an extra characteristic 'hump' in the oxidative peak of adenosine. Histamine, unfortunately, had the same feature and could not be discriminated from adenosine. In this work, the traditional triangle waveform was slightly altered to include a 0.75ms hold at 1.25V during the anodic scan. Since histamine is oxidized at a slightly lower potential than adenosine, the hold allows histamine to completely oxidize before adenosine begins to be oxidized and thus, separates the peaks. Exogenously applied histamine and adenosine were separated with this method in a rat brain slice as well, though the hold potential had to be raised to 1.35V. Future work with this waveform includes applying Principal Components Analysis to determine concentrations of adenosine and histamine in mixtures. This will determine whether quantitative co-detection of these analytes can be performed. It may then be possible to explore the roll of adenosine in neuromodulation of histamine.

Abstract Text

Supercapacitors store electrical charge in a double layer at the interface of an electrolyte and a surface, primarily porous carbon with high surface area. The energy density (ED) of such a capacitor is determined by $ED = \frac{1}{2} CV^2$, where V is the potential difference between the plates of a capacitor and C is the capacitance density. Therefore, extending the operational voltage of such devices, which is limited by the electrochemical window of the electrolyte or solvent, can improve the device energy density.

Typically, the electrochemical window of an electrolyte is limited by oxidation of the anion at positive voltages and reduction of the cation at negative voltages. For determining electrochemical stability, we used a recently developed method that involves linear regression in the approximately linear ranges of the linear sweep voltammogram.¹ The new method is much less sensitive to variations in ion mobility and electrolyte concentration than the traditional method based on arbitrary cutoff values of the current density. We studied the effect of cation structure (aromatic vs. saturated) and straight or cyclic alkyl substituents attached to a nitrogen on the stability towards reduction. Even though aromatic cations, such as imidazolium ions, are largely used as ionic liquids in supercapacitors, our finding indicates that saturated cations (e.g., tetraalkylammonium cations) are more electrochemically stable. It was found that symmetry and steric hindrance of substituents on the quaternary ammoniums does not improve electrochemical stability. Future work is focused on understanding how electrochemical stability can be correlated to molecular properties such as molecular orbital energy levels.

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Alan B. Placencio, Karina J. Diaz, María P. Oyarzún, Rodrigo A. Segura

Abstract Text

This work consists in the development of electrochemical sensors for the determination of selenium using modified electrodes with gold nanoparticles generated by electrochemical (CV/AuNPs/eq) and chemical method (CV/AuNPs/sq) using the technique of anodic stripping voltammetry (ASV) with sweep square wave voltammetry (SWV). CV/AuNPs/eq was characterized by cyclic voltammetry (CV), atomic force microscopy (AFM), scanning electron microscopy (SEM) and spectrometry X-ray scattering (EDS) finding a homogeneous distribution of gold nanostructures with a size of 75 nm. Chemical synthesis of gold nanoparticles was characterized by transmission electron microscopy (TEM) and UV-vis spectroscopy (surface plasmon resonance) obtaining spherical gold nanoparticles with an approximate size of 5 nm. CV/AuNPs/sq was characterized by cyclic voltammetry (CV). Under optimal conditions of accumulation potential (E_{acc}) - 0.80 V, accumulation time (t_{acc}) 120 s and 15 Hz frequency, validation was developed. CV/AuNPs/eq presented a linear range between 10 to 50 $\mu\text{g L}^{-1}$ with a limit of detection (LD) of 0.120 $\mu\text{g L}^{-1}$ and the linear range for CV/AuNPs/sq was 5-55 $\mu\text{g L}^{-1}$ with an LD of 0.183 $\mu\text{g L}^{-1}$.

Abstract Text

One of the major problems of today's world is in its heavy dependency on fossil fuels for energy requirements. So the increase uses of sustainable energy resources are very important. Hydrogen, the most abundant element on earth is the cleanest and ideal fuel (carrier), has been considered as the fuel of the future. The simplest way of hydrogen production is the electrolysis of water. In this sense, a wide variety of metal electrodes have been modified by conducting polymers which exhibit good catalytic activity in several electrochemical processes.

Chitosan has long been marked as one of the most promising natural polymers, has chemical inertness, high mechanical strength, biodegradability, biocompatibility, high-quality film-forming properties, and low cost. For this purpose, chitosan-assisted synthesis of conductive polymers has been extensively studied in recent years.

This study is focuses on the development of new forms of conducting polymer/metal nanoparticle composite materials as low-cost, efficient catalysts for hydrogen production from water. For this purpose, the electropolymerization of aniline was achieved on low cost graphite pencil electrode in the presence of chitosan in electrolyte medium. Conductive and mechanically strength composite films were obtained by incorporating chitosan to the polymer chains. Then the platinum (Pt) particles were electrodeposited on the composite on nano scale which has exhibit high catalytic activity on hydrogen production. The catalytic activities of all composite materials were investigated for electrocatalytic hydrogen evolution reaction. The electrocatalytic activities of the composite electrodes were studied by cyclic voltammetry, Tafel polarization curves, electrochemical impedance spectroscopy. The structure and morphology of the electrode materials were also investigated.

Abstract Text

Spectroelectrochemistry is a well-known technique used to achieve concurrent multimode selectivity in one sensor. The sensor usually consists of an optically transparent electrode (OTE) coated with a charge selective polymer film. These polymer films are employed to pre-concentrate analyte at the OTE surface so that it can be sufficiently detected optically through electrochemical modulation, while lowering the detection limit. OTEs such as Indium Tin Oxide (ITO) have been used extensively in this method but little is known about the applicability of such sensors using other OTE materials, such as Boron Doped Diamond (BDD). We have developed an attenuated total reflectance (ATR) absorbance and fluorescence-based sensor with a BDD OTE coated with sulfonated ionomer films, Nafion and SSEBS. This is demonstrated using tris(2,2'-bipyridyl)ruthenium(II) ion [Ru(bpy)₃2+] and the results are compared to those obtained on ITO. One distinct advantage of BDD OTEs over ITO OTEs is their significant increase in sensitivity for organic compounds, such as para-aminophenol and hydroquinone. Using this sensor we were able to manifest new applications to broaden the use of spectroelectrochemistry and BDD as an electrode material.

Abstract Text

For feedback controlled monitoring of the popular anesthetic, propofol, we used a voltammetric sensor coated with a highly-plasticized polymer membrane [1]. The sensitivity of the sensor is controlled by diffusion coefficient (D) of propofol in the membrane, while the detection limit and the selectivity depends on the partition coefficients (P) of the analyte and interfering compounds. Both D and P are strongly influenced by the composition of the membrane. To optimize the membrane composition for sub-micromolar detection limit and adequate selectivity, the diffusion and partition coefficients have to be measured in a variety of membranes.

In our contribution, we show that both D and P can be determined voltammetrically using planar electrochemical cell with a carbon fiber microelectrode. To show the feasibility of the method, first we determined the diffusion coefficients in a variety of organic solvents (e.g. tetrahydrofuran, dichloromethane) and plasticizers (e.g. octanol, ortho-nitrophenol octylether), both with and without supporting electrolyte. Diffusion coefficients were calculated from the steady state current recorded in solutions of electrochemically active compounds prepared in the different solvents. Once the diffusion coefficients were known, the steady state current measured in water-immiscible plasticizers -- following a liquid-liquid extraction -- could be used to calculate the organic/aqueous partition coefficients.

By coating the cell with a membrane, the same method could be used for determining D and P in the membrane. In this contribution, we report the diffusion and partition coefficient of a variety of compounds (e.g., ferrocene derivatives, propofol, p-acetamido phenol) in organic solvents/plasticizers and membranes.

Abstract Text

The spectroelectrochemical characterization of an optically transparent electrode (OTE) micro-fabricated sensor is investigated. The stability of the microsensor was improved by electroplating silver and chemically oxidizing silver chloride onto the platinum reference electrode. The sensor combines three modes of selectivity (electrochemistry, selective partitioning, and spectroscopy). The selective partitioning component of the sensor consists of a charge-selective polymer thin-film for preconcentration of the model compound. The spectroscopy component of the sensor is investigated using luminescence modulation. The use of the OTE fabricated microsensor with these three modes enhances the sensitivity of the sensor as well as selectivity for detection of trace concentrations of a target molecule.

Abstract Text

Restriction endonucleases are the main tool of modern genetic engineering. They are essential in recombinant technology, sequencing of a large DNA strands, genotyping, mapping, and also they play a crucial role in a molecular diagnostics. Because of their biological importance and wide use, a number of methods have been developed to assay restriction enzyme activity. However, all these protocols are time and DNA consuming, laborious, and usually require isotope or fluorophore labeling. Thus, the search for a new, simple and economical methods for endonuclease activity determination is ongoing.

In our work we have focused on monitoring enzymatic reaction using electrochemical biosensor and square wave voltammetry (SWV). A PvuII restriction enzyme and a 20-mer oligonucleotide dsDNA self-assembly monolayer (SAM) on gold, containing a restriction recognition site of a chosen enzyme, were used as a model system. The measurement of enzyme activity is based on decrease of current signal derived from the redox active probe—methylene blue (MB) present in the solution. The impact of DTT, BSA, TRITON X-100, and glycerol that are commonly used in enzymes solution on dsDNA-SAM was examined using electrochemical impedance spectroscopy (ESI). The influence of the distance of the restriction site from the electrode surface on the assay sensitivity was also evaluated. The kinetics of the enzymatic reaction using developed sensors with various oligonucleotide sequences will be presented as well.

Abstract Text

The electrospinning carbon fibers made from polyacrylonitrile (PAN) have attracted attention due to their easy processing, high carbon yield and robust mechanical properties. In this work, a glassy carbon electrode modified with carbon fibers was developed for the simultaneous determination of trace levels of lead and cadmium by anodic stripping voltammetry (ASV) (Figure 1). Compared to the bare glassy carbon electrode, the carbon fiber modified electrode greatly improves the sensitivity for cadmium and lead. The electrode was demonstrated with analysis of real samples. The interactions between lead and cadmium was investigated in detail.

Abstract Text

Oxygen reduction reaction (ORR) is of interest in the areas of amperometric oxygen sensing, fuel cell, and etc. Since the ORR is a sluggish reaction requiring a high overpotential, relevant electrocatalysts are employed. Most commonly used catalyst, Pt, however, has the limitations of high cost, scarcity of supply, and susceptibility to poisoning by alcohol fuel. In our previous studies, we investigated the electrocatalytic activity of silver halide compounds for the ORR of fuel cells.

In continuation to our previous work, we performed first-principles density functional theory (DFT) calculations to investigate the reaction pathway of ORR on the 100 surfaces of electrocatalysts composed of metal halide (MX, X = Cl or Br). The catalytic mechanism of these electrocatalysts for ORR was elucidated by calculating the binding energies of ORR intermediates (e.g., O₂, O, OH, OOH, HOOH, and H₂O) on the catalysts.

Our theoretical study provides a possible explanation for the experimental findings of 4 electrons or 2 electrons reduction paths on the metal halide electrocatalysts in comparison to pure Pt and pure metal electrocatalysts.

Abstract Text

Next generation techniques for bio-manufacturing, medical diagnostics and environmental monitoring demand high performance and low-cost chemical sensors. Electrochemical sensors are poised to significantly impact these technologies, because of their relatively low cost, simple construction, and ease of use. Unfortunately, the broad range of electrochemical sensors demonstrated by researchers has produced only limited commercial technologies. These limitations are partly due to the complexity of real-world samples and the inhomogeneity of sensing environments. Active control of an electrode's temperature is one potential route to overcoming these challenges by both delivering a stable and known sensing temperature across measurements and providing an additional tunable experimental variable for improving measurement sensitivity and selectivity.[1,2]

Here we present the design, fabrication, and temperature characterization of microfabricated, temperature-controlled electrodes. The use of microfabrication provides several advantages by improving sensor reproducibility, control, and throughput. Heated disk electrodes with rapid thermal responses and independently controlled temperatures were fabricated with underlying Pt microheaters (Figure 1(a)). Fluorescent temperature imaging techniques were used to evaluate temperature gradients and thermal response times and their impact on sensor design and performance. Electrochemical measurements were performed on model systems (e.g. $\text{Fe}(\text{CN})_6^{3-/4-}$) in which coupled heat and mass transport impart signal enhancement, as shown in the cyclic voltammograms in Figure 1(b). We have also explored the impact of various temperature control routines, such as temperature steps, pulses and oscillations, on electrochemical signal content.

Abstract Text

We have developed a new method to characterize the neurotransmitters bound to the dense core protein nanoparticles. We measure current transients from single vesicles impacting an electrode. When these transients are analyzed, 70% of the decay curves can be fit to a double exponential curve suggesting that the dense core inside the vesicle plays a role in the response. In addition, we are looking for collision events for dense core proteins alone as they impact the surface of a microelectrode. The transmitter molecules in the dense core protein should be oxidized at the electrode surface leading to a current that can be quantified by Faraday's law. Dense core protein located in secretory vesicles is composed of charged polypeptides from the Chromogranin family. These can be isolated from chromaffin vesicles by density gradient centrifuge. This protein matrix accumulates and stores high concentrations of neurotransmitters, Ca²⁺ and ATP within the secretory vesicle. However, the mechanisms of accumulation and release of neurotransmitter molecules are unknown and highly debated. The aim of this project is to study how the protein matrix in large dense core vesicles affects the storage and regulation of neurotransmitters both in the dense core and in the nano-environment of each vesicle.

Abstract Text

Electrochemically mediated desalination is an energy efficient and membraneless method to separate salts from water by using electrochemistry. The process relies on the generation of a local electric field gradient near an electrode embedded at the junction of a bifurcated microchannel structure. At the electrode, a small percentage of the naturally abundant chloride in seawater is oxidized to chlorine, consequently producing a localized ion depletion zone and electric field gradient that increases ion electromigration, therefore separating ions to produce partially desalted water. Moreover, we describe how applied potential bias, chloride concentration, flow rate, and electroactive surface area affect the desalination process.

Abstract Text

Today, ion-selective electrodes (ISEs) are capable of detecting nanomolar concentrations of metal ions. However, ISEs require a long pre-conditioning step in a solution containing the analyte ion. During that period, a zero-current ion flux is established while the ionophore is saturated with the analyte ion. This required step highly limits ISEs' in-field application. Here, we present ISEs for Na^+ , Ag^+ , and I^- with Nernstian response and submicromolar limits of detection that do not require pre-conditioning step.

Na^+ -ISE and Ag^+ -ISE contain 10 mmol kg^{-1} of sodium ionophore X and copper (II) ionophore I, respectively, and 5 mmol kg^{-1} of sodium tetrakis[3,5 bis(trifluoro-methyl) phenyl] as ion-exchanger. I^- -ISE contained 1 mmol kg^{-1} mercuracarborand-3 and 0.75 mmol kg^{-1} of tridodecylmethylammonium chloride. All ISEs were prepared using a PVC/DOS matrix. Further, 25 μL of 0.1 M AgNO_3 and 25 μL of 0.1 M NaI was added directly to the Ag^+ -selective and I^- -selective cocktails, respectively. No analyte ion solution was added to the Na^+ -ISEs. Potentiometric measurements were conducted without any conditioning time using a high-input impedance EMF-16 multichannel data acquisition system. The results obtained indicate that introduction of analyte ion directly to the ion-selective cocktail allows the ionophore to chelate with the analyte ion and execute the ion-exchange process solely within the membrane. Thus, establishing the zero-current ion flux at that step without needing a pre-conditioning step.

Abstract Text

The goal of this project is to synthesize different ratios of methyl-methacrylate (MMA) to decyl-methacrylate (DMA) to create a matrix that will allow improvement of the limit of detection of Ion-Selective Electrodes (ISEs). Usually ISEs are prepared using poly(vinyl chloride) (PVC) plastisized with bis(2-ethylhexyl sebacate) (DOS) as matrix support. PVC-DOS is the most common choice since it is commercially available and has a coefficient of diffusion of $\sim 10^{-8}$ cm²/s. However, DOS can leach out of the membrane matrix with time prejudicating the performance of the electrode. Recently, the copolymer MMA-DMA, which has a coefficient of diffusion of $\sim 10^{-11}$ cm²/s, has shown to allow low limits of detection in the nanomolar range when utilized in membranes for ISEs. Thus solid contact ISEs were created by coating a gold wire with a polymer conductor (poly-3-octylthiophene), a polymeric membrane that contains an ionophore sensitive to a particular ion of choice, an ion exchanger [3,5-bis(trifluoromethyl) phenyl]borate, as well as the copolymer MMA-DMA. The limit of detection was evaluated with different ratios of MMA-DMA and the best limit of detection was found when the ratio of 41.5-58.5 was used. The authors acknowledge the College of Sciences and Department of Chemistry at the University of Central Florida for financial support of this research.

Abstract Text

Stainless steel is a versatile material used in the oil & gas, construction, mining, pharmaceutical, and food/beverage industries. Stainless steel is resistant to corrosion because of the passive oxide layer that forms as a result of its chromium component. However this oxide layer is destroyed faster than it is created in low-oxygen and poor circulation marine environments. A synthetic hydrotalcite film can protect the stainless steel surface from attack by chloride ions. Hydrotalcite is a layered material which contains alternating positively charged metal hydroxide layers and negatively charged layers composed of anions and water. The anions in the negatively charged layer may be exchanged. This anion exchange property could allow the synthetic hydrotalcite film to trap Cl⁻ ions that would otherwise destroy the protective oxide layer. The film can be deposited electrochemically which allows greater control over thickness and deposition over irregular substrate geometries. Electrodeposition is also cheaper than most other film deposition techniques. Hydrotalcite is a naturally occurring clay in its Mg-Al form. In this study a zinc substituted film will be generated in situ at the electrode by the reduction of nitrate resulting in hydroxide formation. The electrodeposited synthetic hydrotalcite structure was confirmed by FTIR and XRD. Film morphology was observed by SEM and improvements in corrosion resistance were supported by linear polarization after various immersion times.

Abstract Text

Fast-scan cyclic voltammetry (FSCV) with carbon-fiber microelectrodes is a popular technique for [i]in vivo[/i] and [i]in vitro[/i] detection of various electroactive species including catecholamines. FSCV is utilized within several different fields of science including chemistry, biochemistry, neuroscience, and psychology. Inconsistencies in carbon-fiber microelectrode calibration methodology have become apparent because of its popularity within different disciplines. Proper calibration of carbon-fiber microelectrodes is essential so that faradaic current measured [i]in vivo[/i] can be related back to appropriate concentration values. Calibrations are performed in buffers that mimic the extracellular fluid of the brain, but previous work has shown the response of the carbon-fiber microelectrode strongly depends on buffer composition. Currently there are several buffers commonly used for electrode calibration including phosphate-buffered saline (PBS), tris(hydroxymethyl)aminomethane (Tris), and a carbonate-based artificial cerebral spinal fluid (aCSF). Here the response of carbon-fiber microelectrodes was characterized for a variety of analytes in these buffer systems including dopamine, pH change, oxygen, serotonin, norepinephrine, and epinephrine. For each analyte in each buffer, limit of detection, sensitivity, 10%-90% rise time, and signal to noise ratio were quantified. These results will be helpful in improving electrode calibrations and comparing results obtained under a variety of working conditions.

Abstract Text

It is highly desirable to develop sensitive and simple methods for detection of lead ion since lead ion is a toxic metal ion due to its causing a number of adverse health effects. A novel label-free electrogenerated chemiluminescence (ECL) biosensor for the determination of lead ion was developed on the basis of DNAzyme consisting DNAzyme strand (5E) and substrate strand (5DS) with a ribonucleotide adenosine served as molecular recognition element and ruthenium(II)-(1,10-phenanthroline) (Ru 1) as an intercalation ECL signal compound. The ECL biosensor was fabricated by coupling lead ion-specific GR-5 DNAzyme, 5'-ethynyl-(CH₂)₄-5E-3'-5'-CTC-(CH₂)₄-ACA GAC ATC ATC TCT GAA GTA GCG CCG CCG TAT AGT GAG-3' (5E) to 4-azidoaniline modified glassy carbon electrode using "click chemistry", and then hybridizing 5DS (5'-CTC ACT AT rA GGA AGA GAT GAT GTC TGT-3') with the 5E to form a double-stranded DNA (5E-DS) and further intercalating Ru1 into the 5E-DS. Upon binding of lead ion to the 5E-DS, the formed complex catalyzed the cleavage of the 5DS at the site of the rA, and the 5E-DS was dissociated and Ru1 was released, led to decrease ECL signal. In this paper, electrochemical "click chemistry" immobilization of GR-5 DNAzyme was developed. The ECL intercalator, the concentration of Ru1 and the incubation time were optimized. The results showed that the decreased ECL signals were directly proportional to the concentrations of lead ion in the range from 20 pM to 1.0 nM with an extremely low detection limit of 7.2 pM lead ion. The biosensor showed a high reproducibility and long-term storage stability. The biosensor was successfully applied to determination of lead ion contents in blood samples. This work demonstrates that using Ru1 intercalation and "click chemistry" for the fabrication of the ECL biosensor with high sensitivity and significant regeneration ability is promising approach for the design of label-free ECL biosensor for the determination of metal ions.

Abstract Text

Hydroquinone (HQ) and catechol (CC) are two important isomers of phenolic compounds, which are often used in cosmetics, pesticides, flavoring agents, antioxidant, secondary coloring matters, and photography chemicals. The absorption of HQ or CC from the gastrointestinal tract can induce some disease such as renal tube degeneration and liver function decrease. Because of their high toxicity and low degradability in the ecological environment, HQ, and CC are considered as environmental pollutants by the US Environmental Protection Agency and the European Union. A simple and high selectively electrochemical method for simultaneous determination of HQ and catechol (CC) has been developed at an electrochemically activated screen-printed carbon electrode (SPCE) modified with Prussian Blue (PB). The PB acted as a mediator and thereby enhanced the rate of electron transfer in chemical reaction. Various optimization studies such as the pH of the measuring solution, linear range of response, sensitivity and detection limit, were conducted to obtain maximum amperometric responses for analytes measurement. Under the optimized condition in DPV, the oxidation peak current of HQ and of CC is linear over a range from 4.0×10^{-6} M to 9.0×10^{-5} M HQ and from 1.0×10^{-6} M to 9.0×10^{-5} M CC. The obtained detection limit for HQ and CC was 1.17×10^{-7} M and 4.28×10^{-7} M, respectively. The proposed activated PB-SPCE also exhibited good selectivity and was successfully applied to the simultaneous determination of HQ and CC in spiked tap water.

Abstract Text

Fibrillation of proteins constituting biologic drugs is an undesirable property that can render these drugs useless in the treatment of patients. Fibrillation occurs when proteins become misfolded and aggregate.^[1] A variety of factors can cause fibril formation, such as agitation of protein solutions, increased temperatures in the surrounding environment, or simply a large timeframe between the time of drug manufacture and use.^[2] This study explores the development and application of a method to fluorescently-label insulin aggregates and fibrils with Nile Red in order to monitor the growth of these species using fluorescence correlation spectroscopy (FCS). The FCS method employs the determination of protein hydrodynamic diameter which is used in the study as the basis for kinetically analyzing insulin aggregation and its subsequent fibrillation. Studies are also in progress to compare and contrast the accuracy of the method's determination of protein hydrodynamic diameter with the corresponding results obtained via dynamic light scattering (DLS). Future work will target expanding the method to other proteins capable of undergoing fibrillation.

Abstract Text

Sodium azide is used in agricultural, laboratory, and commercial purposes, and thus is a significant environmental concern. In addition, several poisoning incidents have been reported due to the toxicity of azide. A simple and selective inorganic azide detection method using fluorescence has been developed. Based on Strain-Promoted Azide–Alkyne Cycloaddition (SPAAC) mechanism, the probe's fluorescence is turned on upon selective reaction with sodium azide. Quantitative analysis can be achieved in linear range of 2-100 μM .

Abstract Text

In the last years there has been a great interest towards the development of optical nanosensors. To this end, fluorescent nanomaterials have been implemented in analytical systems for the detection of toxic metal species. Recently, fluorescent carbon dots (CDs) have received much attention due to their attractive properties such as strong fluorescence, tunable color emission and high photostability. Mercury and its compounds are well-known environmental pollutants. Among mercury species, methylmercury is the most toxic to living systems due to its ability to cross biological membranes resulting in accumulation and bioamplification through the food chain. Since the main human exposure to this toxic is linked to fish consumption, the control of methylmercury levels has become of paramount importance. Conventional methods for detecting methylmercury are typically based on the use of complex hybrid techniques involving a chromatographic separation coupled to a specific detector. Further efforts should be focused on development of simple and fast assays with the possibility of on-site analysis.

In this work, a novel assay that integrates the synthesis of fluorescent CDs and sensing within a single step for methylmercury detection is presented. To this end, high-intensity sonication of carbohydrates is used for the synthesis of CDs in the presence of the target analyte. It has been observed that ultrasound facilitates the permeation of methylmercury through the passivation coating of CDs made of PEG, which causes the fluorescence quenching as a result of a non-radiative electron/hole recombination. This novel assay allows detecting methylmercury at nM level in only 1 min using very low amounts of organic precursors and a portable micro-fluorospectrometer.

Abstract Text

DNA-driven, homogenous assays for the quantitation of proteins are simple and easy to perform, yet there are still challenges to widespread acceptance for diagnostics due to non-optimal signal-to-noise (S/N) ratios. This problem stems from difficulty in optimizing assay conditions in the presence of background. In this study, we devised a high-throughput analytical tool, thermofluorimetric analysis (TFA) using a qPCR instrument, which allows separation of signal and background components from total readout in solution. This approach takes advantage of the different thermal stabilities of background components and signal components. Using this tool, we easily optimized the conditions for several homogenous fluorescence assays such as proximity fluorescence resonance energy transfer assay (pFRET) and proximity ligation assay (PLA). Non-amplified pFRET assays with TFA showed a limit of detection (LOD) of 6 picomoles of thrombin in mouse serum. Importantly, the direct fluorescence readout for pFRET, which is typically ineffective in autofluorescent serum samples, was made effective using this approach. Amplification of signal with PLA allowed further improvements in LOD, as low as 200 attomoles of thrombin in mouse serum samples. This work shows that TFA is not only a highly valuable tool in optimizing proximity immunoassays, but we also show that probe valency can be studied further and optimized with thermally resolved fluorescence readout.

Abstract Text

The development of new chemical-mechanical planarization (CMP) slurries designed for polishing microelectronic structures of decreasing linewidth has driven the demand for improved metrologies to characterize the abrasive component of emerging CMP slurries. Evaluation of particle size for small abrasive particles (hydrodynamic diameter < 20 nm) and the adsorption of slurry additives onto dispersed abrasive particles in a CMP slurry is an evergreen need which can be achieved using a single-molecule spectroscopic method, fluorescence correlation spectroscopy (FCS).

FCS employs a confocal fluorescence microscope to both excite and collect the fluorescence emission from abrasive particles rendered fluorescent by the adsorption of fluorescent dyes. In this presentation the application of FCS for the characterization of the smallest particles in the particle size distribution (PSD) of silica abrasive particle dispersions used in CMP slurries is described. PSDs are determined from FCS data for the dispersions by employing algorithms capable of analyzing the polydispersity of the distributions. To further evaluate the method's capability, the PSDs of silica dispersions were compared before and after fractionation by ultracentrifugation. This analysis demonstrated the enhanced sensitivity of FCS for analyzing smaller particle fractions relative to dynamic light scattering determinations of the same particle fractions. These data better defined the experimental FCS conditions needed for accurate PSD analysis and enabled the determination of Langmuir adsorption isotherms for dye binding to silica abrasive particles.

This research has been generously funded by Intel Corporation.

Abstract Text

In our work we proposed a novel approach to quantification relatively small amounts of water present in low polarity, aprotic solvents using fluorometry. This approach takes advantage of protolytic reaction of fluorophore : 4-methylumbelliferone dissolved in the solvent with water, acting as a base. The low emission intensity neutral 4-methylumbelliferone is transformed in reaction with water to a highly fluorescent anionic form. Thus the increase in emission intensity is observed for increasing water contents in aprotic solvents. It is shown that organic impurities of protolytic character (amines, acids) not only do not interfere with water contents determination but increase the sensitivity of emission vs. water contents dependence. Using fluorescence more of measurements eliminates the disadvantages resulting from turbidity of the sample, which may be a common phenomenon in industrial solvents. For low water contents and highly lipophilic solvents this method yields (in practical conditions) higher sensitivity compared to Karl Fischer titration.

Abstract Text

Mangiferin is a natural polyphenol glucosylxanthone obtained from the mango tree, honey bush and other sources. The clinical applications of mangiferin are well known. It is commonly used during the diagnosing of dysentery, infection, inflammation, allergies, cancer and diabetes. Studying the interaction between mangiferin and human serum albumin (HSA) is important as it provides an indirect insight into the transportation and the distribution of the ligand with the carrier protein. Furthermore, any binding results obtained could be useful for elucidating ligand-carrier protein binding patterns.

In part, the study of mangiferin is useful in medicine; however, its structure and binding affinity make it potentially useful as a binding agent. Based on the given information, a proposed specific use of mangiferin is as a competitive binding agent to the serum albumin. However, given it is likely to compete with other common HSA binding ligands such as cyanine dyes, any change to the absorbance or emission properties of the latter can easily serve as a tool to monitor ligand binding.

Our initial studies have revealed that Human serum albumin exhibit high binding affinity for mangiferin similar to the water-soluble cyanine fluorophores, which interacts at the subdomain IIA and IIIA. It is also believed that the Mangiferin binds to the hydrophobic binding region of subdomain IIA, where the tryptophan residue, trp-214, is present. This binding is proposed to be due to specific hydrophobic, H-bonding effects and other non-covalent interactions. Considering there is limited research data available on this binding relationship, our competitive studies are quite useful in fully understanding the causation for high binding affinity to human serum albumin and further explaining this rather complex binding equilibrium.

Abstract Text

Bacterial endotoxin is a component of gram-negative bacterial cell walls and causes fever or shock when it enters the human blood stream. Therefore, the concentration of bacterial endotoxin in pharmaceutical and dialysis solutions needs to be strictly controlled. The conventional methods for the detection of bacterial endotoxins use reactions with limulus amoebocyte lysate (LAL) that lead to gel-formation, a change of turbidity, or a change of color. Since of the problems including the long measuring time and the low sensitivity in the conventional methods, the novel method performing in more rapid and higher has been required. Here, we report a novel endotoxin detection method based on a combination of the limulus reaction and bioluminescence using mutant firefly luciferase. Our method gave higher sensitivity for bacterial endotoxins in a shorter time. However, it also had the problems of stability and reproducibility introduced by the unstable reagents.

In this study, lyophilizations for all of the reagents were studied to achieve good performance, including both long-term stability and good reproducibility. The lyophilized reagents allowed the optimization of both the concentration of LAL and the lyophilize condition, the bacterial endotoxin at a concentration of 0.001–0.01 EU/mL was detected within 20 minutes. The correlation coefficient was >0.99 and the relative standard deviation was <15%. A good correlation for the conventional method was also observed. The correlation coefficient for the turbidimetric method was <0.86. The concentration of bacterial endotoxin in pharmaceutical and dialysis solutions can be measured easily, rapidly, and at a high sensitivity by our method.

Abstract Text

The primary goals of disinfectants are to kill bacteria and inactivate viruses. However, disinfectants can also react with many other chemical matters present in water, forming potentially toxic disinfection by-products (DBPs) that can be found in finished drinking water. And because of the widespread use of chlorination, the two major prominent DBPs in chlorinated drinking water are trihalomethanes (THMs) and haloacetic acids (HAAs), which are regulated by the United States Environmental Protection Agency (USEPA). It is well investigated that THMs and HAAs are formed from both disinfectants and natural organic matter (NOM). However, to date several hundred and non-regulated DBPs can be found in drinking water. These DBPs other than the regulated THMs and HAAs are known as emerging disinfection by-products (eDBPs) and may be more toxic than current regulated DBPs.

In our laboratory, a preliminary kinetic spectrophotometric method was performed to investigate the reaction and use of dimethylaminopyridine (DMAP) as a derivatization reagent to analyze HAAs and three classes of emerging disinfection by-products (eDBPs) in drinking water, including haloacetamide, haloacetaldehyde and haloacetonitrile.

The research will focus on expanding the use of DMAP to derivatize two additional classes of eDBPs, which are halomethanes, and halonitromethanes. Absorbance and fluorescence of the reaction between DMAP and each of the five classes of eDBPs along with HAAs will be measured. Additionally, a structural identification of the reaction products using mass spectrometry (MS) will be presented to understand the reaction mechanism between DMAP and eDBPs. This research will provide information in attempt to develop reliable spectrophotometric method for the determination of eDBPs in drinking water.

Abstract Text

Although alkylammonium formate (AAF) ionic liquids are quite viscous and are thought to form micelle type structures, the potential enhancement of fluorescence by fused ring organic compounds using AAF solvents has not been studied in detail. We have compared two ionic liquids, ethylammonium formate (EAF) and isopropylammonium formate (IPAF), as solvents for the fluorescent determination of pharmaceuticals. Solid phase extraction of these AAF solvents using activated carbon or a polystyrene-pyrrolidinone polymer has been shown important to reduce the excitation background, particularly at 280 nm as compared to 350 nm. As the % EAF in water was varied from 10-90%, the fluorescence of riboflavin and naproxen remained quite constant until decreasing slightly at 80 and 90% EAF. However, over the same solvent range, warfarin showed a marked enhancement of fluorescence, more than double. Varying the % IPAF over the same range, riboflavin, in contrast, showed an increase in fluorescence of about 5 times from 10% to 60% before decreasing at higher % IPAF levels. Although not the case for EAF, tryptophan showed enhanced fluorescence in a 90% IPAF-10% water solution as compared to just an aqueous solvent. The fluorescence of other indoles such as serotonin, indole-3-acetic acid, and melatonin in varying percentages of IPAF is under study. The higher viscosity of IPAF and likely better micelle formation both seem to be contributing factors for the more pronounced solvent based fluorescence enhancement as compared to that for EAF.

Abstract Text

The Abraham general solvation model can be used to predict partition coefficients for many compounds. This model describes and predicts the chemical properties of drugs with biological barriers. Solute properties are calculated using logarithmic analysis of both gas and liquid chromatographic retention times, which predict molecular descriptors of new and untested drugs. Our research used six gas chromatography columns and six liquid chromatography columns to develop accurate predictions. Retention times of drugs were measured and the solute properties were calculated. Using the molecular descriptors found in literature, the Abraham model was used to predict process coefficients. For each of the columns used, a correlation equation was developed for predicting descriptors. A standardized data process has been created in order to easily and quickly obtain molecular descriptors for new designer or illicit and illegal drugs. In order to get the descriptors, a drug must simply be run on the columns and retention times collected. Once collected, the retention times are compiled into the correlation equations and the molecular descriptors are calculated.

Abstract Text

Various steroids, such as dexamethasone, betamethasone, cortisone, hydrocortisone, and prednisolone, are commonly used as anti-inflammatory medications. Separation of mixtures of these steroids is challenging due to similarity in their chemical structure. Here, we describe the development of reversed-phase chromatographic methods for separation of these steroids. Particular interest is paid to chemical differences between solute pairs, such as the presence or absence of carbon-carbon double bonds, the presence or absence of hydrogen-bonding ability, and the presence of carbon-fluorine bonds. Due to the minor difference in structure between solute molecules, highly selective chromatographic systems are required. Of particular interest is the use of stationary phases which contain specific functionality, such as embedded-polar-group phases or fluorinated phases. In addition, biologically-inspired stationary phases, such as those containing a cholesterol or membrane structure, are examined. In combination with these selective stationary phases, we employ mobile phases with selective additives. Derivatized beta-cyclodextrins have been shown to form strong complexes with some steroids, and here that ability is used to vary chromatographic selectivity. The effect of other variables, such as mobile phase modifier choice (methanol vs. acetonitrile) and temperature are also considered.

Abstract Text

When conducting impurity analysis of pharmaceuticals, researchers need to detect trace level impurities along with the main analyte, which is present at a high concentration. To accomplish this, a detector that provides linearity over a wide concentration range is required. Furthermore, a high S/N (signal-to-noise ratio) is also required of the detector in order to provide high-accuracy quantitation of any impurities present at trace levels. Here, we introduce our evaluation of the sensitivity and linearity obtained in impurity analysis using the new SPD-M30A photodiode array detector with the optional high sensitivity cell (optical path length 85mm). To compare its performance with that of the former model (with 5mm path length cell), 2 μ L of a 0.02 mg/L ketoprofen standard solution was injected using the same analytical conditions, and the respective S/N values were verified. Comparison of the results indicate that the S/N for the SPD-M30A with the high sensitivity cell is more than 10 times greater than that of the peak for the former model, demonstrating excellent quantitative performance. To check the linearity of ketoprofen detection using the SPD-M30A with the high-sensitivity flow cell, we conducted measurements using a sample concentration range of 0.01 – 500 mg/L. Excellent linearity was obtained in a range of 0.01-50 mg/L, with a correlation coefficient (R²) greater than 0.999. Since the linearity was not maintained when the concentration exceeded 50 mg/L, we used the Intelligent Dynamic Range Extension Calculator (i-DReC) function in LabSolutions software to extend the range of the calibration curve to 500 mg/L. With this function, the correlation coefficient (R²) improved to better than 0.999, and the error associated with each calibration point improved to less than 5%.

Abstract Text

Approximately 50 % of all drug molecules used in pharmaceutical products are reported to be ionic compounds. Ion chromatography is generally appropriate to analyze inorganic or organic ions, but not suitable for active pharmaceutical ingredients (APIs) analysis due to their hydrophobicity. On the other hand, reversed phase liquid chromatography (RPLC) is mainly applied for analysis of APIs, but cannot retain commonly-used ions for drugs. Consequently, it is difficult to analyze APIs and their counter-ions simultaneously.

In this study, we evaluated the ReDual column, our newly-developed mixed-mode column, for simultaneous analysis of APIs and their counter-ions. Mixed-mode column usage has increased because of the ability to analyze a wide range of compounds in a single run by multimode retention mechanisms. The ReDual column was able to analyze APIs and their counter-ions simultaneously. In addition, we investigated how retention behavior changes with parameters such as pH, ion strength, and concentration of organic solvents in the mobile phase.

Abstract Text

HPLC-based lipophilicity methods most often employ silica-based C18 columns for ballpark octanol-water logP estimates. Transcellular permeability, however, is better modeled by alkane-water logP. Despite growing interest in logP_{alk} this parameter is underutilized due to various experimental barriers and lack of robust high-throughput platforms for measurement.

The goal of this study was to evaluate a C18-functionalized PS-DVB-based column for its capacity to provide logP_{alk} estimates for a diverse set of solute and drug compounds when operated in fast gradient mode. Linear solvation energy relationship (LSER) analysis was used to characterize this system and to provide a meaningful basis from which the balance of intermolecular forces could be compared with those of other chromatographic and partition

Abstract Text

Method validation is an important regulatory requirement for pharmaceutical organizations to demonstrate that a method is suitable for its intended purpose. A compliant laboratory must provide documented evidence and assurance that the analytical method generates accurate and reliable results. As the validation is a complex and prone-to-errors process, a well organized plan is essential for successful validation and to ensure that the appropriate regulations and guidelines are being followed.

Here, we will present validation of a UPLC method for metoclopramide HCl and related substances. The study was performed using Empower 3 Method Validation Manager (MVM) software. The entire validation workflow from creating a validation protocol to acquisition, reviewing and processing, calculations, approval, and final reporting of the validation results will be discussed. The MVM software tracks every step of the validation process, flagging any steps or data that do not meet the validation requirements. This ensures compliance to the validation requirements and acceptance criteria defined in the protocol. Validation calculations and statistics are performed directly within the MVM software.

In this study, we validated the UPLC method for linearity, detection and quantitation limits, accuracy, repeatability, intermediate precision, specificity, and robustness using MVM software. First, we created a validation protocol to define the validation requirements and the acceptance criteria for each validation test. Then, we executed the validation study. We will demonstrate that method specificity is enhanced using orthogonal detection, ACQUITY QDa mass detector in conjunction with UV, to track peak homogeneity for the API and it's related substances.

Abstract Text

There are benefits to the use of smaller diameter columns. These include increased sensitivity, a reduction in the amount of sample required, and substantially decreased solvent consumption and waste generation. To reap these benefits, technical hurdles in solvent delivery, sample introduction and the management of extra-column dispersion must be surmounted. Recently, commercial systems have become available that can address these challenges. Optimized microscale system configurations enable the migration of chromatographic methods from the common, analytical scale 2.1 mm diameter columns to microscale columns with 1.0 mm and 300 μm diameters. The goal of such a transition must be a method that not only exhibits the enhancements mentioned, but also conserves the selectivity, resolution and reliable quantitation of the original. Effective method migration, then, will necessitate thoughtful adjustments to method and instrument parameters in order to preserve the analytical quality of the original chromatography. A systematic protocol for this process is needed. This work presents the results of investigations into solvent delivery, injection behavior, UV and MS detection, and column temperature effects observed in small molecule microscale separations. The results are presented in the context of their overall influence on the chromatographic measures of a successful method migration. The experimental observations, when combined, will serve as a protocol for method migration from the analytical scale to the microscale.

Abstract Text

Given the diverse selection of pesticides used globally with differing regulatory limits in various countries, multi-analyte screening strategies capable of efficiently detecting residue violations are required. The QuEChERS methods have simplified and streamlined sample preparation for pesticide analysis of many fruits and vegetables. In recent years the use of accurate mass instruments has been at the forefront of food and environmental screening discussions. This has also been reflected in the evolving SANCO and CODEX guidelines that promote the use of accurate mass technology to address the challenges faced by industry.

Such accurate mass technology should provide high resolution, without compromising system sensitivity. Another challenge often associated with non-target analysis is the time required for effective data processing. In this pesticide screening study, a new quadrupole- time of flight mass spectrometer system shows accurate detection of all pesticide residues, while maintaining high resolution in compliance with global regulations. Furthermore, a 3D peak detection algorithm system simplifies data processing, where by a single scientific information system performs data acquisition, efficient data processing and data management requirements. With access to an extensive scientific library a comprehensive workflow to screen, quantify, and confirm residues in a single solution is demonstrated as a simple and efficient procedure for data interrogation.

Abstract Text

Instrument design in mass spectrometry (MS) relies on the use of magnetic and electric fields for manipulating the trajectories of ions inside a mass spectrometer. For example, radio-frequency (RF) fields are commonly applied to quadrupoles, hexapoles, and octapoles to guide ions from ion generation sources to analyzers and/or detectors. Hence, RF power supplies are typically used with various MS types. In this presentation, we will discuss results from the applications of a novel power supply for generation of RF signals in the range of 100 KHz to 20 MHz (up to 400 Vp-p) using readily available and inexpensive off-the-shelf components. Moreover, we will present a method for designing programmable control modules using common hobby-grade microcontroller electronics that have not previously been explored for use in MS instrument designs.

The instrument module consists of a miniature (< 1 inch³) variable frequency oscillator, a small (3"x7"x1") commercial RF amplifier, and a home-built air core transformer. The programmable "brain" of the module was developed using heavily documented, open source, and inexpensive microcontrollers. Application of these design techniques can lead to potentially cheaper and faster mass spectrometer instrument prototyping.

Results from mass spectral analysis using the recently developed radio-frequency ionization (RFI) technique [1] coupled to a Fourier transform-ion cyclotron resonance (FT-ICR) MS using an RF signal of 12.10 MHz and 380 Vp-p will be reported. In addition, novel applications of this new RF generator, such as ion isolation and ejection in FT-ICR MS, will be discussed.

Abstract Text

Two-dimensional separations are useful to separate complex mixtures. Most techniques, however, require multiple steps. Pressurized simultaneous chromatography and electrophoresis is a novel technique that produces two-dimensional separations of complex mixtures in a single step. In addition, two mixtures may be spotted opposite each other onto a single pre-wetted TLC plate and separated concurrently for comparison. The TLC plate is pressurized between two acrylic plates while mobile phase is forced through the plate via syringe pump. An electric field is applied across the wetted plate orthogonal to the flow of mobile phase. Mixtures are separated according to their polarity and charge-to-mass ratio by chromatography and electrophoresis, respectively. By controlling pressure and mobile phase flow, separation occurs in as few as 4 min. A range of flow rates and electric potentials were tested to find and report the conditions that lead to the lowest plate height. Pressurized simultaneous chromatography and electrophoresis offers an effective, inexpensive, and fast alternative over other two-dimensional separation techniques.

Abstract Text

Ionic liquids (ILs) are semi-organic compounds with attractive physical and chemical properties such as negligible vapor pressure, low melting points and feasible miscibility within a range of solvents. A key factor of ILs is the ability to design these solvents by manipulating the component anion or cation. This is a major reason why ILs are referred to as designer solvents and have been in keen interest in a range of scientific disciplines. This rise in interest has also led to the increased production of ILs, however the toxicity of these designer solvents is not well known. A major concern in utilizing ILs is to develop effective remediation methods in case of environmental contamination. Studies have indicated that potassium permanganate can be used to breakdown pyridinium based derivatives therefore 1-butyl-3-methylpyridinium bromide ([bmpy]Br) was studied and a separation technique was determined. In this research the separation of [bmpy]Br and two reaction intermediates was developed using 5 mM KH₂PO₄. Further research in the degradation of BUMP can potentially exhibit an extraction method for environmental remediation.

Abstract Text

Breast cancer is a prevalent disease found mainly in women. When the cancer reaches metastasis, it is expensive and difficult to treat. Diagnosis of breast cancer is traditionally done by mammography and prognosis has recently headed to the direction of detecting certain biomarkers in blood or serum, often by RT-PCR. Studies have shown that prolactin-inducible protein (PIP), human epidermal growth factor receptor 2 (HER2) and cytokeratin-19 (CK19) are three among the biomarkers prognostic for breast cancer. Therefore, quantification of these markers could provide important information about breast cancer metastasis. Previous research in our lab has developed a method to detect these biomarkers in buffer and serum samples using molecular beacons (MB). The limit of detection of our assay is improved by preconcentrating the mRNA biomarkers with designed immobilization oligonucleotides. Design of the immobilization oligonucleotides impacts effectiveness of the preconcentration, apparently in part due to overlap of the MB and immobilization oligonucleotide binding regions on the mRNA biomarker as well as the temperature of the elution.

Abstract Title **Identification of Controlled Substances in Forensics with Handheld Raman Spectroscopy**

Primary Author Cassara R. Cook
Maryville University

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Katherine Bakeev, Thomas M. Spudich

Abstract Text

Identifying controlled substances has proven to be a costly and time consuming task for crime laboratories. At the end of 2005, there were 222,678 backlogged requests related to controlled substance analysis alone (Durose, 2008). Additionally, the variation in content of the samples increases the difficulty of analysis. Portable Raman Spectroscopy is an ideal technique for qualitative identification of these samples due to its timely, cost-effective, non-destructive nature. Samples can be analyzed through a variety of containers, minimizing transfer of the sample and preserving the forensic evidence. Furthermore, the ease of instrument operation minimizes the costs of training incurred by crime laboratories, allowing detectives and other officers to complete preliminary identifications in the field, minimizing flow of samples through crime laboratories. The goal of this project is to determine the accuracy, reliability, and precision of portable Raman Spectroscopy in the forensic identification of controlled substances, in particular, "real-world" samples. Utilizing B&W Tek's Tactic ID[®], there was a collaboration with crime labs in the St. Louis, MO community to test these principles, where obtained spectra from samples of controlled substances and mixtures. Comparisons will be made between Raman identification results to those determined by validated analytical methods in the crime lab.

Abstract Title **Determination of Metal Content in Paper for Forensic Identification Using ICP-OES or ICP-MS**

Primary Author Rachel M. Goestenkors
Maryville University

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Thomas M. Spudich

Abstract Text

The determination of the metal content in paper can be used in forensic identification to trace the paper to suspects. Examples include forged checks, money and last will and testaments. Only a small sample of the document in question is needed to determine the metal concentration, if a database is established, the concentration found can be compared to those in the database to determine the type of paper. By digesting the sample of paper it can then be analyzed by either ICP-OES or ICP-MS, to determine the concentration of specific metals by comparing the values obtained to the standards used. Previous work (1) has been done using ICP-MS as the analytical method, where the limit of detection for the elements was found to be ranging from 1.0 ug/g to 0.001 ug/g. This article showed results for eight elements Mn, Sr, Al, Mg, Ba, Fe, Zn, and Pb. ICP-OES was chosen for this research because it is more cost effective and it is hypothesized that similar results can be obtained. The same elements are analyzed along with Sn, Zr, Ag, Ce, Sc, Th, and Y.

Abstract Text

The basis of this research is to develop an effective method to measure potassium ion concentration in plasma and red blood cells (RBC's) simultaneously. Potassium concentration is vital in human health due to its role in biological systems including maintaining osmotic balance between cells and interstitial fluid. A concentration outside of the normal range can lead to muscle weakness, decreased reflex response, and even respiratory paralysis and cardiac arrhythmia. Current studies have shown the importance of measuring both extracellular and intracellular potassium concentrations simultaneously, particularly, for early detection of the development and risk of hypertension.¹ The most common methods for potassium measurement used today are classical potentiometry² and atomic photometry. These techniques are effective to measure potassium in plasma and/or RBC's after sample preparations, but have limitations for simultaneous measurement.

We report here pulsed chronopotentiometry as a fast and reliable method for the measurement of intracellular and extracellular potassium concentrations simultaneously. Here, current pulses of varying magnitude are applied to extract ions from the sample into the membrane. Depletion of ions at the membrane surface occurs when the concentration of ions in the solution can no longer sustain the flux of potassium across the membrane and this point is detected by a potential drop on the potential-current response curve.³ This limiting-current is proportional to the potassium ion concentration according to Sand equation. After measuring potassium concentration in unlysed blood, the same sample is lysed and re-measured, giving the total concentration. Simple arithmetic allows for intracellular concentration to be calculated.

Abstract Text

In this study, we employ the principles of ion transfer across liquid/liquid interfaces to observe ion-selective currents of thyroid hormones with micro and nanopipette electrodes. The selective detection of thyroid hormone, thyroxine, in sodium phosphate buffer solution and serum is demonstrated via cyclic voltammetry through ion transfer at the water/1,2-dichloroethane interface. Our motivation originates from the importance of developing rapid analysis systems for hormone levels in the blood and will expand applications of point-of-care testing. Electrochemical measurements with micro and nanopipette electrodes are especially suited to point-of-care testing due to rapid analysis times, simple calibration, and ability to provide hormone concentration levels in blood serum. Thyroxine hormone is of particular interest due to its clinical relevance as a marker for thyroid disease. Untreated thyroid disease can have disastrous effects on an individual's health and lead to other autoimmune diseases such as type II diabetes. Future work in the development of electrodes selective for triiodothyronine and thyroid-stimulating hormone will also be presented.

Abstract Title **Synchronous Scan Fluorescence Analysis of Bourbon Whiskey with Solvent-Enhanced Resolution**

Primary Author Chelsea Zorn
Elmira College

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Hillary Andaluz, Jared S. Baker

Abstract Text

Bourbon whiskey is made from grains such as corn, rye, wheat and malted barley. After fermentation, the resulting white whiskey, or “white dog”, is matured in new charred-oak casks. During the process of maturation, the whiskey picks up its distinct flavor and coloring from the oxidized oak. It is the variety and differing composition of these organic flavor components that distinguish each brand of whiskey. Various spectroscopic methods have been devised in order to monitor quality of flavor and alcohol content of whiskey due to the fast and non-destructive nature of the technique. Numerous techniques have relied upon absorption in the near-infrared to the visible to identify a variety of analytes in alcoholic beverages. Fluorescence spectroscopy offers the potential for an additional means for a fast, efficient, and non-destructive way to quantitate a variety of complex fluorescent species present in the whiskey sample. Specifically, synchronous scan fluorescence spectroscopy is a technique that can result in the formation of narrow spectral bands and has the capacity to handle the simultaneous analysis of the numerous fluorophores present in the whiskey sample. The work presented herein reveals the influence of solvent polarity on the resolution of the SSF emission of the various organic fluorophores in whiskey, and also evaluates the solvatochromic shift that occurs in the presence of a variety of solvents.

Abstract Title **The Quantification of Gabapentin or Bexarotene in Tissue Samples by HPLC-ESI-TOF-MS**

Primary Author Katherine E. Wehde
The Ohio State University

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Ahsley Conley, Justin C. Harris, Noel Paul, Shweta Mandrekar, Yan Wang

Abstract Text

Gabapentin and bexarotene are both under investigation as treatments after spinal cord injury. Gabapentin is being studied for use after high-level spinal cord injury (above thoracic level six) to prevent abnormal neuron sprouting and aberrant synaptogenesis which causes a life threatening condition Autonomic Dysreflexia (AD). Without treatment, AD causes high blood pressure which can induce stroke, seizures, and even death. Bexarotene is being studied as a therapy to concurrently activate signaling pathways that suppress destructive inflammation while promoting activation of tissue repair functions in macrophages. It is expected that activation of these signaling pathways will attenuate secondary tissue damage at/nearby the site of injury and will enhance axon growth and plasticity culminating in improved recovery of neurological function after spinal cord injury. High performance liquid chromatography electrospray ionization time-of-flight mass spectroscopy (HPLC-ESI-TOF-MS) was used for the quantification of gabapentin or bexarotene in serum samples. Solutions of samples were prepared and concentrations of drug were determined on the basis of calibration curves created using standards prepared in tissue. The samples were spiked with an internal standard directly after tissue harvest and prior to any further manipulation to correct for variations in sample preparation and analysis. This separation and detection method is suitable for quantitative sample analysis at low concentrations. With the developed method, it has been shown that HPLC-ESI-TOF-MS is capable of determining the concentrations of gabapentin or bexarotene in serums, and this method of detection will assist neuroscientists in the determination of efficacious dosages as well as administration methods.

Abstract Title **Investigation of the Stability of G-Quadruplex Structures and the Effect on Aptamer Behavior**

Primary Author Casey Fong
Rensselaer Polytechnic Institute

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Christina M. Albanese, Linda B. McGown

Abstract Text

The nucleobase guanine has proven to be extremely unique due to its ability to form complex secondary structures known as G-quadruplexes. G-quadruplex structures are comprised of stacked guanine tetrads, which form via the association of four guanines through Hoogsteen hydrogen bonding. DNA sequences rich in guanine are capable of forming such structures, and a number have been confirmed in vitro. Recent evidence has strongly supported G-quadruplex formation in vivo as well. Many of the G-quadruplex structures confirmed in vitro have been found to function as aptamers, oligonucleotides that bind target molecules with high affinity and specificity. Furthermore, guanine-rich regions are prevalent within the human genome, particularly within the promoters of human oncogenes, and have been determined to have regulatory significance. Therefore, these regions represent areas of interest and may provide a source of potential aptamer sequences. In this research we aim to identify the conditions that govern the stability, formation, and aptamer capabilities of G-rich human oncogene promoter regions. Conditions of interest include pH, temperature, and small molecule interactions. Formation of G-quadruplex structures is assessed by circular dichroism (CD) spectroscopy. Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF MS) is used to screen for protein capture by the G-quadruplex-forming DNA sequences. By better understanding the effects of these conditions, we aim to improve the use of G-quadruplex structures as aptamers for the diagnosis of diseases associated with their target proteins, as well as to develop tools to analyze and study the biological significance of G-quadruplex structures within oncogene promoter regions.

Abstract Text

Aptamers are short, single-stranded nucleic acids that specifically bind to target molecules with high affinity. They derive their functionality from the unique secondary structures they form, such as the G-quadruplex structure. In this research project, the processes that govern the affinity capture of proteins at aptamer-modified surfaces are studied using an affinity Matrix-Assisted Laser/Desorption Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF MS) platform developed in our lab. In our method, the aptamer sequence is covalently attached to a fused silica or indium tin oxide (ITO)-coated surface. After incubating the surface with target proteins or protein mixtures and rinsing off any unbound or weakly bound species, MALDI matrix is added. Captured proteins are then analyzed directly at the aptamer-modified surfaces by MALDI-TOF MS. Our initial studies focus on the thrombin binding aptamer (TBA), which binds to thrombin via G-quadruplex formation and functions as a model for aptamer behavior. Various parameters, including aptamer surface coverage, target protein concentration, linker concentration, incubation time, and rinsing procedure, have been investigated and were found to affect the binding processes of the TBA-thrombin system. By determining the optimal conditions for protein capture by aptamers, we aim to develop a better understanding of the intricacies of these affinity interactions. These optimized conditions can then be applied to the investigation of other aptamer systems, as well as potential aptamer sequences based upon the G-quadruplex structure, such as the c-myc and c-myc oncogene promoter region sequences. Such insight into the inner workings of aptamers will lead to the development of more sensitive biosensor devices and more accurate diagnosis of diseases associated with these captured proteins.

Abstract Title **Treatment of Hydraulic Fracturing Contaminated Water Using Closterium Moniliferum: Ba and Sr Elemental Analysis**

Primary Author Lance M. Jubic
Westminster College

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Helen M. Boylan, Karen Resendes, Larry Miller

Abstract Text

The acquisition of metals is essential for a variety of protein and cellular functions, including sensing of environmental conditions. The single-celled green algae *Closterium moniliferum* selectively accumulates the toxic, heavy metals barium and strontium, which are then incorporated as barium sulfate crystals as statoliths in the terminal vacuoles. Thus, *C. moniliferum* may be used to contain accidental release of Ba and Sr into the environment from industrial activities, such as hydraulic fracturing. Hydraulic fracturing technology collects natural gas through the injection of hydraulic fracturing fluid into shale rock. When the flowback water and produced water are collected, they are enriched in dissolved Ba and Sr. These metals are concentrated to thousands of milligrams per liter. To assess its candidacy for remediation, this study sought to characterize the *C. moniliferum*'s growth, intracellular uptake rates of Ba and Sr, and absorption of Ba and Sr onto the cell wall. The algal population growth was negatively correlated with the percentage of fracking fluid present in the media. However, the population was sustained in as much as 1% hydraulic fracking fluid. Algae cells were cultured in a variety of media, including media enriched in Ba, Sr, or frack water. Cytosolic Ba and Sr accumulation was determined using atomic spectroscopy. Additionally, Ba and Sr surface absorption to the exoplasmic cell wall was investigated. While known to be incorporated as vacuolar statoliths, Ba's and Sr's interactions with surface sugars and proteins are poorly understood. Fourier transformed infrared spectroscopy (FTIR) was utilized to characterize functional group stretching in response to Ba and Sr binding. Hydroxyl groups were primarily responsible for Ba and Sr absorption. The results suggest *C. moniliferum* should be continued to be investigated as a means of passively remediating hydraulic fracturing contamination.

Abstract Title **Obtaining Accurate Spectra from an LCTF Microfluorometer for Use on Heterogeneous Micro Environments**

Primary Author Maggie Malone-Povolny
University of Saint Thomas

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Gary Mabbott

Abstract Text

The primary objective of this research was to develop a method of obtaining accurate spectra from a liquid crystal tunable filter (LCTF) microfluorometer. Like with any instrument, the various components of this instrument displayed non-ideal behavior. By comparing the raw spectra from the instrument to one from a conventional instrument, a set of proportionality constants was generated that served to correct all future spectra taken by the microfluorometer. By overcoming artifacts in the light source, filter, and camera, the spectra from this microfluorometer were found to be in agreement with spectra obtained by conventional instruments. This research utilizes this instrument's ability to study the fluorescence of micro-volumes in order to determine varying fluorescence between microenvironments. Fluorophores that are added as a stain to cell membranes can be distinguished from the same fluorophore in solution around the cell, due to the effects of each of these two environments. Current efforts are aimed at the generation of a calibration curve to measure the concentration in micro-volumes of fluorescent species.

Abstract Text

In this study including the field of fingerprinting metabolomics approach for food safety and quality assessment, the evaluation of untargeted compounds using LC-ESI/TOF/MS and multivariate statistical analysis method is proposed for the assessment of classification, contamination and degradation of infant formula. LC-MS fingerprinting metabolomics is the method judging from the statistic of the principal components analysis (PCA) of the mass charge detected by mass spectrometric detection of the separated compounds by chromatographic technique. This study shows that this methodology can be applied for the food defense regarding to the contamination of unknown contaminations and degradations of infant formula samples. A few reports were discussed that LC-MS metabolomics was used for the classification of origin, process and other effects for various agricultures. Thus, in this study, the fingerprinting metabolomics is applied to evaluate the safety and quality assessment of infant formula. For the detection of many peaks using LC-MS, the reversed phase and HILIC modes are used to monitor more detected numbers in infant formulas in the positive scan mode than the single phase. The repeatability of the non-targeted contents from 4 kinds of infant formulas based on the principal components analysis (PCA) was less than the relative standard deviation of 15% for all groups. The PCA pattern showed that significant differences in the classification of types and origins, the contamination of melamine, pesticides and several metals, and the degradations for one week and expiration date were evaluated using fingerprinting LC-MS metabolomics. With this strategy, the differences from the untargeted compounds could be utilized for quality assessment of infant formula.

Abstract Title **Characterization of the Stability of Supported Bilayer Membranes in Polydimethylsiloxane Microfluidic Devices**

Primary Author Livia Shehaj
Trinity College

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Michelle L. Kovarik

Abstract Text

Supported bilayer membranes (SBMs) have been used to coat capillaries and microfluidic devices. These coatings are similar to cell membranes and prevent adsorption of proteins, DNA, and other biomolecules to channel walls. Combined with the small dimensions of microfluidic devices, such coatings are an optimal tool for biological and biomedical research. To characterize the stability of SBMs, we prepared hybrid PDMS-glass devices containing straight, 3 cm channels. The channels were filled with small unilamellar vesicles, which self-assemble into supported bilayers. Conductivity measurements of the electroosmotic flow were used to characterize the presence and stability of the SBMs. Our primary focus was the stability of coatings using natural vs. synthetic lipids. Preliminary results indicate that the synthetic lipid coatings are more stable than the natural lipid coatings, suggesting that the variations in length and saturation of natural lipid tails may affect the stability of the coatings. Additional studies are in progress to confirm these results. Electroosmosis measurements of the two lipid coatings were relatively stable (RSD 8-18%) for 2-4 hours when a constant voltage was applied across the channel. At longer time points, electroosmotic mobility increased to that of a bare chip suggesting the coating was destroyed. The stability of these membranes was also studied over a two week period to determine how long a device can be stored before use. Our results suggested that a chip can be stored for about a week and still yield consistent results. After a week, the coatings deteriorated, as evidenced by increasing electroosmotic mobility. On-going work is exploring effects of cholesterol on SLBs to further enhance the stability and storability of these coatings.

Abstract Title **Exploration of Active Ingredients Contained Within 'Legal High' Supplements: Elucidation and Characterization of Synthetic Drug Compounds**

Primary Author Andrew Heinle
Waynesburg University

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s)

Abstract Text

Across the world synthetic drugs are becoming increasingly popular. As forensic research and crime labs alike identify questionable substances, there is a steady production of newer products being synthesized to fill the niche of 'legal highs' desired on the black market. These drugs are appealing to people who are looking for ways to pass drug screenings and avoid legal issues; all while ignoring rather severe health risks. If a greater number of unknown substances can be identified, the sooner such compounds can be scheduled and banned. Through liquid and gas chromatography/mass spectrometry, nuclear magnetic resonance spectroscopy, infrared spectroscopy, and Electrospray ionization-MS/MS/MS studies, a number of synthetic cannabinoid and synthetic psychoactive compounds will be studied. The test matter will be obtained from shops within Western Pennsylvania and West Virginia. The research will be performed under Professor Michael Cipoletti, Program Director of Forensic Science at Waynesburg University. Most synthetic compounds, taken as drugs, are very dangerous. This is most often overlooked by users, due to the so-called legality of such substances. Similar discovery and identification research needs to continue to grow in order to lead to the banning of all synthetic drugs. Studies that elucidate and characterize unknown synthetic drugs can help lead to the discovery of producers and distribution sites throughout the world.

Abstract Title **Investigation of a One-Step Synthesis-Grafting Method to Modify Glassy Carbon Electrodes**

Primary Author Garrhett G. Via
Wittenberg University

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Kristin K. Cline

Abstract Text

Glassy carbon (GC) electrodes were modified with substituted aryl groups via a one-step synthesis and grafting procedure developed in our lab. This procedure involves grinding the electrode in a water paste of sodium nitrite, p-toluenesulfonic acid and an aryl amine, such as p-nitroaniline, m-nitroaniline, 2-aminoanthraquinone, 4-aminosalicylic acid or 4-aminobenzoic acid.

Voltammetry of modified electrodes showed peaks for attached nitrobenzene and anthraquinone groups. Raman spectra of the resulting paste included a peak near 2300 cm^{-1} , indicative of a diazonium group. Addition of 2-naphthol to the paste gave intensely colored products, indicative of azo dye formation. These results suggest diazonium ion formation followed by electrode grafting perhaps by either a radical or cationic mechanism.

After modification, electrodes were cleaned ultrasonically; dilute acid was found insufficient for removing weakly bound groups, while 10 minutes of sonication in acetone was effective. After sufficient cleaning, the coverage of p-nitrophenyl groups on GC was about 0.5 nmol/cm^2 (near monolayer) as determined by integration of voltammetric peaks.

Ferrocenecarboxylic acid and dopamine electrochemical reactivity was not significantly hindered at the modified electrodes. Surfaces modified with p-carboxybenzene groups were tested for their ability to preconcentrate copper ions. Enhanced binding of copper on grafted GC compared to bare GC was observed; however the copper response was considerably lower than that seen on electrografted surfaces, likely due to lower surface coverage and thus fewer binding sites available to the metal ions.

This work was made possible by the Virginia Ellis Franta Fund for Chemistry.

Abstract Title **Behavior of Calcium and Magnesium Ions in the Great Miami River, Ohio**

Primary Author Chi X. Nguyen
Wittenberg University

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Sarah K. Fortner

Abstract Text

The Great Miami River is dominated by agricultural land use with lime applications in the late winter and spring months. The objective of this study was to examine seasonal flow, and the behavior of calcium (Ca^{2+}) and magnesium (Mg^{2+}) in the Great Miami River at Hamilton, Ohio (9,402 km^2). Using an automatic sampler, 280 water samples were collected between January 2013 and May 2014 by the Miami Conservancy District. Samples were filtered (0.4 μm) and analyzed for major cation concentrations using an Ion Chromatograph at Wittenberg University. Median $\text{Ca}^{2+} + \text{Mg}^{2+}$ concentrations were lowest in the spring (0.8mM), associated with the highest median flow during sample collection (89 m^3/s). Median seasonal $\text{Ca}^{2+} + \text{Mg}^{2+}$ yields were highest during the winter (34,000 kg/h) and similar during the spring, summer, and fall (22,400 kg/h; 20,200 kg/h; 21,100 kg/h). The molar ratio of $\text{Ca}^{2+} + \text{Mg}^{2+} : \text{Mg}^{2+}$ was examined versus flow for each season to identify enrichment associated with calcite (CaCO_3) lime applications. Spring calcium-enrichments were as much as double winter values at similar flow. Interestingly, the median enrichment for summer falling limb samples (3.5) was higher than the median for the rising limb (3.0). Chemical weathering of agricultural lime in the spring and recharge of summer groundwater likely explain enrichment trends. As with other agricultural watersheds in the Mississippi River Basin, the area-normalized yield of $\text{Ca}^{2+} + \text{Mg}^{2+}$ was elevated with respect to yields in forested watersheds. This is similar to trends observed in alkalinity, and consistent with lime enrichment.

Thank you to the Virginia Franta Fund for supporting this research effort.

Abstract Text

Analytical techniques for the purification have been highlighted in the biomedical and food engineering. In the early 1970s, counter-current chromatography (CCC) was reported in pioneering work by Dr. Ito. This analytical technique provides an advantage over the chromatographic purification by eliminating the use of a solid stationary phase that is limited and dangers of irreversible adsorption. In 1980s, the CCC technique has been improved in terms of resolution, separation time and sample loading capacity, then these is named to high-speed CCC (HSCCC) Recently, HSCCC is accepted as an efficient preparative technique, and widely used for the purification of various natural and biological products. In this study, we apply this techniques for the purification of natural and food components such as crocetin and malachite green. Thus, this technique has been useful for the purification of all-purposed chemical components from various products. In this application, specific information and basic data of HSCCC would be discussed.

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Michael A. Johnson, Sam V. Kaplan

Abstract Text

Post-Chemotherapy Cognitive Impairment (PCCI) occurs after pharmacological chemoagents are administered to fight carcinomas. PCCI entails a general decline in complex problem solving, learning, memory, and motor function in up to 30% of patients who receive chemotherapy treatment. Previous studies in our group have found dopaminergic neurons are unable to release proper amounts of the neurotransmitter dopamine upon stimulus after treatment with certain chemoagents. Furthermore, the dopamine transporter experienced a similar attenuation. Here, oxidative free radical activity was investigated by probing for spontaneous hydrogen peroxide release in chemotherapy treated rats using fast-scan cyclic voltammetry. Neurochemical analyses were performed after rats underwent chemotherapy treatment with 20 mg/kg injections of Carboplatin for four weeks. Mercaptosuccinic acid, a glutathione peroxidase inhibitor, was applied to brain slices of saline and chemotherapy treated rats to induce an increase in oxidative activity. Spontaneous hydrogen peroxide release appears to increase in chemotherapy rats, thus indicating a potential source of the neurocognitive symptoms of PCCI.

Abstract Text

Pharmaceuticals and their degradation products have been observed in the environment, where they pose potentially negative effects to humans and other organisms. Degradation products may be more environmentally persistent and more toxic than their parent compounds. To investigate the environmental fate of a commonly prescribed antidepressant, we measured the solar photodegradation rate of sertraline (Zoloft®) (SER) in samples simulating the natural aquatic environment. Aqueous drug samples were prepared in 5 mM phosphate buffer (pH=7.0), with and without the organic degradation product humic acid (HA). These samples were photoexposed in a solar simulator and aliquots were taken at relevant time points followed by analyzed using HPLC and LC-ESI-MS. The photodegradation of sertraline followed a pseudo-first order rate law, as expected; using this data, the half-life of sertraline in the various aqueous solutions was calculated. We observed that HA acted as a photosensitizer, speeding up the photodegradation of sertraline. Products of SER photodegradation were detected and structures proposed.

Abstract Text

The use of enzymes in analytical assays is both expensive and inconvenient requiring extraction, purification and storage in specific conditions of temperature and pH. Nanomaterials-based enzyme mimics have attracted considerable interest as alternative catalysts to natural enzymes. This presentation will report studies of the oxidase like properties of nanoceria particles and their use as analytical probes for the detection of phenolic compounds. We will describe a comparative analysis of the oxidase like activity in relation to the physicochemical characteristics of these particles, and define conditions of use in terms of reaction conditions, buffer composition and pH, that is essential for the future use of these particles in analytical assays. Applications of this method for the detection of dopamine and catechol selected as model phenolics will be demonstrated. Performance of this method will be compared to that of an enzyme based detection of the two compounds. The results demonstrate that nanoceria particles can be used to replace oxidase enzymes in the development of cost effective and sensitive methods for the detection of these compounds.

Abstract Text

Pharmaceuticals enter wastewater treatment plants as the result of human excretions or improper disposal and are often not wholly removed during the treatment process. These compounds then enter the aquatic environment and are exposed to sunlight, which facilitates photochemical degradation. In this work, the photodegradation of diphenhydramine and ranitidine, two over-the-counter medications, was investigated in dilute aqueous solutions. Solutions were buffered at environmentally relevant pH levels; humic acid was added at varying concentrations in order to simulate natural water samples. All solutions were exposed to light in a solar simulator with aliquots taken at preset time points and analyzed by both HPLC and LC-ESI-MS. The rates of photodegradation were found to follow pseudo-first order rate laws and the half-life of each compound under different conditions was determined. LC-ESI-MS and MS/MS were used to detect and identify the products of photodegradation.

Abstract Text

Chemometrics is the application of multivariate analysis on complex chemical data sets. Spectroscopic instruments have the ability to produce large amounts of information on analytes. However, it is common to only utilize one wavelength for analysis, and this approach cuts out a large portion of the data. Chemometrics offers a way to analyze samples while using all the information contained within the spectra. Chemometrics is generally not taught to undergraduates and is often approached in industry and research settings as a black-box. The black-box approach refers to analysts using chemometrics without understanding the algorithms and assumptions being applied as part of the model. This work has been an undergraduate interdisciplinary research project between chemists and statisticians spanning two years. Understanding the algorithm of principle component analysis (PCA), learning how to collect samples for chemometric methods, and applying PCA for chemical predictions have been goals of this project. The research being presented is the use of PCA to study fluorescence of glucose oxidase complexed with 8-anilino naphthalenesulfonic acid and laser induced breakdown spectroscopy of barium and strontium in frack water precipitates.

Abstract Text

While ozone in the stratosphere is essential for life on earth by blocking harmful ultraviolet radiation, tropospheric ozone has many negative effects. Ground level ozone contributes largely to smog formation and is responsible for 90% of annual pollution-related crop loss. It has many acute and chronic biological effects on plants, including inhibition of photosynthesis. A multi-week high school chemistry lab was designed to demonstrate the effects of electrochemically produced ozone on golden pothos (*Epipremnum aureum*), a common indoor house plant. Photosynthesis and respiration rates were analyzed by Vernier CO₂ and O₂ gas sensors both before and after exposure of the plant to ozone. Atmospheric ozone concentrations were also determined using colorimetric analysis with Schoenbein paper. This multi-week experience will not only demonstrate comprehension of basic chemistry concepts presented in the course but also real-world environmental issues in today's society.

Abstract Text

The ongoing use of cell phones and other electronic devices leads the scientific community to wonder how these technologies affect the users. While in vitro studies are limited in describing how an organism is directly affected by the microwave radiation produced by these devices, they are helping in determining how biomolecules are altered in response to the exposure. One biomolecule, glucose oxidase, (GOX), is used for medical purposes in glucose meters; thus its stability is key for its accuracy. Microwave exposure of GOX and the resulting structural changes can be studied through fluorescence spectroscopy, involving an ANS probe and tryptophan residue analyses. The GOX aqueous samples are exposed to 150 W of microwave radiation for 15 minutes before fluorescence analyses. Preliminary studies have demonstrated that the fluorescence intensity changes significantly, for both analyses, upon microwave exposure relative to the native GOX state and relative to the thermal control. Further work involves fluorescence analysis during exposure as well as renaturation studies of GOX.

Abstract Text

The choice of basis set is one of the most important choices made in a computational calculation because of its effects on the way each quantum mechanical calculation is executed. Several types of basis sets exist, each defining the system with a distinctive mathematical approach for the energy calculation. The choice of basis set typically depends on the type of model and the level of accuracy needed or wanted. In this work, we show the variance in basis set choice on the accuracy of vibrational frequencies (VF) in several small molecules. We use the computational software package, Gaussian 03 using WebMO 14, running Density Functional theory, and two Coupled Cluster theories, (CCSD and CCSD(T)). The basis sets assessed are, cc-pVDZ, and cc-pVTZ which were chosen because of their inherent accuracy in the calculated values. Data were then compared to standards from the National Institute of Standards and Technology (NIST) experimental VF database. Our results suggest that the most appropriate basis set choice is cc-pCVTZ with an average absolute error of 1.94% relative to NIST experimental data. We also examined the efficiency of our Gaussian 03 program, which is determined to have an average absolute error of 0.648% compared to the NIST computational database standards. We conclude that for small molecule VF, the most appropriate and accurate basis set is cc-pCVTZ, and that results from our modeling program are statistically similar to NIST values. Funding was provided by the Westminster College Chemistry and the Westminster College Drinko Center for Experiential Learning.

Abstract Text

Immunoassays are a class of ligand binding assays that quantify the presence of an antigen of interest through an interaction with a specific antibody (Ab). Immunoassays can be performed in several formats; a popular implementation is the use of fluorescence polarization (FPIA) detection. In an FPIA, fluorescently labeled antigen is used to report on binding events. Upon excitation with a controlled polarization of light, the degree of retained polarization upon fluorescence emission will depend on the degree of rotation of the molecule in solution. In respect to the immunoassay mixture, the labeled antigen will rotate fast when not bound, producing a high degree of depolarization. However, when bound to a large Ab, the rotation will be retarded, and the depolarization will diminish. For a sensitive FPIA, a large change in size upon binding is necessary to elicit a large change in polarization.

In this work, we tested if truncation of a fluorescently labeled insulin could optimize an insulin FPIA. The Ab-binding domain, located at the C-terminus of the beta chain, was retained while the alpha chain was removed. With this modification, a smaller peptide resulted that exhibited a larger depolarization of light in the absence of Ab. In the presence of Ab, the polarization increased as expected. To characterize binding of Ab to the modified peptide, we titrated a solution of modified peptide with Ab while monitoring the polarization. A Scatchard analysis revealed a K_d of 500 nM. The binding affinity following the modification depicted lower affinity than the full insulin molecule ($K_d = 8$ nM), yet it is promising as a complementary tool for FPIA.

Abstract Text

Polydimethylsiloxane (PDMS) microfluidic devices have been developed as diagnostically useful, disposable, and portable “Lab on a Chip” (LoC) devices. LoC devices are fabricated for a wide variety of functions including immunoassays, analysis of bodily fluids, and DNA amplification. The current fabrication method for PDMS chips utilizes photolithography with a transparent photomask containing the desired device design, which creates a negative mold for the PDMS. Currently, when a design needs to be redesigned, a new photomask must be created. Photomasks are commonly made by outside facilities and can delay progress by days or weeks. A modular design of these photomasks could eliminate this delay by providing many possible arrangements and options of the design during fabrication.

The modular method consists of utilizing multiple masks containing simple elements, which when combined, produces a final design that achieves the desired channel structure. The various masks join at specific points when the photomasks are aligned, allowing for the various combinations. We demonstrated this methodology by successfully fabricating a device that has two inlets and one mixing channel to produce aqueous droplets in an oil carrier phase. These droplets have been shown to be powerful high-throughput microreactor systems that reduce reagent consumption, have the capability of producing multiple reactions, and decrease reaction times. The modular nature of this method allows rapid modification of photomasks for a greatly reduced device-to-device turnaround time.

Abstract Text

A Group of Uniform Materials Based on Organic Salts (GUMBOS) encompasses organic solid-state salts which exhibit properties similar to those of ionic liquids (ILs). The tunable characteristics of GUMBOS permit applications in chemical, technological, and biological disciplines. As previously reported by our group, carbazole-derived GUMBOS are good hole transport and emissive materials for applications in blue organic light emitting diodes (OLEDs). The unique luminescent and electrochemical properties of carbazole-based GUMBOS enable potential use of these materials in OLEDs. Herein, syntheses of nanoparticles derived from carbazole-based GUMBOS (i.e., nanoGUMBOS) using templated and non templated ultrasonication approaches are described. The carbazole-based cation was coupled with different counteranions: Iodide ([I]), trifluoromethanesulfonate ([OTf]), and (pentafluoroethylsulfonyl)imide ([BetI]). The average sizes of these nanoGUMBOS were determined using transmission electron microscopy and the optical properties were evaluated by use of absorbance and fluorescence spectroscopy. Absolute photoluminescence quantum yields were also measured using an integrating sphere. The size range of nanoGUMBOS was from 49 nm up to 204 nm depending on the synthetic method and experimental conditions. The molar extinction coefficient and fluorescence intensity, as well as quantum yields, were tuned with the synthetic conditions and average sizes of nanoGUMBOS. The highest quantum yields were reported for [CI][BetI] (14 %) as compared to [CI][I] and [CI][OTf]. These size-dependent optical properties have allowed us to widen the potential applications of these organic nanomaterials for use in optoelectronic devices such as OLEDs.

Abstract Text

Nitroanilines are used as chemical intermediates in the manufacturing of dyes, pesticides, gasoline, specific pharmaceuticals, and poultry medications. There are three isomeric forms of nitroanilines that differ from one another in the position of the nitro substituent. The three isomers, namely 2-nitroaniline, 3-nitroaniline, and 4-nitroaniline, can be distinguished by Raman spectroscopy. The Raman signal can be enhanced by the use of gold or silver nanoparticles in a technique known as Surface Enhanced Raman Spectroscopy (SERS). In this project, colloidal gold nanostars and Klarite™ substrates based on nanoscale patterning of a gold coated silicon surface were used for SERS analysis and characterization of the three isomers. Even though the three nitroaniline isomers have similar structures, their SERS spectra were easily distinguishable from one another and from aniline. The degree of Raman signal enhancement were of the order of 2-nitroaniline > 3-nitroaniline > 4-nitroaniline. The enhancement effects of colloidal gold nanostars versus Klarite™ substrate was compared. The enhancement factors of the different isomers were used to investigate the steric hindrance effects associated with nitroaniline chemisorption as well as the inductive effects due to the position of the nitro substituent group. Computational modeling based on Density Functional Theory (DFT) was also conducted to study the adsorption characteristics of the analytes on gold colloid.

Abstract Text

Phosphorus is an essential nutrient for maintaining a healthy ecosystem; however, heightened levels of phosphorus can have negative effects, including algal blooms, which upon decomposition, can lead to oxygen depletion, resulting in regions lacking aquatic life. It is therefore important to monitor phosphorus levels in bodies of water. Current quantitative methods for phosphorus detection in water are based on the standard method 4500-PE, which detects phosphorus colorimetrically through the reduction of an antimony-phosphomolybdate complex. This standard method, however, often requires sample preservation along with a large amount of reagents. In addition, an absorbance spectrophotometer must be employed for sensitive detection. In order to develop a more rapid, low-cost, on-site device for detection, a paper-based fluidic device (PFD) has been developed requiring microliter reagent volumes for detection of phosphorus as phosphate using a modified ascorbic acid reduction method. These PFDs are smaller than a business card, and are fabricated on cellulose filter paper using a wax printer and a hotplate to develop channels for reagent mixing. Upon mixing of phosphate-containing sample and a combined reagent consisting of sulfuric acid, ammonium molybdate, potassium antimonyl tartrate, and ascorbic acid, a blue color develops. The intensity of the blue color is directly related to the phosphorus concentration, which was measured visually or through densitometer software. It has been found that as little as 150 ppb phosphorus can be detected. This method can be applied in the field to detect and possibly pinpoint sources of nutrient loading into a body of water.

Abstract Text

The need for a better method of blood drawing and analysis is increasing for the demands of the aging population in the US. By utilizing dried blood spot (DBS) cards and media, a smaller amount of blood is required and can be taken and shipped by the patient for analysis. This allows analytes in blood to be quantified with small amounts of sample. Sampling of blood for DBS analysis is also simple and can be completed by the patient at home by finger or heel pricks. Previously, the DBS cards had to undergo microwave digestion to analyze the inorganic analytes in blood using inductively coupled plasma–mass spectrometer (ICP-MS). However, using an excimer laser, the blood can be ablated from the card and analyzed directly, cutting out hours of the sample preparation work. Accuracy in laser ablation (LA)–ICP-MS can be achieved by utilizing isotope dilution mass spectrometry (IDMS), which eliminates the use of calibration curves and allows the standard to be on or in the matrix. This method has been standardized and is covered in EPA method 6800 update V, 2013. LA can also be used to quantify organic molecules and peptides in whole blood that play important roles in maintaining human body functions by coupling it with a molecular mass spectrometer, such as Q-ToF-MS. The quantification of peptides allows a better understanding for doctors to more often follow their patients and improve treatment. IDMS is used for the quantification of both inorganic and organic ions.

Abstract Text

Thin silicon nitride films are a common building block of nanofabricated devices. They offer favorable physical properties, such as the ability to form free-standing <100nm-thick films, but their complex surface chemistry presents challenges. We developed a process to electrolessly plate thin gold films onto silicon nitride membranes, and into through-membrane pores, so that we could use thiol-based chemistry to more readily modify the surface chemistry. We discovered that the gold film grain structure allowed us to perform surface-enhanced Raman spectroscopy (SERS). Thermal annealing of the films dramatically changed the gold film structure, as revealed by both the SERS signal and field-emission scanning electron microscopy (FESEM). Mean grain radii, for example, could be readily increased by tens of nanometers by post-deposition annealing under suitable conditions. We exerted control over the film spatial distribution across longer length scales by preceding the plating with a photochemical surface protection route that allowed us to generate patterned gold films. We will describe the various gold film plating approaches and present applications.

This research has been supported by NSF CAREER award CBET-1150085, in part by NSF EPSCoR Cooperative Agreement #IIA-1330406, and by the University of Rhode Island.

Abstract Title **Analysis of the Inhibitory Activity of Dieckol through Cloning and Mutagenesis of [alpha]-Glucosidase** □

Primary Author Marc A. Williams
Westminster College

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Sarah Kennedy

Abstract Text

This project focuses on the inhibitory effects of dieckol, a phlorotannin found in [*i*] E. cava [*/i*], on [alpha]-glucosidase. The use of [alpha]-glucosidase inhibiting drugs like acarbose, miglitol, and voglibose have been shown to reduce the activity of the protein by competitive or non-competitive inhibition. Through cloning and mutagenesis of the [alpha]-glucosidase gene, it is possible to change the structure of the protein and explore the binding site of the dieckol inhibitor. Mutants have been selected to help determine the specific amino acid residues essential for binding dieckol by testing their activity in the presence and absence of the dieckol. The mutants will undergo enzymatic assays with and without dieckol to analyze difference in binding affinity and inhibition between the wild type and mutant enzymes.

Abstract Text

Multiple cationic biocides used to inhibit microbial growth are commonly incorporated into multipurpose contact lens solutions (MPS). The most widely used cationic additives are polydisperse, complicating their analysis using conventional HPLC with UV detection. This study investigates the use of Ultra Performance Liquid Chromatography (UPLC) coupled with UV detection and electrospray Quadrupole Time-of-Flight Mass Spectrometry (QTOF-MS) for the analysis of the polycationic biocides including polyhexamethylene biguanide (PHMB). The resulting UPLC methods developed were found to provide sensitive and reproducible measurements at sub-ppm concentrations with UV detection when authentic MPS samples were prepared via weak cation-exchange solid phase extraction (> 92% recovery) and analyzed via the method of standard additions ($R^2 > 0.95$). Further, mass analysis of the eluting UPLC peaks has provided mass identification of multiple structures from the PHMB polymer, with oligomers ranging in size from 2 – 6 units. Uptake studies of PHMB and alexidine dihydrochloride have also been performed with a range of lens materials. Lenses immersed in stock biocide solutions in conventional contact lens cases for varying amounts (i.e., up to 96 hours) were analyzed by UPLC to ascertain the remaining biocide concentration. The results demonstrate substantial uptake of these biocide materials by the contact lens, resulting in a significantly reduced concentration of biocide in the lens cases. The possibility of preferential distribution of PHMB in particular as a function of oligomer size/length is also explored.

Abstract Text

The development of novel transition metal complexes with high binding affinities to DNA aims to resolve many of the therapeutic issues faced by traditional metal-based drugs (e.g., cisplatin) known to suffer from poor selectivity and elevated toxicity. Here we describe results of DNA binding and replication inhibition for TM complexes, including $[\text{Cr}(\text{diimine})_3]^{3+}$ systems that display long-lived ^2Eg excited state lifetimes and strong excited-state oxidizing power. Owing to their unique properties, UV excitation of these Cr(III) complexes in the presence of DNA results in emission quenching and leads to strand cleavage, and can further result in adduct formation. In investigating the disposition of TM complexes toward DNA, Capillary Gel Electrophoresis (CGE) and Polyacrylamide Gel Electrophoresis (PAGE) have been used to elucidate modified migration behavior following treatment with target complexes and light. Increased interaction with thymine-containing DNA in particular has been observed by CGE, suggesting a central role for thymine in DNA binding. In addition, polymerase chain reaction (PCR) followed by agarose gel electrophoresis has been used to evaluate the effects of TM complexes on replication for DNA vectors ranging from 128-144 bp. In these systems, we observe that irradiation of DNA in the presence of Cr(III) complexes results in a significant disruption of replication as well as the formation of DNA adducts, dependent on ligand identity/lability. Microcapillary CGE studies have provided verification of DNA damage and reduced replication efficiency suggested by agarose gels, but in a much more convenient and quantitative format with enhanced throughput.

Abstract Text

Since the initial discovery of cisplatin as an effective DNA chemotherapeutic, there has been interest in identifying biologically active transition metal complexes with increased selectivity and decreased toxicity. In recent years our lab has synthesized and characterized a variety of Cr(III) complexes in the form of $[\text{Cr}(\text{diimine})_3]^{3+}$ or $[\text{Cr}(\text{diimine})_2\text{X}]^{3+}$, resulting in range of enantiomeric substances with the potential to serve as DNA photocleavage agents. In supporting this effort, chiral capillary electrophoresis (CCE) has proven to be a convenient and effective tool to assess both chirality and product purity in a single run while using minimal sample. In addition to confirming the successful synthesis of the target complex, in some cases CCE can further be used to investigate the extent of interaction with DNA. Owing to the wide range of diimine ligands utilized, numerous chiral additives have been investigated to achieve separation, including the tartrate additives antimonyl-*D*-tartrate and dibenzoyl-*L*-tartrate, both which preferentially complex the $[\lambda]$ isomer. For example, compounds containing smaller diimines (e.g., 1,10-phenanthroline) demonstrate superior resolution with antimonyl tartrate, whereas larger, hydrophobic ligands that strongly intercalate DNA (e.g., dipyridopheazine) are best resolved using dibenzoyl tartrate. In addition to tartrate salts, sulfated cyclodextrins and a range of other amino-acid based derivatives have been shown to be useful for CE separation of chiral transition metal complexes.

Abstract Text

Peroxynitrite (ONOO⁻) is a strongly oxidizing species that is produced in vivo by the reaction of excess superoxide (O₂⁻) and nitric oxide (NO⁻). Peroxynitrite generation in vivo has been linked to cancer, as well as cardiovascular and neurodegenerative diseases. ONOO⁻ has a very short half-life (~1 sec under physiological conditions), making its direct detection difficult. Therefore, this research is focused on the development of an indirect method for monitoring ONOO⁻ production in macrophage cells using a novel fluorescent probe, HKGreen-3. HKGreen-3 has been shown to be selective towards ONOO⁻.¹ Initial studies on the effect of pH on the yield of the fluorescent product was investigated. Due to the generation of side products during the reaction, a separation method was necessary for accurate quantitation of the desired product. This was accomplished using microchip electrophoresis with laser induced fluorescence detection. In order to obtain optimum resolution between HKGreen-3, side products, and the peroxynitrite product, both normal and reverse polarity electrophoretic separations were studied while varying surfactant concentrations. The use of reverse polarity only resulted in an increase of all migration times compared to normal polarity. After optimization was complete, this method was used to detect the ONOO⁻ specific product in macrophage cells. Current studies are focused on the separation and detection of peroxynitrite in macrophages stimulated with lipopolysaccharide and phorbol-12 myristate acetate to produce NO⁻ and O₂⁻, respectively.

Abstract Text

As a fatal, neurodegenerative movement disorder for which there is no cure and no effective treatment, research of Huntington's disease is crucial. Clinical depression, which is often identified well before a definitive diagnosis of HD is made, is a common problem in patients. Serotonin is a key neurotransmitter implicated in the occurrence of depression; despite this fact, to our knowledge, investigations of the ability of neurons to release serotonin have not yet been published in the literature. The substantianigrareticulata (SNr) is richly innervated with serotonin-releasing terminals, and is thought to play a large role in movement, as well as reward. In this work, fast-scan cyclic voltammetry (FSCV) at carbon-fiber microelectrodes was used to compare serotonin release in acutely dissociated brain slices from wild-type and R6/2 Huntington's disease model mice. An electrochemical waveform, designed specifically to increase the sensitivity of the electrode for serotonin while decreasing sensitivity for dopamine, was used to quantify serotonin release in the substantianigrareticulata (SNr). Using this method, we were able to positively identify and quantify serotonin release. Our data reveal that release is sharply diminished in 12-week-old R6/2 mice ($18 \pm 3.4\%$ of WT), while it is relatively unaffected at 6 weeks of age ($61 \pm 9.8\%$ of WT). In summary, this study shows a link between serotonin release and Huntington's disease, which warrants further investigation of the mechanisms by which serotonin release is impaired in R6/2 mice.

Abstract Title **Age Related Human Scent Differentiation by Gas Chromatography-Mass Spectrometry (GC-MS)**

Primary Author Douglas Beussman
St. Olaf College

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Sarah Elder

Abstract Text

The use of analytical instrumentation to study differentiable human scent is an area of great forensic interest. Not only can the identification of individual scent profiles validate canine evidence in criminal investigations, but it can also determine a scent-based chemical fingerprint. Human scent comes from bacteria, eccrine and sebaceous gland excretions, and volatile organic compounds (VOCs), which are emitted from the dead epithelial cells of the skin. These VOCs can be present in different concentrations and combinations from person to person, making them important in determining differentiable scent profiles. Our goal was to study the VOCs in scent profiles and investigate the possible effects that variables such as age and sex have on human scent. Fifty samples taken from the unwashed hands of men and women aged 1 to 95 were studied. Samples were sealed in glass jars for 18-24 hours to allow the VOCs to concentrate in the headspace. Headspace cryogenic preconcentration and GC/MS were then used to analyze the resulting VOCs. The relative amount of ethanol was found to vary widely from sample to sample, so this compound was investigated as a potential marker for age and/or sex. Among the fifty subjects, samples given by young boys under the age of 16 were found to have the highest amounts of ethanol of any age or gender group. The amount of ethanol also decreased as the age group of the male donors increased. Conversely, samples given by young girls under the age of 16 contained low amounts of ethanol, with a general increasing trend in ethanol abundance with increasing female age groups. Although only a limited sample size has been studied, these data might suggest that both age and gender have an effect on the human scent profile, and that the abundance of certain VOCs within a profile might change over the course of a lifetime.

Abstract Title **Understanding the Scott Test for Detection of Cocaine**

Primary Author Tsungtsueh Wu
University of Wisconsin-Platteville

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Nicole Kloepfer, Rima Minazetinova

Abstract Text

The Scott Test, developed by Scott in 1973, has been modified in the study to improve the sensitivity towards the detection of cocaine. Identification of illegal substances using presumptive color tests is a technique widely employed by forensic laboratories and law enforcement agencies. Presumptive color test reagents are readily available, easy to use, and produce fast results, making them ideal for the use in field, in laboratory, or in the home. According to a survey performed by Carol L. O'Neal et al., more than 90% of the Drug Enforcement Administration laboratories frequently use Scott reagent for cocaine and Marquis reagent for other controlled substances. There is an increase in the worldwide consumption of cocaine in recent years. Although the Scott test has been around for almost four decades, there were only a few research papers available and they all have a limited explanation on how this test works. The theory behind the Scott test described that cobalt thiocyanate or primarily a cobalt ion forms a complex with the cocaine molecule, causing color to change from pink to blue.

Current study was designed to investigate the effects of many variables in the presumptive color test formulation to the sensitivity of detection towards cocaine. Using the factorial experimental design, the study will investigate the effect of cobalt concentration, solvent, ratio between cobalt ion and thiocyanate, glycerin concentration, presence of hydrochloric acid, mixing sequence, and pH. The study utilizes spectrophotometric technique to compare the responses of different circumstances for a 200-microgram cocaine sample. This study will gain an initial understanding on how Scott test works in different circumstances and will point future research directions to elucidate the false results caused by other interfering chemical species. This presentation will also make the users of Scott test aware of the possible cause of false positive and false negative.

Abstract Title **Integrated Perfusion and Separation Systems for Entrainment of Insulin Secretion from Islets of Langerhans**

Primary Author Michael G. Roper
Florida State University

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Lian Yi

Abstract Text

In vivo, insulin oscillations are found with a period of ~5 min. This oscillatory insulin signature is due to synchronization of millions of islets of Langerhans. Synchronization may occur through entrainment from in vivo glucose oscillations. Although intracellular [Ca²⁺] oscillations, which have been used as mimics of insulin oscillations, have been entrained to oscillatory glucose levels, there have been few demonstrations of direct entrainment of insulin secretion. To achieve this goal, a microfluidic system was developed that was capable of measuring temporally resolved insulin secretion from islets and was coupled with a gravity driven perfusion system to test if glucose waveforms can entrain insulin oscillations.

Gravity-driven flow through flow splitting channels was used to generate and deliver complex glucose waveforms to the islet chamber. This system was able to deliver sinusoidal waveforms with a period as low as 1.15 min with minimal peak broadening. Islet chamber dimensions and perfusion flow rate were adjusted for efficient sampling from single or groups of islets. Insulin secreted from islets was electrophoretically sampled and measured every 10 s with an online competitive immunoassay. This assay showed good reproducibility of the B/F with RSDs <4% and a detection limit of 2 nM.

Results showed insulin secretion from single islets was oscillatory with ~5-min periods. Both single and groups of islets were entrained to glucose sine waveforms. In addition to examining entrainment, this system will be useful for further studies of insulin secretion mechanisms and drug testing.

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Dain Brademan, Zachary Rolfs

Abstract Text

Clothing fibers can potentially be used as crime scene evidence if the fibers can be compared with their source. Current methods, including FTIR, are able to distinguish the color and type of fiber, but cannot tell similar fibers apart. Isotope ratio mass spectrometry (IRMS) can be used to compare and differentiate these fibers based on their unique isotope ratios even between similar types. Past work has found different cotton clothing items to be statistically differentiable from each other using the carbon, hydrogen, and oxygen isotope ratios of the threads. In this research, we investigated if silks and wools obtained in different years and with different weave patterns were differentiable. Stained cotton was also investigated to determine if normal stains change the observed isotope ratios. It was found that all the silk and wool samples were statistically differentiable from each other with 95% confidence and that grass stains, dirt stains, and washing did not significantly affected the isotope ratios of cotton.

Abstract Text

In actual forensic cases, powder residue inside empty plastic drug packaging may be the only available indication of drug presence. However, residue contains only trace amounts of drug, especially if “cut” or adulterated with other substances. An analytical method was sought to determine whether package residue could easily be collected and analyzed via a simple rinsing process, and to assess whether the sample would contain enough drug to provide reliable evidence of drug possession. Five abused drugs and nine common adulterants were selected. Samples containing 10% drug were created for each drug-adulterant combination. Each sample was placed in plastic packaging, with the bags subsequently emptied. The bags were then rinsed with water in order to collect any drug residue remaining in the package. Liquid samples were analyzed via Liquid Chromatography-Mass Spectrometry (LC-MS). Extracted ion monitoring was used to isolate the signal from the drug of interest to assess relative presence in the samples. Results showed that all five drugs were consistently detected in residue samples of adulterated drug containing 10% drug by mass.

A more quantitative analysis of methamphetamine, a highly abused drug, was then performed by making methamphetamine samples for each adulterant with drug amounts ranging from 4% to 0.1%. R^2 values, limit of detection (LOD), and limit of quantification (LOQ) values were calculated for methamphetamine samples. Results showed that the method is capable of detecting methamphetamine in bag residues at levels approximately 36 to 755 times lower, depending on the adulterant, than typically found in street samples.

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Katherine Nash

Abstract Text

Proteins perform a multitude of functions in biological life and are of vital importance when analyzing cell behavior. This study was performed in collaboration with several institutions in which proteomic techniques were used to identify proteins expressed in [*Tetrahymena thermophila*] under various conditions and in specific structures. [*T. thermophila*] is a single-celled freshwater ciliate protozoan. It is a model organism, providing insight into cellular workings that can be extrapolated onto other species. Proteins were extracted from the organism and separated using SDS-PAGE gel electrophoresis. The protein bands were excised from the gel and digested with trypsin, with the resulting tryptic peptides purified with C18 pipette tips. Samples were analyzed using MALDI-TOF/TOF mass spectrometry. Tryptic peptides were further fragmented using tandem mass spectrometry techniques to allow sequence information to be obtained. These mass spectra were compared and matched with theoretical [*T. thermophila*] protein amino acid sequences using the MASCOT search database.

Abstract Text

Developing effective assays to easily measure molecular activity in cells is highly relevant for studying signaling pathways and identifying novel compounds for drug discovery. Here, we introduce a rapid, label-free analytical assay for measuring endogenous enzymatic activity. Conventional methods for measuring enzymatic events rely on time-consuming sample preparation including centrifugation, lysis, and lysate purification. More importantly, these conditions may lead to sample loss or decreased enzymatic activity thus limiting the validity of the readout. While cell-based assays have been developed as an alternative to conventional methods, these approaches utilize antibody capturing and fluorescence labeling, and therefore can only offer an indirect measurement. In this work, we develop a novel, label-free enzyme assay for simultaneous cell culture and lysate analysis that overcomes the inherent limitations of conventional and cell-based assays. This approach combines surface chemistry amenable for cell culture, along with self-assembled monolayer laser desorption/ionization mass spectrometry (SAMDI-MS), thus enabling cell culture and analysis on the same monolayer-coated surface. The surface chemistry was tailored to display a cell binding ligand (RGD) and reporter peptides bearing a target specific sequences. Using this approach, we simultaneously measured phosphatase and caspase-3 activity by in-situ lysis of a small population of cells cultured on monolayers and thus demonstrated that multiple enzymatic activities can be detected on the same monolayer. Furthermore, having established parameters to perform cell culture and obtain lysate analysis, we utilized the high-throughput capabilities of SAMDI-MS to screen a small molecule library and identify compounds that modulate phosphatase activity.

Abstract Title **Development of a Microfluidic, Urine-Based Assay for D-Lactate: A Diagnostic Test for Malaria**

Primary Author Meti Debela
Skidmore College

Date: Monday, March 09, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Julie Bryant, Sibin Wang

Abstract Text

According to the CDC, approximately half of the world's population lives in an area where they are in danger of being infected with the parasite *Plasmodium falciparum* which causes Malaria. More effective treatment of the disease would be greatly aided by a simple, rapid diagnostic test. This project details the development of a urine-based test for d-lactate which could be deployed in either paper or plastic microfluidic devices. D-lactate is produced at very high levels by the *Plasmodium* merozoites which are undergoing a very high rate of glycolysis and detoxify the resulting methylglyoxal using the methylglyoxylase pathway which results in d-lactate. Our assay exploits the selectivity of d-lactate dehydrogenase and a colorimetric or fluorometric detection reaction. We have found that this assay gives excellent selectivity and sensitivity at all relevant physiological levels. The presented work will detail our efforts to stabilize the biomolecules and implement this assay on both plastic and paper microfluidic devices.

Abstract Text

Organic contamination of the groundwater is a major area of interest in agricultural and industrial sites as well as lands involved in hydrofracking. The goal of this project is to develop an automated microfluidic device which can preconcentrate, separate and then detect low abundance organic contaminants in water. For the preconcentration step, we are using magnetic Osorb beads from ABS materials which are embedded with magnetite. We have determined optimum pre-concentration volumes and releasing solutions for a number of analytes. Separation results will also be presented along with prototype centrifugal chip designs.

Abstract Text

Enzyme-linked immunosorbent assay (ELISA) is one of the most powerful methods to determine a protein using antigen-antibody reaction and enzyme reaction. ELISA is widely used for analyzing biological samples because of its high sensitivity and selectivity. A 96-well microtiter plate and a microplate reader are commonly used for conventional ELISA since a large number of analyte can be tested simultaneously by using the plate and the plate reader. However, to perform ELISA in the field seems to be difficult because of the size and cost of the microplate reader. To solve this problem, we developed a novel microplate reader with nine fluorescence detection points using laboratory made organic light-emitting diodes and photodiodes as light source and photo detector, respectively. The size and weight of the microplate reader was 50 x 50 x 200 mm and 95 g, respectively. A 9-well microtiter plate for the developed microplate reader was also fabricated. The bottom of the well was made of pure PDMS to transmit the fluorescence from the sample solution in the well to the photodiode, whereas the wall of the well was made of PDMS containing 5 % activated carbon to prevent cross talk with adjoining well. The fluorescence detection system consisting of the 9-well microtiter plate and the plate reader was applied to sandwich-ELISA for the rapid determination of IgA in human saliva, a marker for human stress. The detection limit (3 σ) for IgA was estimated to 9.1 ng/mL and the sensitivity of detection was sufficient to evaluate human stress, since human saliva contains 110-220 μ g/mL of IgA. The sensitivity of the developed microplate reader was comparable to that of commercially available microplate reader. Compared with conventional ELISA using a 96-well microtiter plate, the processing time could be reduced to half and the reagent volume could be cut to one third, respectively. In addition, the developed system was successfully applied to the antibody test on rubeola.

Abstract Text

ChemSpider is an online database of over 30 million chemical compounds sourced from over 500 different sources including government laboratories, chemical vendors, public resources and publications. Developed with the intention of building community for chemists ChemSpider allows its users to deposit data including structures, properties, links to external resources and various forms of spectral data. Over the past few years ChemSpider has aggregated almost 20000 high quality NMR and IR spectra and continues to expand as the community deposits additional types of data. The majority of spectral data is licensed as Open Data allowing it to be downloaded and reused in presentations, lesson plans and for teaching purposes. This poster will present our existing technology and our plans to host a million spectra in our developing online data repository.

Abstract Text

We have developed a new method of electrochemical cytometry to measure the total content of single neurotransmitter vesicles and we have compared this to exocytotic release to measure the extent of partial release. We have carried out vesicle impact experiments at electrode microarrays and used this to model the vesicle diffusion coefficient.

The electrochemical response to single adrenal chromaffin vesicles filled with hormone transmitters as they impact a 33- μm diameter disk-shaped carbon electrode will be shown. The vesicles appear to adsorb onto the electrode surface and sequentially spread out over the electrode surface trapping their contents against the electrode. These contents are then oxidized and a peak results for each vesicle that bursts. A large number of current transients can be observed if the concentration of vesicles is high relative to the area of the electrode. Comparison of the contents of these biological vesicles to the release of catecholamine from single cells supports the concept that only a fraction of transmitter is released during exocytosis. Additionally, substructure of the vesicles is apparent in the shape of the current transients. Finally, we have succeeded in carrying out vesicle impact electrochemical cytometry inside living cells. Here we have been able to compare directly the contents of vesicles to the amount released from the cell.

Abstract Text

Some thirty-five years ago, the electrochemical detection of neurotransmitters in vivo became possible with the miniaturization of electrodes to the micrometer scale. Over the past two decades, advances in electroanalytical chemistry have enabled selective quantification of subsecond fluctuations of electroactive molecules such as dopamine, a neurotransmitter that is important in movement and reward processes. Studies that utilize fast-scan cyclic voltammetry, an electroanalytical approach that combines selectivity with sensitivity to report on rapid dopamine fluctuations at bare carbon electrodes in the brain, are of broad interest to both cellular and behavioral neuroscientists, and are truly advancing our understanding of goal-directed behavior. However, the voltammetric approach that has proven to be so powerful has largely been used only to study dopamine, and the dynamic fluctuations of countless classes of molecules in the brain remain uncharacterized. This talk will discuss the development of innovative new analytical tools aimed at improving the detection of dopamine and enabling real-time electrochemical measurements of additional classes of molecules in the brain. Novel electrode materials, electrochemical waveforms, and approaches to the voltammetric detection of hydrogen peroxide at enzyme-modified electrodes will be discussed.

Abstract Text

In this talk, I will present our recent research on nanoscale electrochemical imaging with fluorescence-enabled electrochemical microscopy (FEEM). FEEM is a new electrochemical technique developed in our laboratory to image individual redox events with exceedingly high spatial and temporal resolutions. The central idea of FEEM is the coupling between a redox reaction of interest and a fluorogenic reaction on a closed bipolar electrode. This allows one to use fluorescence to monitor conventional electrochemical processes. Our group has developed very large electrochemical arrays containing millions of ultramicroelectrodes (UMEs) and nanoelectrodes and used these arrays to image biological events. Here, I will describe our recent progress on the use of such arrays to image neuronal activity from single neuronal cells and their network.

Abstract Text

This presentation will describe new motion-based bioassays based on changes in the speed or distance of nanomotors induced by biomolecular interactions or on the selective capture, sorting and transport of target biomolecules. Different motion transduction schemes will be illustrated for monitoring a wide range of biomolecular interactions of nucleic acids, proteins, bacteria or cancer cells. The resulting assays add new and rich dimensions of analytical information and offer remarkable sensitivity, coupled with simplicity, speed and low costs. Microengines functionalized with different receptors will be shown to capture selectively and transporting target DNA and cancer cells from raw complex body fluids. New microengines with a 'built-in' recognition capability will also be discussed. The latter obviated the need for the receptor immobilization. The greatly improved capabilities of chemically-powered artificial nanomotors could pave the way to exciting and important bioanalytical applications and to sophisticated nanoscale and microchip devices.

Abstract Text

In the nervous system of all animals studied to date, including mammals, D-amino acids are present. As examples, D-serine, D-aspartate and D-alanine are present at high levels in specific brain and endocrine regions, although their functions are not well understood. Because neurochemistry is well conserved across metazoan life, we find these molecules in a range of animals, and are studying their formation and function in cell to cell signaling. We are developing a range of analytical tools to characterize the chemical content of small brain regions, even down to individual neurons. Using capillary electrophoresis with laser induced fluorescence and mass spectrometry detection, we have determined which neurons synthesize D-Asp, and have measured the formation, transport and release of D-Asp in a stimulation dependent manner; we have even characterized the enzyme responsible for D-Asp formation. We are currently measuring the presence of other D-amino acids in neurons and endocrine structures and adapting sampling approaches to measure their activity-dependent release. Besides amino acids, neuropeptides are an important category of neuromodulatory compound. While proteins (and thus, their peptide products) are ribosomally translated using only L-amino acids, D-amino containing-peptides (DAACPs) do exist, although are difficult to characterize using mass spectrometry alone because the modification does not have an associated change in mass. We have developed a series of mass spectrometry approaches to identify DAACPs from complex mixtures of peptides. Our DAACP discovery funnel has already identified several candidate neuropeptides and more appear likely. Thus, this enigmatic post-translational modification to a peptide may be more common than previously thought.

Abstract Text

Measurements of the phase of femtosecond nonlinear optical signal fields opened up the possibility of measuring optical frequency Two-Dimensional Fourier Transform (2DFT) spectra that are in some ways analogous to 2DFT NMR spectra, which correlate pairs of frequencies from the same molecule. Since initial demonstration and development at optical frequencies, femtosecond 2DFT spectroscopy has been extended down to the THz region, up to the deep ultraviolet, and widely used to study gases, liquids, solids, glasses and proteins. There is now a quantitative theory for this nonlinear spectroscopy in three frequency dimensions that generalizes the one-dimensional Beer- Lambert law of linear spectroscopy. An overview of the principles, capabilities, and prospects for femtosecond 2DFT spectroscopy will be followed by discussion of recent results on molecules and photosynthetic proteins, where the usual adiabatic picture of fast electrons and slow vibrations fails for all accessible coordinates.

Abstract Text

Ultrafast coherent two-dimensional infrared (2D IR) spectroscopy is a powerful approach for obtaining structural features and equilibrium dynamics of peptides and proteins. In this talk, I will first present the results of 2D IR experiments on oligopeptides that serve as a paradigm for studies of backbone conformations in proteins. Using multiple pulse sequences and polarization configurations as well as strategic isotope substitutions, we demonstrate that 2D IR can provide diagnostic cross-peak patterns for distinguishing different secondary structure, probe the onset of secondary structure, and reveal complex vibrational couplings between the amide-I and amide-II modes. Experimental spectra are compared to simulations based on nonlinear response theory, vibrational eigenstates and couplings derived from DFT-optimized structures, and trajectories from molecular dynamics (MD) simulations. Our results show that 2D IR can provide a large set of spectral constraints that are useful for determining peptide structure and testing theoretical models. In the second part of my talk, I will describe the use of waiting-time dependent 2D IR to study ultrafast molecular dynamics, such as vibrational relaxation, energy and coherence transfer, frequency fluctuation correlation, and chemical exchange. Recent applications on peptide-membrane interaction, conformational exchange, and hydrogen bond dynamics will be discussed. Experimental results are compared with those from MD simulations, DFT calculations, and stochastic simulation.

Abstract Text

Mechanisms that govern light-induced chemical reactions are of interest to a broad scientific community of physicists, chemists, and biologists. Time-resolved resonance Raman spectroscopies are among the most indispensable tools used in such investigations, because resonance enhancement enables studies of dilute solutions and active sites in complex systems. Sensitivity of time-resolved resonance Raman spectroscopies to dynamics on the 100-fs time-scale requires use of a stimulated (rather than spontaneous) Raman probe. Such techniques are referred to as femtosecond stimulated Raman spectroscopies (FSRS). This talk will introduce two new approaches to FSRS. In both methods, five incident laser beams are used to eliminate most of the background that challenges signal detection in the traditional three-beam FSRS geometry; data acquisition rates and signal-to-noise ratios are improved by 1-2 orders of magnitude using five beams. Applications to photodissociation processes in triiodide and oxymyoglobin will be discussed.

Abstract Text

Analytical spectroscopy is dominated by 1D UV/vis, infrared, fluorescence, and Raman spectroscopies but NMR has a rich variety of methods based upon multiple spin coherences. Successive pulses excite multiple spin states on time scales that are shorter than the loss of quantum mechanical phase. This talk will describe a new coherent family of coherent electronic and vibrational spectroscopies that are analogues of NMR methods and an enhancement of traditional incoherent spectroscopies. The family is based on using separately tunable lasers to excite a mixture of electronic and/or vibrational quantum states called a multiple quantum coherence (MQC). Since the lasers are temporally and spatially coherent, so also is the mixture of quantum states. Pairs of states within the MQC emit cooperatively throughout the excitation region in beams that depend on the frequency differences between the pairs. The method is multidimensional and measures the resonance enhancements as a function of the excitation frequencies, time delays between excitation pulses, and the output frequency. Two dimensional cross-sections through the multidimensional variable space create spectra that define the couplings between vibrational and/or electronic states and the coherent and incoherent dynamics. The methods share many of the advantages of multidimensional NMR methods. The multidimensional capabilities provide high selectivity that permit analytical measurements on complex samples. The coupling requirement eliminates much of the spectral congestion in complex samples because only spectral features that are coupled will appear in the spectra. The ultrafast excitation pulses provide temporal resolution on femtosecond time scales so the coherent dynamics can be measured in addition to the slower incoherent population dynamics. Example applications will illustrate the capabilities of these methods and how they can be used for analytical spectroscopy and materials chemistry.

Abstract Text

It is now possible to conduct coherent spectroscopy across an amazing swath of the electromagnetic spectrum, from radiofrequency to x-ray ranges. The ability to generate tailored coherent fields throughout the spectrum is exploited to control molecular and collective responses as well as to measure them. Recently developed capabilities in two spectral regions will be presented. First, terahertz-frequency fields can now be generated that are strong enough to generate nonlinear responses of molecules and materials. Their use for coherent spectroscopy and control of rotations of polar molecules, yielding transient orientation of molecular dipoles, and their use to drive crystalline-phase electronic and structural phase transitions that can be monitored by time-resolved x-ray diffraction, will be illustrated. The strong THz fields are themselves the products of coherent control, generated by spatially and temporally shaped optical pulses that drive polar crystal lattice vibrations that radiate in the THz range. Spatial and temporal shaping of optical fields is used for fully coherent multidimensional optical spectroscopy and control of collective electronic as well as vibrational responses. Studies of correlated exciton and multi-exciton states including exciton-polariton Bose-Einstein condensates will be described.

Abstract Text

Compared to other condensed phase media, very little is known about the inhomogeneous environment at the interface between two immiscible liquids in spent nuclear fuel reprocessing. It is expected that unique structural and dynamical properties exist in this interfacial region. However, due to the small size of the region which is buried between the two immiscible liquids, it is challenging to experimentally probe these properties. Many studies have utilized spectroscopic and X-ray techniques to probe the interfacial chemistry of two immiscible liquids. While these techniques have greatly enhanced our knowledge of interfacial phenomena in the past decade, they are unable to directly probe many properties. At the University of Utah, we are using modern, biphasic analysis techniques including biphasic electrospray ionization, biphasic atmospheric pressure chemical ionization, and biphasic calorimetry to characterize the thermodynamics, kinetics, hydration, and ion transfer of f-element cations at the interface of immiscible liquids.

Abstract Text

Analytical sensors are needed to monitor the composition of radioactive wastes during storage and processing. Complex salt solutions, solids and gases in nuclear waste storage tanks need to be monitor constantly to ensure the integrity of waste tanks and to safeguard the processing and disposal of nuclear wastes. Raman spectroscopy is an ideal analytical tool for waste tank analysis because it can be used for identification and quantitation of the chemicals in the waste. Advances in Raman technology, both in compact instrumentation using solid-state lasers, charge coupled device detectors and fiber optic sampling, allow the application of Raman as a remote monitoring technique. Fiber optic probes connected to the Raman instrument can be delivered inside waste tanks for remote characterization of waste materials. A Raman/turbidity sensor, Raman telescope probe and Raman gas cell have been developed for nuclear waste monitoring applications. The development of these Raman sensors will be presented.

Abstract Text

The goal of this work is the development of a sensor for ^{99}Tc that is applicable for characterizing and monitoring for the presence of technetium in the environment and in nuclear waste. The dominant form of Tc species in the vadose zone and ground water at Hanford and other US-DOE sites is pertechnetate, TcO_4^- , while lower oxidation states are believed to be present within select nuclear waste storage tanks. The sensor consists of an innovative fluorescence-based spectroelectrochemical configuration that we have developed by combining the following elements: spectroscopy, electrochemistry, device fabrication, thin film technology, and synthetic inorganic chemistry. The spectroelectrochemical sensor has been demonstrated on a variety of chemical systems including authentic radioactive waste samples. In pursuit of our project goals, we have discovered and report the first examples of excited-state luminescence from technetium complexes. We have examined a series of trans-dioxo complexes of Tc(V), a Tc(I/II) phosphine complex, and technetium(I)-tricarbonyl complexes and compare their respective photophysical properties with the corresponding rhenium analogues. In a recent application, we have focused on making thin chemically-selective films for sensing radioactive technetium compounds and in this effort have developed a fluorescence-based spectroelectrochemical sensor. Characterization of the technetium excited states as well as application of the respective chromophores for use in a spectroelectrochemical sensor for technetium will be discussed.

Abstract Text

Tritium is a radioactive beta decay material which is required for fusion research. It has a half-life of 12.3 years that translates to approximately 50,000 curies in just 6 grams of material in its T₂ gas form. It can readily undergo exchange reactions with protium sources such as hydrocarbons and water. Even the hydrogen out-gassing from high vacuum systems of a mass spectrometer will cause significant analysis constraints. Tritium turns fluorocarbons to thick syrup and the activity level can charge up detectors. As a result instrumental analysis must handle several chemical and material constraints. Examples from experiences at the Savannah River National Laboratory (SRNL) will be discussed in the presentation. For example, instruments need to replace o-ring seals with metal vacuum seals and instruments need to be able to work at negative pressures in closed systems inside of secondary inert containment glove-boxes to limit exposure and other risks. Chemical analysis becomes a challenge. For example a simple methane analysis can go from CH₄ to CHD₃, CH₂D₂, CH₃D, CD₄, ...CH₃T, ...CHDT₂, ...CDT₃, ...CT₄ dependent on the HDT mix while still giving a single GC peak for methane, but variant spectra in the IR and Raman, and complex mass spectroscopy patterns that require high resolution systems. Passivated high resolution mass spectrometers with minimal residual hydrogen background are required for some analysis. To find alternative analysis solutions SRNL has built a Tritium Instrumentation Demonstration System to test and evaluate analytical instruments that complement mass spectrometry. These systems are totally contained and connected to tritium recapturing systems and supported with trace level ion chambers and evacuation processes.

Abstract Text

Monitoring and control of actinide oxidation states is critical to maintain safety and efficiency in nuclear materials processing. The absorption spectra of the actinides are sensitive to oxidation state, solution acidity (nitric acid), and temperature, making it difficult to establish an accurate universal regression model for all possible process conditions. Furthermore, for plutonium, oxidation and/or disproportionation will naturally occur at some conditions, meaning that stable standards cannot be made without introducing chemical stabilizers that can influence the calibration. Here, we describe two approaches to creating analytical methods for the measurement of chemically unstable forms of Pu. The first is a process absorption spectroscopy method whereby spectra are classified into one of several regimes. Localized calibrations are based on spectra taken as the solutions naturally evolve – the total Pu concentration remains constant but the relative amounts of different oxidation states vary. The relative concentrations of these species are determined by principal components analysis, the results are used as the basis for subsequent predictive models. Because this approach is resource-intensive, we have incorporated calibration transfer schemes to allow a single calibration to be ported to multiple instruments. The implementation of these schemes into a Pu processing facility at Savannah River Site is described. The second approach is to use spectroelectrochemistry to control the Pu oxidation state at any acidity, again avoiding the use of chemical stabilizers. Ideally, complete control of the solution could be obtained. In practice, the range of conditions where spectroelectrochemistry can be performed may not be as large as initially hoped. We will describe the successes and apparent limitations of the method, as well as operational considerations for its use as a routine analytical method.

Abstract Text

Antibody-drug conjugates (ADCs) harness the specificity of tumor-recognizing mAbs to deliver a cytotoxic agent directly to cancerous cells thus avoiding the systemic toxicity associated with standard chemotherapy. The potency of ADCs depends on the structural integrity of the mAb, the cytotoxic agent, and the conjoining linker. High resolution mass spectrometry (MS) has long been used to elucidate protein primary structure and, more recently, has become important in biopharmaceutical development where it is leveraged to characterize the structural integrity of biopharmaceutical products. We present here 2 case studies highlighting the application of MS in biopharmaceutical development to define the higher order structural integrity and micro-heterogeneity of ADCs. The first case study involves the application of hydrogen-deuterium exchange mass spectrometry to the direct comparison of the higher-order structure of a mAb and the corresponding ADC which is composed of the mAb with engineered cysteine residues in the Fc domain that are conjugated to pyrrolbenzodiazepine (PBD) dimer drug-linkers. Our findings indicated that there were no significant conformational differences between the mAb and the corresponding ADC. The second case study focuses on the application of MS to the analysis of thermally stressed mAbs and ADCs that are prepared as freeze-dried lyophilized cakes. We will present recent results showing that lyophilized proteins that undergo thermal stress can form covalent adducts with the buffer and excipient components present in the formulation.

Abstract Text

Ultrahigh-resolution mass spectrometers in combination with platform/standardized methods offer significant improvements for the structural characterization of protein therapeutics, especially for monoclonal antibodies (mAbs). Specialized LC/MS-subunit analysis characterization methods were developed for mAbs that provide rapid, definitive confirmation of the light and heavy chain amino acid sequences and detection of posttranslational and storage-induced modifications at the subunit level, including deamidation. In addition, LC/MS-subunit analysis offers rapid de novo detection of potential sequence variants at the subunit level during early stages of process development. This approach has been advantageous for screening multiple cell clones for higher-level sequence variants prior to final clone selection.

Abstract Text

Constant analytical progress has resulted in better understanding at the molecular level of the attributes that are crucial for safety and efficacy of protein drugs. Parallel to these advances, regulatory agencies have recommended a Quality by Design (QbD) approach to integrate the knowledge of these critical quality attributes (CQAs) in drug manufacturing. A logical next step for the biopharmaceutical companies that have embraced QbD and CQA during process development would be the applications of these concepts for data-directed manufacturing and quality control associated with drug disposition. In this communication, we present the design of a MS-based approach for automated assessment of product quality attributes of therapeutic proteins. Our goal is to leverage the deep knowledge of CQAs acquired during research and development to provide feedback mechanisms for real-time control of drug manufacturing and a new paradigm for release testing. The approach is based on the detailed analysis of the drug by peptide mapping using a combination of high accuracy / high resolution MS data generated by Orbitrap technology and automated identification and quantification of CQAs with a dedicated quantitative software program. Application of these principles results in extensive sequence coverage of complex proteins and quantitative measurement of multiple attributes, such as glycoform distribution and amino acid modifications. Concrete application of this approach for quantitative analysis of monoclonal antibodies in a quality control environment aligns well with QbD principles by focusing on the attributes of the drug essential for function. Current results indicate that this knowledge-based, multi-attribute single method can be used for real-time assessment of drug quality during manufacturing and has the potential to replace several conventional electrophoretic and chromatographic methods currently used to release biologics.

Abstract Text

Mass spectrometry has increasingly become an indispensable tool in biopharmaceutical process development, in addition to its common use in product characterization. Recent advances in instrument capability, both hardware and software, provide the required sensitivity, resolution, speed and dynamic range for detection of low level product related variants and process related impurities. A common approach employed is peptide mapping with reversed phase HPLC or UHPLC, with online LC-MS/MS analysis using data dependent acquisition.

Several specific areas of mass spectrometry application in biopharmaceutical development are included in this presentation. One is sequence variant analysis in support of cell line selection and cell culture process development. Low level, previously unknown amino acid substitutions due to either mutation or mistranslation are identified with the use of mass spectrometry. Recent studies on analytical approaches towards improved detection coverage and the use of appropriate assay control will be presented. A second area is the characterization of product color due to oxidation and advanced glycation end products modifications on lysine residues. These variants are highly heterogeneous in nature and are present at very low levels, both representing significant challenges in analytical technologies. Cell culture media and process conditions that yield reduced color modification have been identified. We describe in the third area recent advances in the use of mass spectrometry to complement the conventional immunoassay approaches for host cell protein (HCP) analysis. Analytical methodology and case studies will be presented for both the identification and quantification of HCP to support the optimization of purification process.

In summary, we demonstrate that mass spectrometry is a critical analytical tool for development of biopharmaceutical products that are safe, consistent, and well characterized.

Abstract Text

Samples of purified biologics typically contain extremely low levels of sequence variants of the active pharmaceutical ingredient as well as host cell proteins. The reliable detection and identification of such molecules is greatly hindered by the presence of the active pharmaceutical ingredient. Nevertheless, the tremendous advances in mass spectrometry enable the identification and quantification of even these very low abundant proteins.

We present mass spectrometry-based approaches that enable a sensitive identification and quantification of low abundant protein species directly in samples containing large quantities of purified biologics. Potential pitfalls of such proteomic approaches and remedies to avoid misinterpretation of the results are discussed.

Abstract Text

Nano-/quantum-biodesive is a piece of contrivance, equipment, machine, or component, which is created by the overlapping multidisciplinary activities associated with nano-/quantum-technology and biotechnology, intended for biological, medical, and clinical purposes. In this lecture, I will describe the development of nano-/quantum-biodesives for biomedical applications, including single cancer cell diagnosis for cancer metastasis, circulating tumor cell (CTC) detection by microfluidic devices, nanopillar devices for ultrafast analysis of genomic DNA and microRNA, nanopore devices for single DNA and microRNA sequencing, nanowire devices for exosome analysis, single-molecular epigenetic analysis, quantum switching in vivo imaging of iPS cells and stem cells, and quantum technology-based cancer theranostics. Euglena-based "biomimetic mechanical system" enables us to develop reliable circulating tumor cell (CTC) separation and detection technique for cancer metastasis diagnosis. Immunopillar devices realized the fast and low invasive "from blood to analysis" type biomarker detection of cancer with fM detection sensitivity within 2 min. Additionally, nanopillar devices give us ultrafast separation of DNA and microRNA within 60 μ s and nanopillar-nanopore integrated nanobiosive enables us ultrafast single molecular DNA sequencing. Nanowire devices coupled with super-resolution optical microscopy are extremely useful to analyze exosomes from cancer cells and exosomal microRNA analysis. Quantum dots are applied to develop nanobiosive for single cancer cell diagnosis, single molecular epigenetic analysis, quantum switching in vivo imaging for iPS cell and stem cell therapy and theranostic biosive for cancer

Abstract Text

A current focus of biological research is to quantify and image cellular processes in living subjects. To analyze such cellular processes, genetically-encoded reporters have been extensively used. The most common reporters are firefly luciferase, renilla luciferase, green fluorescent protein (GFP) and its variants with various spectral properties. Herein, novel design of split GFP and split luciferase will be described; the principle is based on reconstitution of the split-reporter fragments; The basic strategy of the reconstitution is to split a reporter protein into two non-active fragments that are fused to a pair of interacting proteins. The interaction between the two proteins brings the two fragments into close proximity, allowing reconstitution of an intact reporter protein. To demonstrate the usefulness of the reconstitution technology, we have applied the reporters for developing a genetic method to identify mitochondrial proteins and their localization, and imaging dynamics of endogenous mRNA in single living cells. We have recently used split-luciferase reporters with different spectral characteristics for GPCR- β arrestin interactions in living subjects. We have developed another design of reporter proteins; a cyclic luciferase by protein splicing to monitor protease activities in living cells and mice. Herein, we will focus on recent advances in the imaging technologies with fluorescent and bioluminescent proteins.

Abstract Text

One of the challenges in cancer therapy and diagnosis is to develop novel nanomaterials that can carry out targeted, controlled release of anticancer drugs and siRNA as well as to enhance imaging and diagnosis. We have been developing mechanized nanoparticles based on mesoporous silica nanoparticles (MSNs) that contain thousands of pores where chemicals can be stored. MSNs can be surface modified to provide tumor targeting capability. Efficacy of camptothecin-loaded MSNs to inhibit tumor growth was demonstrated in animal model systems. Extensive analysis of safety and biocompatibility of this type of material was carried out.

We equip MSNs with nanovalves that can cap the pore opening with a bulky chemical group. By opening and closing nanovalves, it is possible to achieve controlled release of the content. One type of nanovalves responds to change in pH and opens in acidic pH conditions that are encountered inside the cell or in the tumor environment. Another type of nanovalve contains a disulfide bond so that the nanovalve can respond to reducing conditions inside the cell. We have also developed MSNs that respond to light. This system uses azobenzene, a photosensitive chemical that changes conformation in response to light exposure. We call this drug delivery system nanoimpeller that releases anticancer drugs in response to blue light. More recently, we have developed a second generation nanoimpeller by incorporating a two-photon responsive fluorophore. This enabled the use of red or near infrared red light that are tissue penetrating. Finally, we have developed MSNs that respond to magnetic field. This MSN contains iron oxide core that has super paramagnetic property. Exposure to oscillating magnetic field increases temperature of MSNs opening the nanovalve and releasing contents. Iron oxide core also provides MRI enhancing property. Thus, these MSNs have multiple features that are ideal for imaging and therapeutic purposes.

Abstract Text

Discoveries at the nanoscale continue to affect all of us at the global and local scales. This is especially true for the next generation of biomaterials as their development demands improved imaging and analytical performance. Hitachi is responding to this challenge with its HT7700 and the EXALENS, a high resolution objective lens that sets the new performance standard for 40-120kV microscopy. By achieving a smaller spherical aberration coefficient, a lattice resolution of 1.4Å is demonstrated. EXALENS excels at high resolution transmission electron microscopy (TEM) imaging at low accelerating voltages with minimal beam damage, facilitating analyses of soft materials, carbon-based nanomaterials, polymers and catalysts. It is the superior choice for brightfield/darkfield scanning transmission electron microscopy (STEM), where thick biological specimens are imaged with reduced chromatic aberration. These improvements in electron optics, as well as recent developments in TEM instrumentation, have made it possible to study dynamic in-situ reactions of nanoparticles engineered for disease diagnosis and treatment.

Abstract Text

Analysis of the affinity and the binding between bio-molecules and between molecule and cell tends more and more towards label-free approaches. Biosensors and Biochips are developed worldwide to propose new, fast, cheap, reliable and multiplexed tools to meet these demands.

SPR Imaging is moving the molecular interaction analysis a step further by offering the multiplex, label-free and real time detection. However, biological samples often contain attomolar or femtomolar concentrations of biomolecules, which is below the detection limit of SPRi. It is not common to combine the SPR to nanotechnology investigation. The high flexibility of the SPRi instrument as well as the biosensor itself open the way to reach ultra low sensitivity measurements.

We present here the exploitation of the powerful approach of Surface Plasmon Resonance Imaging (SPRi) and the unique combination with nanomaterials leading to ultrasensitive level for biomarkers detection. During this presentation we will show you different applications which are promising especially to increase the progress of Health (diagnostic analysis and treatment).

Abstract Text

Tandem mass spectrometry has proven to be an increasingly popular strategy for elucidating structural information from non-covalent complexes. Collisional-induced dissociation (CID) is frequently utilized for disassembly of protein complexes and analysis of the constituents. However obtaining complete sequence information from proteins within non-covalent complexes is challenging, typically requiring either several MS_n events or higher-energy collisional dissociation. Ultraviolet photodissociation (UVPD) is a high energy fast ion activation/fragmentation method which affords rich sequence information. Here we successfully utilize UVPD as an effective MS/MS top-down strategy for characterization of native protein-ligand and protein-protein complexes as well as proteins with post-translational modifications. For example, characterization of protein ubiquitination, a post-translational modification that modulates protein degradation and cell cycle control, is challenging due to changes in the site of modification, the number of ubiquitins attached, and the linkages between ubiquitins. Ultraviolet photodissociation offers a promising strategy to assign the linkage type of polyubiquitin modifications.

Abstract Text

The analysis of samples from biomedical sources presents multiple challenges: limited amounts of material, mixtures of components with closely related structures, labile structural modifications, temporal changes due to growth and development, aging, infection and disease, environmental exposures, etc. We are particularly interested in the qualitative and quantitative detection of protein post-translational modifications and glycoform distributions. Both LC/MS and MALDI-MS approaches are being applied to studies of cardiovascular, infectious and protein misfolding diseases, using high performance MS/MS and IMS/MS methods, in combination with various dissociation strategies.

Abstract Text

In this work, we combine immuno-laser capture microdissection (iLCM) and liquid chromatography mass spectrometry (MS) as a means to study proteins that are specific for pure cell subpopulations in complex tissues. CD24, as a cell surface marker for detecting pancreatic cancer stem cells (CSCs), is directly correlated with the development and metastasis of pancreatic cancer. An in-depth proteomic profiling method for frozen pancreatic CD24+ adenocarcinoma cells using iLCM and LC-MS/MS, compared with CD24- cells dissected from patient-matched normal adjacent tissues will be described. Around 40 nL tissue procured from each specimen, which corresponds to ~1.3 μ g of protein material, was subjected to tandem MS analysis in triplicates. A total of 2665 proteins were identified, with 379 proteins in common that were significantly deregulated in CD24+ versus CD24- cells, with at least 2-fold change in expression. Ingenuity Pathway analysis (IPA) of these differentially expressed proteins further suggests significant involvement of signaling pathways related to cell proliferation, apoptosis resistance, and cell migration and invasion. This proteomic approach identified 27 known potential markers, including ANXA1, 14-3-3 Sigma, TGFBI, and POSTN. Five selected candidates were further evaluated in PDAC by immunohistochemistry analysis of tissue microarrays. Five interesting proteins, CD59, CD70, CD74, TGFBI, and TGM2, were further evaluated on tissue microarrays. CD74 was identified, for the first time, as highly upregulated in PDAC by using the proteomic approach, and immunohistochemical study with accumulating evidence indicating that it plays important roles in tumorigenesis and angiogenesis. These results not only demonstrate that this proteomic approach is a useful tool for marker discovery, but contribute to further understanding of pancreatic tumorigenesis and development of novel therapeutic targets to improve its treatment.

Abstract Text

Modern biological and medicinal researchers increasingly rely on large-scale technologies for the comparative analysis of proteomes. To satisfy this growing demand, maturing proteomic methods must achieve high-throughput, quantitative analyses of near-complete proteomes. Here we describe two efforts in this vein.

The first is the identification of a comprehensive yeast proteome from just over an hour of analysis time. We achieved this expedited proteome characterization through improved sample preparation, chromatographic separations, and by using a new Orbitrap hybrid mass spectrometer equipped with a mass filter, a collision cell, a high-field Orbitrap analyzer, and, finally, a dual cell linear ion trap analyzer (Q-OT-qIT, Orbitrap Fusion). Over an 1.3-hour method, the Q-OT-qIT hybrid collected an average of 13,447 MS1 and 80,460 MS2 scans per run to produce 43,400 peptide spectral matches and 34,255 peptides with unique amino acid sequences. These experiments delivered an extraordinary 67 proteins per minute and demonstrate that complete analysis of the yeast proteome can be routinely performed.

The second is a quantitative approach that blends the accuracy of SILAC with the impressive throughput of isobaric tagging methods. The strategy – neutron encoding (NeuCode) – relies on the mass defect of atoms and their isotopes and harnesses the exceptional resolving power of modern FT-MS systems to selectively reveal or conceal quantitative information when desired. When compared to traditional SILAC, NeuCode SILAC achieves comparable quantitative accuracy and improved proteome coverage. When compared to TMT labeling, NeuCode SILAC's wider dynamic range substantially improved discovery potential. Finally, we combined NeuCode SILAC with reductive dimethylation to compare the salt-stressed yeast proteome in up to 18 different conditions. These results demonstrate that NeuCode SILAC can be configured to accommodate diverse proteomic experiments.

Abstract Text

Native mass spectrometry is now routinely used to measure m/z of intact protein complexes. To gain substructure information on the complexes an activation method in a tandem mass spectrometer is needed. Ion Mobility is also used to provide information on collisional cross sections and unfolding pathways. In this presentation, the use of surface-induced dissociation (SID) coupled to ion mobility will be illustrated. Ion mobility can be used either before or after the surface collision and two steps of surface activation can be used as shown in the figure. Data for a number of protein-partner complexes will be presented, where the partner can be small molecule ligand, protein, DNA, or RNA. Fragmentation to subcomplexes will be shown and the influence of charge on the fragmentation will be illustrated. The results illustrate that substructure information is available through the surface-induced dissociation method. In addition, SID spectra reflect well any initial structural changes caused by "heating" within the instrument. SID-IM-SID will be illustrated and it will be shown that substructural information is provided, along with information on charge partitioning.

Abstract Text

Polyethylene terphthalate (Pe; overhead transparencies) can be exploited as the substrate for microfluidic devices with printer toner (T) used as adhesive to generate rotation-driven microdevices (RDMs) for a variety of analytical processes. We demonstrate that CD-like PeT microchips can be fabricated for fluidic transport controlled by centrifugal forces and valving by laser-printed hydrophobic valves. By simply using rotation speeds that generate enough centrifugal force, fluids could be mobilized through open channels and, at higher speeds, through hydrophobic valves. In a PeT RDM with two fluidic layers fabricated by laser ablating the microfeatures in the Pe sheet and then laminating using the toner for bonding, we show that a simple colorimetric protein assay can be carried out in an automated manner. In doing so, we highlight the ability to integrate a substantial number of fluidic control elements to achieve a basic diagnostic functionality (i.e., protein quantification). The functionality requires fluid metering, mixing, and aliquoting, and thus, represents an effective demonstration of fundamental operations required for a broad range of other applications. One of these involves cell counting via DNA quantitation based on the extent of magnetic bead aggregation as the optical signal. A bi-directional rotating magnetic field (RMF) was critical to effective magnetic actuation of the PeT RDM for multiplexed cell counting. Enumeration of white blood cells in the human blood samples was demonstrated with the RDM with reasonable accuracy for clinical applications (CV=10%). Fusing the cost-effective and versatile PeT RDM with a simple bi-RMF, we present a promising strategy for automation and multiplexing of limited blood count chemistries.

Abstract Text

In this talk I will focus on micro systems and automation tools to address questions in developmental neurobiology and immunology. We have developed a series of microfluidic systems that are fully automated to handle, image, and sort *C. elegans*, a nematode model system for many neuroscience studies. We combine this system with advanced computer vision and statistical techniques to identify and study genes involved in synapse formation. The advantages of this approach include not only the two orders of magnitude throughput improvement but also the ability to find mutants that were previously not possible to find. A second set of microfluidic systems that I will cover in this talk have applications in systems immunology. We take advantage of the ability to create and control sophisticated microenvironment that may vary in both time and space to study T cell signaling dynamics.

Abstract Text

Lipid enzymes such as sphingosine kinase (SK) play critical roles in regulating the function and behavior of cells and their dysregulation is known to be an important factor in a variety of diseases. SK is a crucial regulator of cell proliferation, survival, and differentiation implicated in diseases involving the immune system, including leukemia and autoimmune disease, and a number of compounds are in use or in clinical trials aimed at SK as a molecular target. The power of capillary electrophoresis for single-cell applications will be shown by direct measurements of SK activity in cells of patients with leukemia and in primary natural killer cells of healthy subjects. An automated microelectrophoresis system facilitated rapid separation and quantification of the phosphorylated and nonphosphorylated SK reporter as well other metabolic products of the SK pathway. Single-cell analysis rates of 4 cells/min enabled data collection on hundreds of cells to achieve statistically significant results. Measurements in primary peripheral blood mononuclear cells from patients with different forms of leukemia demonstrated significant intercellular and inter-patient SK heterogeneity as well as in the amounts of other metabolites formed. The variability in SK signaling has important implications for SK inhibitors as therapeutics for leukemia and demonstrates the value of single-cell analysis in characterizing the nature of oncogenic signaling in cancer. Similarly primary NK cells displayed a wide range of SK activity consistent with the very large numbers of NK-cell subclasses thought to be present in humans. Per cell quantification of signaling molecules can also be used to determine the effects of genetic perturbations or pharmaceutical inhibition on a cell-by-cell basis revealing cellular heterogeneity otherwise masked by traditional bulk assays.

Abstract Text

Peptides released from islets of Langerhans, such as insulin, glucagon, and islet amyloid polypeptide, help regulate blood glucose. In vivo, these peptide levels are known to oscillate with periods ranging from minutes to hours. These complex secretion patterns have been shown to have a positive effect on peripheral tissue function, and loss of these patterns are observed in people with diabetes and their relatives. Although these oscillatory signatures are of importance, the mechanisms underlying their development are still unknown.

We have developed several micro-analytical systems that can measure various aspects of the dynamics of islets of Langerhans. In this talk, a method we have developed to simultaneously measure multiple peptides secreted from islets of Langerhans with ~60 s temporal resolution will be shown. This system is being used to examine the oscillatory secretion of peptides from single and groups of islets and how they may interact to form in vivo oscillations. We will also describe a microfluidic device that can be used to mimic the in vivo interactions between the pancreas and peripheral tissues which can produce oscillations with similar time periods as those observed in vivo.

Abstract Text

Developing non-invasive blood-based tests is extremely appealing for presymptomatic screening and early detection of cancer where tissue biopsy is highly invasive and costly. Probing circulating exosomes is an emerging paradigm for cancer diagnosis and monitoring of treatment response. However, biology and clinical value of exosomes remain largely unknown, due in part to current technical challenges in rapid isolation, molecular classification and comprehensive analysis of exosomes. In this presentation, we will discuss on a microfluidic approach to streamline the exosome analysis pipeline via integrating immunoisolation and targeted proteomic analysis of exosomes. This method enables quantitative exosomal biomarker analysis directly from minimally invasive amount of plasma samples within ~100 min, with markedly improved detection sensitivity. We demonstrated phenotyping of exosome subpopulations by targeting common exosomal and tumor-specific markers and multiparameter analyses of intravesicular biomarkers in a selected subpopulation. We were able to assess the total expression and phosphorylation level of IGF-1R by probing circulating exosomes in non-small cell lung cancer patients, as a non-invasive alternative to conventional biopsy and immunohistochemistry. We foresee the microfluidic exosome analysis platform will form the basis of critically-needed infrastructure for advancing the biology and clinical utilization of exosomes.

Abstract Text

Primary hyperparathyroidism, a condition which can be debilitating or even fatal, is caused by the overproduction of parathyroid hormone (PTH) by one or more parathyroid glands. The increased PTH stimulates bone resorption, causing deleterious, elevated calcium concentrations in the blood. The standard of care is to remove the overproducing parathyroid gland as identified, if possible, with medical imaging and then determine whether additional glands need to be removed during the surgical procedure. Fortunately, PTH has a very short circulating half-life, and the removal of additional glands is conducted if the systemic level of PTH does not drop to less than 50% of the original levels after 10 minutes. While in some cases, the FDA-approved systems for PTH quantification can be operated proximally to the surgical suite, this service requires a dedicated technologist and is generally not available nationwide. Typically the immunoassays for PTH are performed in a central laboratory. Primarily due to transport times, the desired information may take over an hour to be returned to the surgeon following the removal of the primary gland. These long turnaround times cause undesirable risks and costs to the parties involved. This work aims to decrease the actual time-to-result in the clinical setting by generating a point-of-care diagnostic capable of being implemented in the workflow of the operating room. Herein, we describe the unique design requirements to achieve faster turnaround times in the operating room and present progress to date in developing a simple, portable diagnostic for PTH utilizing a fluorescent sandwich immunoassay.

Abstract Text

There is great enthusiasm in the microfluidics community for the development of “lab on a chip” systems for portable, point-of-care (POC) analysis. A major challenge in such applications is sample preparation—in particular, bridging the gap from the macro-scale of clinical specimens to the micro-scale of efficient fluidics/detection. The last decade has seen important advances in this area, but most systems today are either (a) very simple, with modest capability to integrate sophisticated sample processing protocols, or (b) require extensive off-chip ancillary equipment to operate (pumps, valves, tubes, interconnects, etc.). In this talk, I will present work towards an alternative scheme for POC analysis that relies on “digital microfluidics” (DMF). In DMF, droplets of sample and reagents are manipulated electrostatically on open devices (with no channels) bearing an array of electrodes covered with a hydrophobic insulator. DMF has the potential to address the challenges described above, allowing for sophisticated, multi-step sample processing on devices that operate with minimal external resources. I will highlight two different applications: on-chip immunoassays for diagnosing infectious diseases (including congenital rubella syndrome) and portable mass spectrometry-based quantitation of drugs of abuse for workplace testing. These examples and others suggest that digital microfluidics may be a useful new tool in the area of POC analysis.

Abstract Text

In 2010 the Medimate Multireader[®] was introduced by Floris et al. as the first electrophoresis based self-test for monitoring charged species, specifically to quantify lithium in finger-stick whole blood. Since its introduction, improvements have been realized in accuracy, precision, detection limit and reliability. This was achieved through improvements in temperature control, ease of use, connector stability, and the use of multiple injection and integrated data-analysis. Here the latest test results are presented for quantification of various species, most extensively for lithium for laboratory and home testing, but also creatinine, calcium and magnesium in whole blood and sodium in urine. By developing the method of repetitive measurement, using a single prefilled lab-chip cartridge, with alternating polarity, we furthermore became able to determine in our platform both positively and negatively charged species in one single run on one sample, a process we call cation and anion electrophoresis (CAE). Measurement results are presented for 7 different sample types. By using this method it positive and negative species can be measured in one analysis run, while it is anticipated that accuracy can be improved and that the dependency on an internal standard can be reduced. The improvements presented will bring the chip-based CE platform closer to point-of-care application.

Figure 1. Multireader CAE separation for serum. Right from the zero line a cation electropherogram, to be read from zero time left to right. Left from the zero line the anion electropherogram, to be read from right to left and with a resistance offset correction at zero time. Please note that these electropherograms are taken from one sample and one chip, by subsequent switching of the injection and separation voltages.

Abstract Text

Infectious pathogens often cause serious economic loss and public health concerns throughout the world. One important characteristic of infectious diseases is that they often occur in high-poverty regions, where people cannot afford expensive and bulky equipment. Although numerous polydimethylsiloxane (PDMS) and paper-based microfluidic devices have been developed to address this issue, PDMS/paper hybrid systems that take advantage of both substrates are rarely reported. Each device substrate has its own advantages and disadvantages. Herein, we have developed different low-cost PDMS/paper hybrid microfluidic systems that take advantage of both PDMS and paper substrates for rapid and sensitive infectious disease diagnosis, especially in low-resource settings. For instance, the novel use of the paper substrate used in a hybrid microfluidic system facilitated the integration of graphene oxide nanosensors on the chip for one-step food-borne pathogen detection, and avoided complicated surface treatment for nanosensor immobilization in a PDMS or glass-only microfluidic system. Additionally, paper was used in another PDMS/ paper hybrid microfluidic system integrated with loop-mediated DNA isothermal amplification (LAMP) for rapid and sensitive meningitis diagnosis, a global disease with high morbidity and mortality. The introduction of paper into the microfluidic device enables stable test results over a much longer period of time than a paper-free microfluidic system. Results can be observed by the naked eye. Although this hybrid system does not require expensive instruments, its sensitivity is even higher than conventional real-time PCR. Financial support from NIH, UT STARS Award, MRAP, IDR2 and URI award from UTEP is gratefully acknowledged.

Abstract Text

LAMP is an isothermal amplification technique that uses the BST polymerase and 6-8 primer sets to perform sensitive and specific amplification of DNA or RNA targets via strand displacement and rolling circle amplification. A billion copies of a target can be generated in one hour. Quantitative detection can be accomplished by densitometry (since MgPO₄ is a precipitant product of amplification) or by adding a DNA adduct dye and exposing to light. The reaction is far more robust to variations in temperature, time, and inhibitors than PCR. The reaction has been used as an established diagnostic tool for infectious disease pathogens, including HIV and SARS. To make LAMP even more sensitive and robust for resource poor or point-of-care settings, we describe the implementation of digital LAMP (dLAMP) in a SD (Self Digitization) chip that we have developed over the past several years. In dLAMP, the sample is divided into an array of small volumes such that each volume contains only one copy of the DNA or RNA molecule in the sample while the majority of the volumes contain no DNA molecules. Isothermal amplification of the array of volumes result in fluorescence (or another signal) only in the few small volumes that each contains a single copy of DNA. The DNA copy number is easily and accurately determined by simply counting the number of small volumes that contain a copy (i.e. fluorescent). We describe the advances we made to translate this SD platform for use in the low-resource and point-of-care setting.

Time: 08:35 AM

Room: 263

Co-Author(s)

Abstract Text

Degradation of paintings and other cultural heritage artifacts occurs through classical chemical reactions which depend on the chemical nature of materials and environmental conditions. However, the kinetics of these chemical reactions operates under extremely unusual conditions due to the condensed and structured materials in which they take place. This gives them an apparent chemical specificity which goes well beyond the much increased time constants. Such specific kinetic aspects and constraints are generally not taught in chemical courses though they are essential for preventing or restoring degradation.

This talk will focus on general issues concerned with the importance of these specific constraints based on classical chemical examples and, as much as possible, several illustrations taken from real artifacts deteriorations.

Abstract Text

Cadmium carbonate (CdCO_3) has been identified in the altered cadmium yellow (CdS) paints found Impressionist, early modernist, and post-Impressionist paintings. When it is concentrated at the surface of the paint layer, CdCO_3 appears to be a result of the photo-alteration of CdS . However, in other cases CdCO_3 is distributed throughout the paint layer. CdCO_3 is highly insoluble (K_{sp} of 1.0×10^{-12}) and would not be expected to migrate from the painting's surface. Plahter et al. have recently proposed that CdCO_3 is present in cadmium yellow paints as residue from the indirect wet process synthesis of CdS using CdCO_3 and Na_2S . To determine the role of CdCO_3 , as well as cadmium oxalates and sulfates, microspectroscopy and microdiffraction were carried out at ESRF ID21 and Petra III. X-ray fluorescence mode (XRF scanning) allowed precise mapping of elemental distribution, and Full Field X-ray Near-Edge Absorption Structure (FF-XANES) allowed mapping the chemical speciation of cadmium and sulfur. FF-XANES CdCO_3 distributions support Plahter's hypothesis for a 1906 work by Henri Matisse.

Yellow orpiment (As_2S_3) and red-orange realgar (As_4S_4) are arsenic sulfides that have been used as pigments since antiquity. Orpiment becomes paler and colourless upon exposure to light, while realgar turns bright yellow. The photo-oxidation process involves the conversion of orpiment to colorless arsenic trioxide (arsenolite, As_2O_3) and realgar is altered to pararealgar (As_4S_4 , an isomer of realgar), and then eventually to arsenic trioxide. This paper will present the μXANES identification of further degradation products of realgar, and their subsequent mobility in different paint systems.

Abstract Text

The study of Cultural Heritage materials requires advanced techniques to shed new lights on ancient technologies and help in their preservation. The implementation of new analytical tools, including mobile laboratories, allows a deep insight on the archaeological and artistic materials. We will show the performances of a new mobile XRF/XRD instrument we built to allow in situ characterization of the nature, the alteration and the mode of preparation of different pigments. The precious character of the most famous works of art and their uniqueness imply particular cautions and require instruments which may give the maximum of information directly on the artefacts, in-situ in the museums or in the archaeological sites.

Abstract Text

In paintings of individuals, artists often make large compositional paint changes such as recycling the canvas for a new portrait or making changes in the head and face of a sitter. Examples include Blue Period works by Picasso such as “Le Gourmet” (National Gallery of Art), which depicts a young boy but is painted over a Spanish woman wearing a mantilla. In this talk we will show the utility of combining information obtained from hyperspectral imaging using three modalities, reflectance (400 to 2500 nm), luminescence (500 to 1000 nm), and x-ray fluorescence (2 to 15 KeV) spectroscopies, to help understand the spatial features and pigments used in the earlier compositions. Case studies will include several Blue Period Picasso paintings and Fragonard’s “Young Girl Reading.” Finally, the use of reflectance imaging spectroscopy to develop a more advanced model of the optical properties of aged varnish will be discussed. These types of model have been used in the virtual cleaning of an Old Master painting in which the varnish layer degraded over time, causing an alteration to the appearance of the painting.

Abstract Text

A group of five paintings on canvas known as Mark Rothko's Harvard Murals (1962) has changed color due to the presence of a fugitive red pigment (Lithol Red) and excessive exposure to natural light in a room with large windows. This project explores the possibility of recreating the original color appearance by using a digital projector as illumination. A camera-projector system determines the characteristics of the painted surface and the projector's non-linear response. By comparison with a target image we calculate a corrective image that is projected onto the paintings recreating the original color appearance.

Restored Kodak Ektachrome photographs of the paintings in their original state from 1963 serve as a reference. These transparencies which have also faded over the last 50 years are scanned using narrow bandwidth light sources ensuring that the recorded optical densities are proportional to the photographic dye concentrations. The original color of the Ektachromes is then digitally reconstructed using a chemical fading model based on these dye concentrations.

With a camera-projector system we calculate the geometric mapping and the radiometric compensation. The geometric mapping yields the coordinate transformations between the projector, the camera, and the digital target image. Subsequently, the color mixing matrix and nonlinear projector response are calculated. With all parameters of the system known, we can calculate the compensation image pixel by pixel and project it with the correct registration onto the faded canvas.

This novel restoration technique uses colored light from a digital projector to compensate for color alteration. It recreates the original color appearance without physically changing the paint surface and is therefore completely reversible. Microfading tests insure that the paintings will not continue to fade as a result of this treatment. As a result, Mark Rothko's Harvard Murals can be viewed and experienced as in 1962.

Abstract Text

Most interesting properties of mid-IR quantum cascade lasers are their high spectral power density, continuous wave or pulsed operation with hundreds of kHz, as well as the coherent and polarized nature of the emitted light. This presentation will report on novel analytical applications ranging from environmental and industrial process monitoring including gases (H₂S, CS₂, NO, NO₂) and liquids (oil in water) to near field imaging. The latter application is based on photo expansion spectroscopy and employs pulsed QCLs and an atomic force microscope. Concerning each application the unique properties of the employed QCL are crucial for successful problem solving.

Abstract Text

The development and performance of materials with specific desired properties, such as strength, ductility, durability, resistance to fracture, opacity, conductance, etc., often depend on sub-micrometer-sized structural features. Understanding the chemical nature of these small features can potentially lead to more rapid convergence on formulation parameters and the efficient production of superior materials. Although surface characterization techniques such as atomic force microscopy (AFM) provide high resolution imagery of the topography of sub-micrometer-sized features, little chemical information is typically derived from these images. Infrared (IR) spectroscopy, on the other hand, is a well-established chemical characterization technique capable of identifying specific molecular components, including their polymorphic form, molecular orientation, and specific chemical environment. Unfortunately, conventional Fourier transform infrared (FT-IR) microspectroscopy instrumentation, does not provide this information at high enough spatial resolution, because it is limited by diffraction physics to be on the order of the wavelength of light used to make the measurement (3-10 micrometers). The recent development of near-field mid-IR spectroscopic approaches, which detect the IR spectral information at the small-diameter tip of an AFM, have improved the spatial resolution by about two orders of magnitude. Several examples are presented which demonstrate how this powerful nanoscale chemical characterization capability can help provide important understanding of how material component interactions relate to the ultimate properties of the material. Examples include polymer blends and composites, microdomain-forming polymer films, and oriented fibers.

Abstract Text

The use of label-free methods for imaging is rapidly emerging as an alternative to conventional labeling techniques. In particular, the use of spectroscopy to image molecular content is termed chemical imaging. We present first progress based on mid-infrared chemical imaging that combines the spatial specificity of optical microscopy with the molecular selectivity of vibrational absorption spectroscopy. Instead of directly imaging probes, recorded data are related to the structural and functional state of the biological material using computation. This process is actually not straightforward and requires a deep understanding of the underlying optical physics and light-matter interaction. An overview of the recently developed theoretical approaches is provided. A combination of theory, re-designed instrumentation and signal processing forms an integrated approach to biochemical analyses, especially for histopathology. Development of this technology will enable the rapid analysis of cells and tissue by fingerprinting the inherent biologic content, extraneous materials and metabolic state without the use of probes. In a variety of applications, we first describe attempts to diagnose and grade cancer in breast and prostate biopsies without human input. Results indicate that a rapid assessment of lesions is possible with high accuracy and their lethality may be predicted using a systems approach to pathology. Applied to engineered 3D tissue models for breast tumors, we show that the imaging technology is useful in rapidly assessing culture quality and that the model systems can act to inform researchers about the involvement of different cell types in cancer progression. Finally, we provide an overview of potential future directions and applications that will emerge from these studies.

Abstract Text

The critical role that two-dimensional (2D) correlation spectroscopy had played in designing and characterizing novel bio-based biodegradable plastics is described. In 2D correlation spectroscopy, a set of spectra defined by two independent variables, e.g., IR wavenumbers, is generated by applying a correlation analysis to spectral intensity changes induced by an external perturbation, such as mechanical deformation and change in temperature. Poly(3-hydroxyalkanoates) or PHAs are an interesting class of aliphatic polyesters found as granular intracellular inclusion bodies accumulated for energy storage by various microorganisms. Certain types of PHAs had been known for many decades, although their properties were rather limited to become a practical replacement for commodity plastics. Fortunately, 2D IR analysis of PHAs under mechanical perturbation provided a critical insight into the effective modification their molecular structure to overcome such shortcomings. More specifically, correlation peaks observed in 2D IR spectra indicated the surprising change in the local mobility of polymer chains even with a minor extension of some of the side groups of PHA. Although the improvement of the macroscopic properties at that level was still disappointingly modest, the result clearly suggested that further extension of side groups should result in achieving the dramatic improvement of properties. This discovery has led to the design and creation of a promising new class of PHA copolymers with excellent toughness and ductility, as well as a convenient range of thermal property for processing. The potential commercial utility of the newly developed bioplastics stimulated extensive studies including further 2D correlation spectroscopy analysis of such materials. Some of the interesting results obtained by the 2D spectroscopy study, such as sequential growth of different crystal structures, are presented.

Abstract Text

During the last few years, there has been an explosion of interest and activity in the field of plasmonics. The goal of plasmonics is to control and manipulate light on the nanometer length scale using the properties of the collective electronic excitations in noble metal films or nanoparticles, known as surface plasmons. An improved understanding of the interactions between adsorbed molecules and plasmonic nanostructures (i.e., molecular plasmonics) is having a significant impact in a number of research areas including electrochemistry, surface science, catalysis for energy conversion and storage, the materials science of nanoparticles, biomedical diagnostics, art conservation science, and nanolithography.

I will focus in on three recent advances in tip-enhanced Raman spectroscopy (TERS) which illustrate the power of this nanoscale vibrational spectroscopy. First, new insights into the nature of the relative intensity fluctuations in single molecule tip-enhanced Raman spectroscopy (SMTERS) will be discussed. Second, our current understanding of the adsorbate surface interactions involved in the low temperature (LT), ultrahigh vacuum (UHV) TERS of the Ag tip/Rhodamine 6G (R6G) /Ag(111) system will be described. Finally, an update on our new results in coupling ultrafast lasers with TERS. This last topic illuminates a path forward toward the goal of understanding chemistry at the space-time limit.

Abstract Text

Terahertz (THz) technology has recently emerged as a potential imaging modality for several applications. THz imaging can achieve a higher resolution than microwave frequencies while also providing greater penetration than optical techniques. Current THz sources are low-power and non-ionizing, making them safe for tissue characterization in biomedical, security and industrial applications.

The differentiation of cancerous tissue compared to normal tissue is of particular interest. Furthermore, unique characterization of the signals reflected from and transmitted through the tumor will allow for rapid differentiation of cancerous and normal tissue regions prior to clinical sectioning. This research aims to develop a THz reflection imaging methodology for in-depth scanning of three-dimensional tissue blocks through comparison with THz imaging of tissue sections and standard pathology assessment. Frozen tissue obtained using snap freezing liquid Nitrogen and formalin-fixed and paraffin-embedded (FFPE) of breast cancer tissue will be demonstrated in this work.

For the security application of THz technology, it is known that dangerous and illegal substances and objects can be concealed in ways that make them difficult to detect using traditional methods (metal detectors, millimeter wave scanners). Examples of these materials are narcotics, powder explosives, ceramic knives, or plastic Guns. For industrial applications, our goal is to investigate the nondestructive inspection capabilities of THz imaging for quality control of power electronic devices and to protect proprietary x-ray blocking scattering (XBS) coating material. We established collaborative work with two local hi-tech startup companies in Arkansas; the Arkansas Power Electronics International and the Space Photonics Inc.

Abstract Text

Since the ultra-fast terahertz (THz) pulse radiation and detection has demonstrated in the late 80's, many kinds of spectroscopy and imaging techniques have developed and are still progressing. In the past a few decades, many researchers have proved that THz spectral region is very attractive to industrial applications as well as fundamental science. In this symposium, we will present recent progresses of THz instruments and some industrial applications. We would say that significant technological breakthroughs in instrumentation that allow us to apply to industrial applications are miniature fiber coupled THz emitter/ detector and rapid THz wave sampling technology. The miniature fiber coupled THz emitter and detector give a flexibility and accessibility in measuring (or monitoring) the target materials flowing through production process. And the rapid THz wave sampling such as electronically controlled optical sampling technology opens the way to real time monitoring and high throughput testing. In recent years, for the sake of introducing of novel materials and production efficiency improvement, it is increasing the demand for new non-destructive testing solutions in various industries. THz technology is considered as one of the promising candidates for measuring thickness or material density of opaque materials. We will show some practical applications for pharmaceutical, semiconductor and other industries.

Abstract Text

Recent practical advancements in THz source, detector, and system technology have enabled researchers to explore a myriad of medical applications in both research and research laboratory and clinical settings. Due to the presence of water in physiological tissue the high THz absorption of water, and the relatively low absorption of non-water tissue constituents, reflective THz imaging is capable of producing high sensitivity surface tissue water content (TWC) maps with greater signal to clutter ratios than traditional medical imaging modalities. Variations in dielectric function due to TWC gradients have been measured in different tissue types and between cancerous and healthy tissues. These advantages coupled with the low, non-ionizing THz photon energy (0.4 - 40 meV) make THz imaging an ideal tool for in vivo imaging of skin burns, skin diseases, and corneal pathologies.

In this talk, a brief overview of the field is provided along with promising and emerging applications and ongoing research. THz electromagnetic models of tissue are presented that utilize Debye theory, effective media theory, and stratified media theory. These models are used to explore contrast mechanisms and predict imaging system performance. THz imaging system architectures are then discussed and tradeoffs are identified. A THz medical imaging system, operating at ~525 GHz center frequency with ~ 125 GHz of response normalized bandwidth is introduced and details regarding principles of operation are provided. Two promising medical applications of THz imaging are presented: skin burns and cornea. For burns, images of 2nd and 3rd degree burns were obtained in rat models in vivo over an 8 hour period. These images clearly show the formation and progression of edema in and around the burn wound area. For cornea, experimental data measuring the TWC of in vivo rabbit cornea are presented demonstrating utility in ophthalmologic applications.

Abstract Text

We introduce a new method for determination of drug binding using a previously underutilized terahertz frequency region. This frequency region corresponds to long range structural vibrations in proteins, which necessarily change with small molecule binding. Here we show dramatic changes in the vibrational spectra measured for the bench marking enzyme lysozyme and discuss applications to anti-tumor and anti-bacterial targets.

Abstract Text

Microdialysis is a sampling technique used to recover small molecules from the extracellular space of the brain for real-time chemical monitoring. Microdialysis has specifically been used to monitor the important neurotransmitter dopamine, and its involvement in drug addiction, behavior, and disease. However, inserting microdialysis probes into the brain damages the surrounding tissue, causing analytes to be collected from abnormal tissue. The extent to which this damage affects microdialysis recovery of dopamine is still completely understood. Coupling fast scan cyclic voltammetry with carbon fiber microelectrodes implanted near probes provides an in vivo calibration method to examine dopamine concentrations in the surrounding tissue. Previously we have found that inserting a probes into rat striatum diminishes stimulated dopamine responses at nearby microelectrodes. Stimulated responses can be restored by giving the dopamine uptake inhibitor nomifensine, proving that dopamine terminals survive near microdialysis probes. Dexamethasone, an anti-inflammatory steroid improves tissue health around microdialysis probes, by reducing the immune response to implantation, and protecting against ischemia and neuronal loss. Retrodialysis of dexamethasone also enhanced dopamine detection in brain tissue near microdialysis probes for 4 and 24 hours. Other drugs that target the immune response triggered by probe implantation may be useful in improving dopamine detection near probes in the brain, and further aid in our understanding of how probe induced tissue responses effect microdialysis recovery. This work was funded by the NIH (NS 081744).

Abstract Text

First introduced in 1966, the technique of microdialysis has been used for over four decades. Microdialysis has gained wide spread use for sampling and quantifying neurotransmitters in the brain. However, microdialysis has several disadvantages; it has poor temporal and spatial resolution and is considered an invasive technique. Profound consequences arise due to the impact of penetration trauma associated with the microdialysis probe; this is especially true with in vivo neurochemical measurements of dopamine (DA).

A prior study from our laboratory demonstrated the beneficial effects of retrodialysis of dexamethasone (DEX), a potent anti-inflammatory steroid, on the tissue penetration injury and DA concentrations in the tissue surrounding the probe during acute (4hrs) microdialysis experiments. Presently, we extended these findings to microdialysis experiments lasting 24 hrs. We used immunohistochemistry and fluorescence microscopy to compare, DA axons and terminals (TH) and dopamine transporters (DAT) near probes perfused with aCSF and DEX for 24 hrs. There were no significant differences in the TH and DAT labeling near the probe track. Since DA terminals in the striatum express both TH and DAT, the impact of microdialysis probes on their colocalization was determined using both Pearson's Correlation Coefficient and Manders' Overlay Coefficient. Overall, the probes had little effect on the correlation of TH and DAT labeling in the nearby tissue. We report here for the first time, that DEX serves to protect and stabilize the activity of the DA terminals near the probes, rather than increasing the number of surviving terminals during probe implantation at 24 hrs.

Abstract Text

As interest in developing [*Drosophila melanogaster*] as a model for human neurological diseases continues to grow, characterization of the neurotransmitter content of flies becomes increasingly important. In addition to dopamine and serotonin, [*D. melanogaster*] has invertebrate specific neurotransmitters, tyramine and octopamine, which fulfill similar roles to epinephrine and norepinephrine. In order to better understand the differences in tissue content of neurotransmitters between different developmental stages and different strains of flies, fast and sensitive methods for separation and detection of neurotransmitters in brain samples are necessary.

In order to quantify the neurotransmitter content of [*D. melanogaster*] brains, our lab has developed capillary electrophoresis coupled to fast scan cyclic voltammetry (CE-FSCV). Using Canton S flies, tissue content of four neurotransmitters were determined across larva, pupa, and adult life stages. Separations of tyramine, serotonin, octopamine, and dopamine were achieved in under 10 minutes, and limits of detection were 9 ± 1 nM for tyramine, 3.0 ± 0.5 nM for serotonin, 12 ± 8 nM for octopamine, and 3 ± 1 nM for dopamine (n=4). Differences in tissue content between the different life stages were most obvious in the pupa, where tyramine levels were highest and octopamine levels were lowest compared to both larva and adults. In addition to developmental differences, we compare the adult tissue content of Canton S flies to w¹¹¹⁸ flies. This comparison is important, as we have observed differences in tissue content of octopamine between wild type strains Canton S and Oregon R. Dopamine levels in w¹¹¹⁸ flies are reduced relative to wild type flies and w¹¹¹⁸ flies also differ to a smaller extent in their tissue content of serotonin.

Abstract Text

Glucose provides the major energy source to the brain. As such, real-time molecular detection of glucose dynamics is imperative to understanding the regulation of brain energy utilization and its involvement in neuropathological disorders such as diabetes, as well as the molecular adaptations that occur upon exposure to substances of abuse. However, to date, existing methods for detecting brain glucose are limited in terms of temporal and spatial resolution. We have addressed this need by coupling our novel glucose oxidase-modified carbon-fiber microelectrode biosensors with fast scan cyclic voltammetry. With this approach, we can detect subsecond fluctuations of glucose with unprecedented selectivity and sensitivity, as well as high temporal and spatial resolution. Optimization of the voltammetric waveform has enabled simultaneous detection of glucose and dopamine at a single recording site. Future work will utilize these microbiosensors to provide insight into the molecular adaptations that occur in diabetes and after exposure to drugs of abuse. We acknowledge the National Science Foundation for their generous funding contributions on this project.

Abstract Text

Parkinson's disease (PD) is a neurodegenerative disease that affects 1 million people in the United States alone. Despite wide research into the relief of the motor symptoms of PD, its non-motor symptoms like depression are largely unstudied. This is mainly due to the poor understanding of the effects of PD on neuromodulators other than dopamine. Histamine and serotonin are two important neuromodulators in PD, linked to many of its non-motor symptoms. To more clearly understand the actions of serotonin and histamine in PD, it is first crucial to understand how they modulate each other in different brain regions. In this work, we do this with fast scan cyclic voltammetry (FSCV) by simultaneously measuring serotonin and histamine with a single carbon fiber microelectrode (CFM). These measurements, combined with pharmacological manipulations enable us to perform a mathematical analysis on the extent, direction and magnitude serotonin/histamine modulation. We plan on taking our studies further and studying serotonin/histamine modulation in PD mouse models.

Abstract Text

Trace level peptide measurements are important for biomarker and biological investigations. Such studies can be performed using microdialysis with immunoassay detection. However, immunoassays often lack sequence specificity and may require large sample volumes (>25 [micro]l). Here we describe advances in capillary liquid chromatography and multi-stage mass spectrometry (cLC-MSⁿ) for measurements of attomole quantities of neuropeptides from low volume microdialysis samples.

To generate robust analyses, we utilized independent high and low pressure LC systems and two 6-port valves to engage loading/desalting and elution on a single 50 [micro]m i.d. reverse-phase column. The LC system is interfaced via a detachable emitter tip to a linear ion trap mass spectrometer (Thermo LTQ-XL). Initial results demonstrated high limits of detection (LOD) due to sample loss to tubing. To overcome this loss we optimized the addition of acetonitrile to samples and achieved sub-pM LOD for 5[micro]L samples (<5 amol) for multiple neuropeptides.

We applied this cLC-MSⁿ technique to measure neuropeptide release following selective activation of specific neuronal populations. We investigated hypothalamic neuronal circuitry with DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) and observed dynamic release of neurotensin and orexin A. We investigated nucleus accumbens (NAc) circuitry using optogenetics and measured concurrent NAc dynorphin release. These findings validate this cLC-MSⁿ technique for [i]in vivo[/i] neuropeptide studies and represent the first measurements of dynamic neuropeptide release with selective neuronal activation methods.

Abstract Text

Spreading depolarization (SD), a spontaneous phenomenon linked to the development of secondary brain injury, is characterized by transient increase of extracellular potassium (K^{+}). In order to recover, the excess K^{+} needs to be cleared and the ionic balance restored. This process is extremely energy-demanding. Repeated episodes of SD in the human injured brains have been shown to create a net energy deficit, the neighboring tissue becoming non-viable, hence resulting in secondary brain damage [1,2].

We are interested in the real-time neurochemical quantification of SD in the injured human brains using online microdialysis. To handle the small sample volume from clinical microdialysis, we have developed a microfluidic flow cell capable of resolving dynamic metabolic and chemical changes during these depolarization events [3]. The flow cell is fabricated on poly(dimethylsiloxane) (PDMS) by soft lithography and consists of an analysis chamber housing the biosensors and K^{+} ion-selective electrodes. The system is used to monitor patients in surgery and in the intensive care unit. Lastly, a required feature for clinical instrumentation is self-calibration – an automated calibration system is also developed to track the performance of the sensors over time.

Abstract Text

Microdialysis is a powerful separation technique capable of monitoring the concentration changes of multiple analytes in the extracellular fluid of the brain. This technique generates small sample volumes in a continuous flow stream. Traditional (LC) methods used for sample analysis forfeit temporal information regarding dynamic processes due to the larger volumes necessary for analysis. Additionally, sample acquisition methods traditionally involve some form of tethering or anesthetizing the animal under study, greatly reducing the available behavioral information. In order to preserve both temporal resolution and behavioral information, the ideal analysis system is one that can be employed on-line, has fast analysis times of small sample volumes, and can be placed on a freely-roaming animal. In this study, we present an approach for coupling microdialysis sampling to microchip electrophoresis and electrochemical detection at a carbon electrode for monitoring neurochemicals in the dopamine metabolic pathway. The device is comprised of a double T PDMS/glass hybrid microchip with detection at two pyrolyzed photoresist film carbon electrodes in series, and was used to separate five analytes in the dopamine metabolic pathway in under 100 s. The developed method was used to monitor the dopamine metabolic pathway in vivo in both rat and sheep after the administration of L-DOPA. The complete device and associated instrumentation can be used remotely and on-animal, for near-real time in vivo monitoring.

Abstract Text

Surfaces and interfaces may exhibit spatial heterogeneity for many reasons, including chemical or structural inhomogeneity, or topographical effects. We have developed an approach to obtain spatial maps of these heterogeneities based on the premise that “probe” molecules exhibit varied interfacial dynamic behavior that is distinctively related to the local chemistry and topology. For example, the characteristic adsorption rate, surface residence time, and local molecular mobility (i.e. surface diffusion coefficient) are often exquisitely sensitive to the details of the local surface environment.

By choosing an appropriate probe molecule (or more than one molecule) and accumulating large numbers of molecular trajectories (generally several million are analyzed), the dynamic molecular behavior can be spatially partitioned and used to prepare spatial maps. The contrast mechanisms of these maps consist of absolute dynamic properties that can be directly compared to homogeneous surfaces that are prepared as calibration samples. A statistical multi-dimensional analysis then allows us to associate the local chemistry of a mixed surface to an appropriate calibration surface chemistry or mixture.

Having identified chemically- or physically-distinct surface regions, the behavior of molecules of interest can be partitioned by region. For example, the surface residence time of proteins can be measured simultaneously on crystalline and amorphous regions of polymer surfaces. Also, anomalously strong binding sites can be identified on filtration membrane materials or chromatographic media, and the influence of these sites on fouling and/or separation efficiency can be determined.

Abstract Text

The development of surface coatings for advanced materials technologies usually requires that a large number of samples be prepared and individually tested to find the few that are best suited for a particular application. An alternative to this often-tedious process is to produce a chemical gradient in which the material composition varies along a single sample. Ideally, each gradient would exhibit gradual, monotonic compositional and properties variations extending from the macroscale down to molecule levels. In reality, they are usually much more complex. Unexpected properties variations appear on a wide range of length scales due to, for example, the spontaneous separation of the gradient components during film preparation. We seek to better understand the nanoscale-to-macroscale chemical and physical complexities of thin-film gradients prepared from organosilane precursors. These gradients are being prepared by both dip-coating and vapor-phase deposition methods. They have potential applications as new materials for chemical catalysis, chemical separations, tribology and tissue engineering. Optical single molecule (super-resolution) detection, spectroscopy and tracking are employed in their characterization. Single molecule tracking studies performed by wide-field video microscopy are used to assess the extent to which probe molecules adsorb to the film surface and to quantify the rates at which they diffuse through the films and across their surfaces under different ambient conditions, as a function of position along the gradient. Spectroscopic single molecule tracking methods are also implemented with the solvatochromic dye Nile Red to determine the local dielectric constant of the films.

Abstract Text

Membrane transport plays vital roles in cellular functions. To better understand real-time transformation of cellular membrane of live cells and their molecular mechanisms, we have developed far-field photostable-optical-nanoscopy (PHOTON) and used it to characterize the dependence of membrane transport dynamics upon the size, charge and chemical properties of substrates (nanoparticles) in single live cells in real-time at single-molecule (SM) and nanometer (nm) resolutions. PHOTON includes photostable single nanoparticle imaging probes, single nanoparticle plasmonic microscopy and spectroscopy. The updated results and applications will be presented. The work is supported in part by NSF (CBET 0507036) and NIH (R01 GM0764401; 3R01 GM076440-04S1).

Abstract Text

Receptors are key components of the cell membrane for coordinating the passage of signals into and out of cells. Diffusion is an important mechanism for this function. We are elucidating the role of diffusion in the function of two receptors: integrins and receptor for advanced glycation end products using fluorescence recovery after photobleaching (FRAP), single particle tracking (SPT) with ligand-labeled quantum dots, and stimulated emission depletion imaging (STED). The role of post-translational modification and ligand structure in altering receptor diffusion is discussed. Among our interesting findings, the covalent attachment of palmitic acid on cysteine residues decreases the mobility of alphaPS2CbetaPS integrins as measured by FRAP and SPT. Additionally, the size of domains of confined diffusion increases after blocking a reported palmitoylation site. STED imaging is a subdiffraction technique that enables the organization of the cell membrane to be measured with 40-nm spatial resolution. The correlation between the cell membrane composition and the actin cytoskeleton is measured using STED imaging. Our work provides vital information on the molecular mechanism of receptor function through altered dynamics and membrane organization. This work is funded by the National Science Foundation (CHE-0845236 and CHE- 1412084).

Abstract Text

We have been exploring the electric fields that arise when nanoparticles interact with other metal surfaces and nanoparticles. The resulting electric fields enable chemical sensitive detection, an effect commonly known as surface enhanced Raman scattering (SERS). Here we will discuss the direct determination of electric fields using nitriles as vibrational Stark probes. Using tip-enhanced Raman scattering (TERS) we can control the interaction between structures and enable high-sensitivity chemical analysis. For example, The resulting electric fields have been shown to enable chemical selective studies on cellular membranes. We have selectively detected integrin $\alpha_3\beta_1$ in the membrane of a cultured cell by binding an RGD-functionalized nanoparticle to the integrin and detecting the interaction via TERS. This approach appears to overcome challenges common to TERS imaging, specifically locating the protein on the vast membrane landscape and discriminating the protein of interest from the surrounding biomolecules. Fundamental studies of the electric fields around plasmonic particles are enabling new possibilities in chemical analysis.

Abstract Text

Reversed-phase liquid chromatography is a widely used technique for separation of analytes in both research and applied settings. The stationary phase material usually consists of micron-sized, mesoporous silica particles functionalized with n-alkane ligands. Understanding the timescales at which analyte molecules are transported through the interior of the particle as well as adsorbed and desorbed from the particle surface is of fundamental importance in the development of more efficient chromatographic materials. The majority of the surface area in these mesoporous silica materials is contained within the particle, making it difficult to observe these processes directly. Intra-particle transport kinetics have generally been inferred from chromatographic retention data. Spectroscopic techniques can provide evidence of dynamics at reversed-phase chromatographic interfaces, but these have generally been conducted at model, planar silica surfaces. In this talk, imaging-fluorescence correlation spectroscopy is used to probe transport of the amphiphilic fluorescent probe molecule, 1'-dioctadecyl-3,3,3'-tetramethylindocarbocyanine perchlorate (DiI), within actual RPLC porous silica particles. Measured parameters are compared with those determined on C18-modified glass coverslips used as planar analogs of RPLC surfaces. Molecular transport within the particles is dominated by surface diffusion due to the high retention conditions. Surface diffusion appears slower within the particle as molecules diffuse along the contours of the interior surface of the particles. The 3-dimensional intraparticle surface diffusion, however, is projected onto a 2-dimensional image, thus the measured transport parameters are not directly comparable to those measured on planar model surfaces. We present an analysis to compensate for the change in dimensionality between porous particles and planar surface to facilitate the comparison of measured parameters in both systems.

Abstract Text

We track three-dimensional (3D) trajectories of negatively charged nanoparticles being retained near negatively charged glass surface using astigmatism-based 3D super-localization fluorescence microscopy. We show that retention of nanoparticles by the surface can happen at the long distance without significant contribution from adsorption. That is, these particles can be trapped in potential energy minima several tens to hundreds of nanometers from the surface by long-range interactions between the particle-surface attractive site(s) and particle-surface. Trapping center, both attractive and repulsive. The trapped particle diffuses actively in the potential energy well with a lateral size on the order of magnitude of 1 micrometer squared before being immobilized on surface or diffusing away. This view may shed new light on how biomolecules/nanoparticles interact with a solid or semi-fluidic membrane surface. All data is analyzed by NIH ImageJ and Matlab.

Abstract Text

Preeclampsia (PE), a pregnancy-related disorder, is characterized by hypertension and proteinuria. Currently, PE cannot be predicted. There would be value in having serum biomarkers able, early in a pregnancy, to identify women at substantial risk for PE. Known PE biochemical abnormalities likely alter the lipid profile of individuals at risk of PE. Therefore, a novel, serum lipidomic analysis of sera from early gestationally-aged pregnant women was undertaken to find useful predictive PE biomarkers. Sera obtained at 12-14 weeks pregnancy from 29 asymptomatic PE cases and 28 controls were processed by hexane/isopropanol extraction (3:2). Direct infusion of organic phase to electrospray-ionization-time-of-flight mass spectrometry (ESI-TOF-MS) was performed followed by analysis of MS data. Peaks having statistically significant quantitative differences ($p < 0.05$) were considered candidate biomarkers. Fragmentation studies to characterize candidate markers using collisionally-induced dissociation are underway. To substantiate utility of candidates, a blinded set of 46 PE cases and 46 controls have been processed and submitted to ESI-TOF-MS. Analysis has uncovered 60 statistically significant serum lipid markers comparing control sera (uncomplicated pregnancies) to sera from cases who developed PE 3-5 months later. The most statistically different serum lipid biomarkers with m/z and p -values are listed in Table 1. Some lipids have been tentatively classified based on LipidMaps (Table 2). Studies to identify the rest of the candidates and evaluate the detected markers blindly are underway. This serum lipidomic approach found several promising predictive serum markers for later PE in pregnant women at 12-14 weeks gestation.

Abstract Text

A heart attack can occur when coronary arteries become blocked due to coronary artery disease (CAD). After a heart attack, scar tissue forms in the damaged muscle. The remaining heart muscle works harder to pump blood through the body. In humans this "scar" tissue remains and can not be repaired. In contrast the Zebra Fish has the ability to regenerate the effected heart muscle and remove the scar. An complete understanding of the biology process may lead to a new approach to treatments for human in the future. To investigate the biochemistry behind this repair in fish three groups of Zebra fish (heart operation, sham operation and controls) were analysed by proteomics, metabolomics and lipidomics methodology. Due to the low sample volume an common platform micro-LC accurate mass MS/MS approach was employed for all of the analysis. The resulting data was processing separately via a multivariate statistical approach using PCA, OPLSDA etc. The proteomics data was subjected to a multi data base search to identify proteins involved in up-regulated pathways. The resulting data showed clear differentiation between the three groups of samples. With the metabolism and protein data being combined to identify upregulated biochemical pathways specific to fish biochemistry

Abstract Text

Preeclampsia (PE) is a potentially fatal complication of pregnancy whose cause is poorly understood. There are no disease-changing therapies except delivering the placenta. There are several proposed theories for PE but none has been proved. The aim here is to expose normal human placental explants to conditions proposed to be causal in PE, and study changes in the LMW proteome for each condition using cLC/QToF. The results will be compared to PE placenta analyzed by the same proteomic approach to determine which alterations are found in actual PE placenta, thus confirming involved pathway(s). To simulate PE conditions, in vitro, placenta were collected (n=12) from uncomplicated, elective C-sections. Each explant was exposed to a hypothesized PE condition. Control explants from the same placenta were cultured for the same time, 48 hr, in a normoxic environment. Each explant was homogenized and acetonitrile precipitation was performed to remove abundant, high molecular weight proteins. A defined amount of protein-depleted sample was injected onto the cLC/MS for analysis. MS spectra for each treatment and controls were compared visually and potential differences evaluated statistically. Data analysis is still underway but 62 markers having significant differences between placental explants incubated under normoxic versus hypoxic conditions have been found. One of these markers was identified as a fragment of hCG. Other provocations including inflammatory cytokines and hydrogen peroxide are just being evaluated but biomarkers have been found. This is the first global proteomic study of less abundant, LMW peptides in human placental tissue probing features of PE.

Abstract Text

In children, non-invasive breath analysis is attractive, since invasive methods such as biopsies or repeated blood collection cause increased risks. Some of the 800 substances detected in human breath have already been described as potential biomarkers of physiological and pathological processes. Direct mass spectrometric techniques, such as proton-transfer-reaction time-of-flight mass spectrometry (PTR-ToF-MS) allow direct and time-resolved analysis of substances in the ppbV to pptV range.

In this study, breath gas of pediatric patients with renal diseases (n = 60), such as haemolytic uremic syndrome or kidney dysplasia, and healthy pediatric controls (n = 60) was analyzed by means of PTR-ToF-MS. Alveolar phases of exhalation were identified through breath resolved MS analysis.

More than 100 VOCs were detected in the breath of nephrological patients and controls. Data were analyzed by means of PCA and subsequent statistical testing. Isoprene concentrations were higher in nephrological patients (105 ppb vs 72 ppb) potentially reflecting hemolysis in kidney disease. Median pentanal and 2-butanone concentrations were elevated in nephrological patients (10.0 ppb vs 5.8 ppb and 0.99 vs 0.59, respectively) mirroring increased oxidative activity in renal disease. Concentrations of exogenous toluene were significantly higher in nephrological patients (1.8 ppb vs 1.1 ppb) probably indicating contact with medical equipment. In contrast, gender did not make any difference.

Breath biomarkers indicate differences between nephrologically ill and healthy children. Non-invasive breath tests may help to understand basic mechanism of the disease and in a perspective allow monitoring and tailoring therapy in pediatric patients.

Abstract Text

Hookah smoking has been popular in the Middle East and surrounding regions for ages and its use is emerging rapidly in Western cultures making it imperative to study various aspects that may result in harm to the smoker, such as toxic trace metals, PAHs, etc. Many studies have been performed on cigarette, cigar, and pipe tobaccos while virtually no studies for these toxins have been performed on hookah tobacco. It is well documented the other tobaccos are known to contain toxic metals such as As, Cd, Cr, and Pb. However, little is known about the metal content in hookah tobacco formulations (e.g. tobacco, glycerin, honey and flavorings). Charcoal, the heat/combustion source in hookah smoking is far different than burning cigarettes and cigars. Experiments show that some charcoal brands may have as high as 10 µg/g of arsenic, making an in depth study on charcoal imperative to assess not only total metals, but metal speciation (forms), particularly for toxic metals.

Microwave assisted digestion in combination with ICP-MS was utilized to elucidate the toxic metal content in both charcoal samples and in an array of different brands/flavors of hookah tobacco smoke. Polycyclic aromatic hydrocarbons were extracted from hookah tobacco smoke using an organic solvent and analyzed by HPLC fluorescence detection. While the Arsenic totals are thought to be unacceptably high, clearly we must investigate which forms of Arsenic are present. Hence, a speciation study was undertaken to assess which inorganic or organoarsenicals are present in the neat charcoal.

Abstract Text

Lung is often the only site of spread from malignancies such as sarcomas and colorectal carcinomas. Local high dose chemotherapy is a very attractive strategy to target therapies at the tumor site while avoiding undesirable systemic side effects of the drugs. Techniques of isolated in vivo lung perfusion (IVLP) were already shown to fulfil the expectations, however, dosing regimen and time of chemotherapy delivery should be carefully optimized to avoid local toxicity and ensure effective treatment in the same time. The main analytical challenge related to such clinical study is lack of the tool permitting non/low invasive monitoring the concentration of administered chemotherapeutics over the time of IVLP as well as distribution of the drug in the lungs with no harm to the organ. Currently available sample preparation methods for tissue analysis are mainly based on the biopsy and therefore are too invasive to be used repetitively over the period of IVLP treatment. Moreover, as the biopsy is taken from the edge of the lungs this may not reflect level of the drug inside the lobes with the course of IVLP.

In vivo solid phase microextraction (SPME) addresses the abovementioned issues. In this work we used in vivo and in situ SPME for determination of concentration of the chemotherapeutic agent in lung of living pigs and in human lungs obtained from the deceased donors, during IVLP treatment. This results showed feasibility of the method to provide fully quantitative data with good spatial and temporal resolution for the given clinical setup. The optimized method was successfully validated according to FDA guidelines as well as compared with liquid-liquid extraction results. The data showed differences in concentration profiles of DXR after administration of three different doses of the drug as well as differences in drug level in different lobes of the lungs.

Abstract Text

Assessing human exposure to chemical warfare agents remains challenging due to low exposure concentrations and complex biomedical sample matrices. We are developing sensitive methods to detect exposure to organophosphorus nerve agents by analyzing blood samples for persistent protein adduct biomarkers. Detection of nerve agent exposure is critical for forensic investigations of alleged use and confirming the identity of the agent(s) used.

Advanced sample preparation procedures and mass spectrometric measurements were used to detect in vitro exposures of human blood, plasma, and serum to the nerve agents sarin (GB), soman (GD), and VX. Butyrylcholinesterase (BuChE) is a freely circulating blood protein that is inhibited by nerve agents, making it a useful analytical biomarker for retrospective assessment of exposure. Sample preparation employed immunomagnetic separation to isolate BuChE from the plasma/serum matrix. The purified BuChE was then enzymatically digested into peptides using pepsin, which yielded nine amino acid peptides (nonapeptides) that are specific for the BuChE adduction site. Each nerve agent-nonapeptide adduct has a unique chemical structure that was separated and specifically detected using high-performance liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS). Method detection limits were sensitive enough to monitor realistic exposure levels, and nerve agent-BuChE adducts were stable at 4 C for at least 26 days. Various plasma anticoagulants were also investigated to determine the effect on nerve agent exposure detection using this method. Detection of persistent protein adduct biomarkers is a promising approach for assessing nerve agent exposure in human biomedical samples.

Abstract Text

Breath VOC biomarkers (BVOCs) hold promise as noninvasive diagnostic tools of the future. Concentration of BVOCs may depend not only on biochemical or pathologic processes but also on physiological maneuvers. As breath sampling may be done in different body positions, we investigated the effect of the sampling position onto BVOC concentrations by means of real-time mass spectrometry.

An online PTR-ToF-MS was used in 15 healthy subjects for breath resolved measurements with parallel monitoring of hemodynamic parameters and pET-CO₂. Paced breathing (12/min) for a total of 8 minutes in a series of different body positions (sitting, standing, lying and sitting again) was applied. Each position was held for two minutes. PTR-ToF-MS 8000 in a continuous side stream mode (sampling flow: 20ml/min, time resolution: 200ms) was used. VOCs were quantified in inspired and alveolar air by means of a custom made data processing algorithm.

Normalized mean concentrations of isoprene, furan and acetonitrile decreased by 24%, 26% and 9%, respectively, during standing and increased by 63%, 36% and 10% during lying mirroring time profiles of stroke volume and pET-CO₂. In contrast, acetone, benzene (exogenous) and H₂S (originating from oral bacteria) concentrations remained almost constant. During analysis in the final sitting position, all concentrations returned to initial values.

Exhaled blood borne BVOC concentrations changed due to body postures. Changes depended on cardiac stroke volume, on origin and physico-chemical properties of the substances. Patients' positions and cardiac output have to be controlled when concentrations of breath VOCs are to be interpreted in terms of biomarkers.

Abstract Text

The objective of this project is to develop a method for enhancing identification and quantitation of amino acids in human tears using capillary electrophoresis with LED induced fluorescence (CE-LIF). Abnormal concentration of amino acids in tears could be an indicator of eye disorders. While there are literature references of amino acids analysis via liquid chromatography coupled with mass spectrometry, CE-LIF is a much more affordable technique, and more appropriate for nanoliters tear volumes available. However, the separation of various amino acids from human tears is problematic due to complexity of tear film matrix that has specific pH, salinity, and interfering components like proteins, peptides, and lipids. A sample preparation method in our lab has been developed for sampling and derivatizing tears using solid cotton thread supports, sequential elution and CE-LIF analysis. Previous work showed most tear amino acids peaks are poorly resolved, clustered together near a dominant taurine peak and below the limit of detection of CE. In this work various sample preparation and separation procedures were studied to improve resolution and detection efficiency of the clustered amino acids. Elution of amino acids was optimized with phosphate buffer of various concentrations, pH, and elution volume portions to adjust sample salinity and recovery. To enhance CE separation, pure organic solvents and organic-aqueous binary mixtures of borate buffers with methanol, ethanol, acetone, acetonitrile, DMSO were studied. Elution recovery and subsequent signal/noise was improved using a 5 step elution procedure. Standard amino acids clustered in previous work including alanine, taurine, glycine were successfully resolved at resolutions ≥ 1.7 and with a 35-45% DMSO containing, 10-20 mM borate run buffer. Real tear samples show at least five amino acids formerly clustered near a dominant taurine peak to be resolved with a resolution ≥ 1.5 and with a signal/noise above three during a separation time of under fifteen minutes. The improved determination of tear amino acid content in tears with CE-LIF underscores the utility of the use of a thread collection method and this technique could become an affordable means for diagnosis of eye health.

Abstract Text

Glutathione (GSH) is a major antioxidant in all animal systems. Cysteine (cys) is a precursor to GSH that plays a strong role in regulating oxidative stress in any system. Detection of these molecules usually involves a chemical reaction with free sulfhydryl functionality and is complicated by disulfide bond formation and separation of individual thiols from a chemically complex matrix. In this study, a method was developed to measure concentrations of thiols in the reduced/monomer and oxidized/disulfide forms along with glutamate, in a 20 nL hemolymph volume from a single adult *D. melanogaster* by CE-LIF. Collection was performed using previously described methods using a capillary to collect exuded hemolymph via capillary action. Defined 10mm lengths of 50/360 I.D./O.D. fused silica capillaries were utilized to quickly and easily handle nL samples. Sample preparation involved defined capillaries to meter appropriate nL volumes of reagents including: a thiol specific labelling agent, monobromobimane (mBBR), a disulfide bond reducer, tris-2-carboxyethyl-phosphine (TCEP), and a primary amine tag, fluorescamine for glutamate content.

Capillary electrophoresis separations were performed following each reagent addition. First, derivitization with mBBR was performed to obtain free thiol concentrations. The second CE separation following the addition of TCEP generated total thiol concentrations. Lastly, derivitization of primary amines was accomplished by the addition of fluorescamine. With this assay, we were able to quantify hemolymph monomer and dimer forms of GSH and cys, plus, glutamate. *D. melanogaster* wild-type and cystine-glutamate transporter mutant were studied with this method. Wild-type males exhibited 82.4% higher cystine levels and 59.1% higher glutamate levels when compared to mutant males. This method was also applied under oxidative stress conditions. No statistical differences for GSSG were seen for males or females under either conditions. Wild-type females under oxidative stress had the largest levels of GSH which were 34.2% higher than male controls and 69.5% higher than female mutants. This is a method that allows us to explore thiol concentrations in a biological model and can be applied to any system for oxidized and reduced forms of thiols.

Abstract Text

Among the methods applied to peptide analyses, capillary electrophoresis (CE) provides high separation efficiency and low cost. The driving force of capillary electrophoresis is electroosmotic flow (EOF), which may be affected by many factors related to the capillary surface chemistry. As a result, very often, CE separation of peptides suffers from the adsorption of analytes on the negatively charged capillary wall, leading to poor analysis reproducibility and poor separation resolution. The goal of this research is to achieve an efficient electrophoretic separation of peptides in an aqueous solution. Our first step was to stabilize and modify EOF making it suitable for peptide separation. Three different cationic additives, including hexadecyltrimethylammonium bromide (HTAB), cetylpyridinium chloride (CPC), and triethanolamine (TRI), were dynamically coated onto the capillary wall, resulting in a reversed EOF due to the nature of cationic molecules. Electrophoretic separation was performed using a 52 cm capillary, a 20mM sodium phosphate buffer, and at 200-300 nm detection wavelength. Preliminary data show that 0.5mM HTAB, 0.5 mM CPC, and 4% (w/v) TRI enhance the separation of Caffeine and Benzoic Acid at pH 6-10. Separation was absent at pH 3 and poor at pH 4-5. The results of peptide CE separation using cationic additives will be presented, as well.

Abstract Text

Gamma-aminobutyric acid (GABA) is hypothesized to play a critical role in the viability of islets of Langerhans, the endocrine portion of the pancreas. It is also thought to play a paracrine role in controlling insulin release from human islets, helping control glucose homeostasis. However, the secretion profile of GABA and other amino acids from human islets remains unclear. The objective of this project is to monitor GABA and other amino acids secreted from human islets in a time-resolved manner.

Amino acids and an internal standard, D-Norvaline, were derivatized with naphthalene-2,3-dicarboxaldehyde and separated and detected on a commercial capillary electrophoresis (CE)-laser induced fluorescence system. Derivatization conditions in the presence of the high salt buffer that islets are held in were optimized, including temperature and derivatization time. Ideal conditions were found at 25 [degree]C and 10 min. The CE separation was also optimized for resolution of the largest number of amino acids and optimal conditions were found on a 25 μ m i.d., 50 cm long capillary with a separation voltage and temperature of 29 kV and 25 [degree]C, respectively. Under optimized conditions, 13 amino acids were quantifiable with limits of detections between 1-10 nM. Using the internal standard, the %RSD of the peak area ratios were between 8-12%.

Amino acids were successfully quantified from islet secretions with this method. As the glucose concentration increased from 3 to 20 mM, GABA secretion reduced from 1.9 pg islet⁻¹ min⁻¹ to 1.0 pg islet⁻¹ min⁻¹. In the future, this method will be used to produce time-resolved secretion profiles of amino acid release from human islets of Langerhans.

This work was funded in part by NIH Grant DK080714.

Abstract Text

Micro free-flow electrophoresis ([micro]FFE) is a separation technique that holds promise for the simultaneous purification, concentration, and separation of proteins. In [micro]FFE, analyte streams are deflected laterally in a planar flow channel by a perpendicularly applied electrical field. Traditionally, this method has been done in an all glass device. Introduction of 3D printing will allow for simplified production and interface to mass spectrometry.

Currently there is no method for introducing samples into a mass spectrometer from a [micro]FFE device. We have investigated capturing proteins onto an intermediate membrane as they exit the separation channel of a 3D printed open-edge [micro]FFE device for MALDI-TOF analysis of the membrane. The potential benefits of this application for proteomics include reduced time and sample complexity, protein capture, concentration, and purification.

A novel 3D printed [micro]FFE device has been developed and characterized. Optimization of the device was done using fluorescently labeled dyes and laser induced fluorescence. Multiple proteins have been desorbed from PVDF membrane by MALDI-TOF after vacuum spot deposition of the proteins on said membrane. This research was supported by NSF Grant # 1152022.

Abstract Text

Western blotting is a highly valued method for protein detection and relative quantitation in complex samples. Despite the utility of the method, it is also characterized by long analysis times, manual operation, and lack of established miniaturized counterpart. We have developed a miniaturized SDS-protein size separation based separation in a microfluidic chip and direct blotting onto a moving membrane, which allows multiple separation traces to be captured on PVDF membranes in minutes comparing to hours of separation and transfer in a typical Western blotting. The system also allows multiple injects from a single sample so that multiple proteins can be probed, to improve information content from a limited sample, or obtain replicate assays for better quantification. In recent work, we have improved resolution, detection limits and throughput. Sieving media, channel dimensions, and sample injection/loading method have been optimized allowing resolution of proteins with just 2 kDa difference to be resolved. Such resolution can be obtained using pinched injection and a 4 cm long channel. Detection limit has been improved by both isotachopheresis and field amplified sample stacking. Throughput has been improved by both decreasing dimensions, allowing faster separations, and developing microfluidic manifolds that allow up to 7 parallel separation channels on one chip. Since each channel can be interfaced to 3 different samples, a total of 21 assays can be finished in 31 min.

Abstract Text

Chromatin immunoprecipitation (ChIP) is the gold standard for probing epigenetic protein-DNA interactions that plays critical roles in cell fate and function, aging and carcinogenesis. While powerful, traditional ChIP protocols require a large cellular input (10^6 - 10^7 cells), which limits their utility to study biopsies, rare cells such as cancer and stem cells, and to assess tumor heterogeneity. ChIP is also laborious, time-consuming, and highly user-dependent. To address these disadvantages, we have developed an automated, droplet-based microfluidic platform that integrates cell lysis, highly controlled enzymatic chromatin processing, and magnetic immunocapture. The end result is purified nucleosomal DNA appropriate for analysis via qPCR or next generation sequencing. The reduced dimensions of the microfluidic device greatly reduce the amount of input sample required and the droplet-based platform greatly reduces material loss caused by sidewall adsorption. This enabling device will provide unprecedented opportunity to study epigenetic profiles down to the level of single cells allowing both the assessment of cell heterogeneity within complex clinical samples and the application of cost-effective epigenetic testing to very small samples in individualized medicine settings directly at the point of care.

Abstract Text

Fast-scan cyclic voltammetry (FSCV), coupled with carbon-fiber microelectrodes, is a powerful tool for measuring real-time chemical dynamics in live tissue as well as at single cells. This approach offers precise temporal and spatial resolution with electrodes typically fabricated in a cylinder or disk geometry. The cylinder geometry exhibits greater sensitivity due to a larger electroactive surface area, whereas the disk geometry offers greater spatial resolution. However, several applications that require sampling from a small area would benefit from enhanced sensitivity. Herein, a novel plasma-etching procedure is described for creating carbon-fiber electrodes in a cavity geometry with precise control of cavity depth. These cavity electrodes exhibit enhanced sensitivity in brain tissue compared to disk electrodes, despite similar overall dimensions. This arises from the heightened surface roughness of the etched carbon-fiber, as studied via SEM, as well as restricted diffusion of analyte away from the electrode surface. This approach is simple and inexpensive, and a significant step forward for electrochemical experiments at preparations including, but not limited to, brain slice experiments.

Abstract Text

Fast-scan cyclic voltammetry (FSCV) is commonly used to perform high temporal resolution electrochemical measurements in biological systems. FSCV is superior to other chemical measurement techniques for this application because it can monitor rapidly changing concentrations of neurotransmitters in real time. Currently, carbon-fiber microelectrodes are the gold-standard probes for FSCV measurements. However, these sensors are restrained to a cylindrical or disk geometry with a diameter dictated by the manufacturer. In this work, chemical vapor deposition is used to synthesize biocompatible, thin-film polymer electrodes composed of poly (3,4-ethylenedioxythiophene) :tosylate (PEDOT:tosylate) which are capable of performing rapid electrochemical measurements. Similar films have been synthesized previously, but high surface resistivity and capacitances have limited the temporal resolution of electrochemical measurements. A low-pressure microwave-generated plasma was used to dry etch the films forming patterned electrodes with micrometer scale features of any desirable geometry. Thickness of the polymer layer and the fidelity of the etched features were characterized using optical and atomic force microscopies. The resulting PEDOT:tosylate electrodes were electrochemically characterized using steady-state cyclic voltammetry and were found to have sufficiently low resistivity and capacitance for use in FSCV. The utility of these electrodes is demonstrated by measurement of redox active neurotransmitters at scan rates ≥ 100 V/s. Further, the biocompatibility of this material is demonstrated through cell-viability assays using PC-12 cells.

Abstract Text

Acetylsalicylic acid (ASA), known as Aspirin, is one of the oldest and most commonly used versatile and effective pharmaceuticals. After swallowing Aspirin, ASA is quickly hydrolyzed to salicylic acid (SA), one of Aspirin's major metabolites. SA is responsible for pharmacological actions such as non-steroid anti-inflammatory, antipyretic and analgesic action in the body. The salicylates, ASA and SA, are not to just deal with many minor illnesses such as the ubiquitous inflammation symptom, fever, and pain reliever, it is has recently been used for curing and/or prevent a wide range of serious conditions such as Alzheimer's, cardiovascular diseases and cancers including breast and colon cancers. Interestingly, a few studies indicated that high-dose aspirin may protect against catecholaminergic neuronal damage in the brain involved in diverse neurological and psychiatric disorders such as Parkinson's disease and Alzheimer's dementia. Dopamine and norepinephrine, the major catecholamines in the brain, have been implicated in a variety of physiological functions and behavioral responses. Despite chronic application of aspirin, an overdose can cause unwanted toxic effects including damage of mucous membrane in stomach and ulcer, its effect on catecholamine systems in the brain has not been studied yet. Here, we present effects of acute and chronic administration of the salicylates on catecholamine signaling in rat brains. The neurochemical features of catecholamines are characterized using in vivo fast-scan cyclic voltammetry with a carbon-fiber microelectrode. Our voltammetric and pharmacological evidence suggests for the first time that high-dose aspirin may alter catecholamine signaling in the brain, which is associated with some well-known side effects of aspirin.

Abstract Text

Fast-scan cyclic voltammetry (FSCV) has found widespread use for [i]in vivo[/i] monitoring of fluctuations in extracellular levels of catecholamines (e.g. dopamine and norepinephrine) and other electroactive neurotransmitters. Due to the high scan rates used in FSCV, accurate monitoring of the analytically relevant faradaic signal requires that the large non-faradaic charging current be stable over time such that its contribution can be removed through digital subtraction. However, gradual changes in this background current (i.e. drift) have limited FSCV measurements to short time intervals (30 - 90 sec), while microdialysis studies suggest that physiologically relevant changes in the extracellular neurotransmitter concentrations can take place over longer intervals. Previous approaches (i.e. chemometrics and analog background subtraction) have been able to mitigate the effects of drift; however, such techniques necessitate the capture of pure drift voltammograms, which poses a number of experimental difficulties [i]in vivo[/i], and can require specialized instrumentation.

To explore electrode conditioning as an alternative means of minimizing drift, the effects of conditioning parameters on the background drift rate and electrode characteristics were investigated both [i]in vitro[/i] and [i]in vivo[/i]. Using flow-cell analysis, the influence of the anodic waveform limit, cycling frequency, scan rate, and solution composition were systematically studied. Subsequently, [i]in vivo[/i] data was collected in anesthetized animals during basal conditions and after drug challenge to evaluate the performance of an optimized conditioning protocol. Preliminary results suggest that the amount of time spent at anodic potentials where oxidative etching of the carbon fiber surface occurs primarily dictates the observed drift rate, with extended etching times resulting in small, slow-changing drift rates that allow for the possibility of longer-duration analysis.

Abstract Text

As one kind of intermolecular interaction, ionic interaction is the most popular phenomenon in nature and plays an important role in the biosystems. The main interaction force between ions (i.e., interionic interaction) includes coulombic force, ionic-hydrogen interaction, cation- π and so on. By rationally designing the structure of ions and tuning the interactions between ions, various kinds of excellent fluorescent and electrochemical sensors have so far been developed. Our recent focus has been on the improvement of selectivity of some recognition units (e.g., enzymes and aptamers) by rationally designing and tuning the interionic interactions.

We have developed the ferricyanide-based second-generation biosensors for selective in vivo measurements of neurochemicals based on regulation of redox potential of ferricyanide mediator by carefully controlling the different adsorption ability of ferricyanide and ferrocyanide onto electrode surface.

More recently, we have demonstrated a novel dual recognition unit strategy (DRUS) to construct highly selective ATP biosensors by combing the recognition ability of aptamer towards A nucleobase and of polyimidazolium towards phosphate. Compared with the traditional strategy only with one recognition unit, the DRUS effectively improves the selectivity of ATP aptamer biosensor with a high selectivity against 100-fold higher concentrations of ADP and AMP. The constructed biosensor based on DRUS can be used for sensing the extracellular ATP concentration in the cerebral system by combining in vivo microdialysis technique and offers a promising neurotechnology to understanding brain function activity. The recognition ability of the second recognition unit (i.e., polyimidazolium) and the mechanism for high specificity are proposed and discussed.

Abstract Text

Histamine (HA) and serotonin are important neuromodulators. Histamine in the brain is involved in many brain systems such as the sleep/wake cycle, control of pituitary hormone secretion and cognitive functions. Serotonin is mostly known for regulating mood. Altered levels of 5-HT and HA in the brain are implicated in Alzheimer's and Parkinson's diseases and depression. Inverse modulation of 5-HT through the HA H3 receptor in the substantia nigra pars reticulata (SNr) has previously been speculated, but 5-HT and HA modulation during the treatment of brain diseases is not well understood due to the lack of ability to measure both neurotransmitters [i]in vivo[/i] in real time. In this work, we employ fast scan cyclic voltammetry (FSCV) at carbon fiber micro electrodes to study how HA and 5-HT modulate one another. We describe a novel electrochemical waveform that can simultaneously monitor the Faradaic processes of HA and 5-HT [i]in vivo[/i] in mice. We demonstrate that robust [i]in vivo[/i] detection of 5-HT and HA using FSCV can be used to effectively study and characterize the chemical profiles of the 5-HT-HA modulation in several regions in the mouse brain.

Abstract Text

The Nano-Interface between Two Immiscible Electrolyte Solutions (ITIES) provides a unique analytical platform for the study of ionic species of biological interest such as neurotransmitters on living bio-structures. A typical nano-ITIES consists of nanometer sized pipette that can be filled with an immiscible solution for its immersion into biologically-relevant fluids. Upon electrochemical polarization, charged neurotransmitters of interest can be transferred from one phase to another, which is the basis for quantitative ionic species sensing. This is particularly useful for the detection of non-redox active neurotransmitters, especially those whose detection on carbon microelectrodes is challenging. Nano-ITIES probes thus possess significant advantages over the state of the art carbon microelectrodes, which need to be enzymatically modified, for the detection of neurotransmitters such as acetylcholine. In addition, nanopipette probes have significantly improved spatial resolution compared to microelectrode.

We studied the detection of several neurotransmitters that pose a significant analytical challenge for state-of-the-art carbon microelectrodes. These include acetylcholine, serotonin and tryptamine. Our results show that our nanopipette probes, with a typical diameter of 30 nm, can detect these neurotransmitters both qualitatively and quantitatively, with excellent signal to noise ratios and in biologically-relevant fluids. Finally, our nanosensor probes were further explored in the imaging of biological nanostructures e.g. synapses on neuronal models from *Aplysia californica*. Scanning Electrochemical Microscopy with nanometer spatial resolution was used for accurate positioning and imaging of neurotransmitter flux from these neurons. The strategy presented here will provide an unprecedented view on the mechanisms of neurotransmission.

Abstract Text

Fast scan cyclic voltammetry is one of very few analytical techniques which can easily make chemical measurements with submicrometer spatial resolution and subsecond temporal resolution. As such, it has been heavily exploited, in conjunction with carbon fiber microelectrodes, to measure the spatiotemporal dynamics of redox-active catecholamine neurotransmitters in living brains. Understanding the details of these dynamics is critically important to understanding brain function on a mechanistic level. For a long time, a feature known as "hang-up" has been observed in the case of FSCV measurements of dopamine, this being a failure of the signal to return to the original pre-measurement baseline. We explain this signal feature as a consequence of a ubiquitous slow electrode response, which can be characterized by kinetic rate constants. This slow electrode response occurs in addition to the much kinetically faster and well known process of dopamine adsorption to carbon fiber microelectrodes in FSCV measurements. Our data do not support the hang-up feature as corresponding to any bulk [DA] concentration at the electrode. As such, we can improve the accuracy of our measurements of [DA] dynamic changes by treating it as a measurement artifact and removing it from our profiles of measured concentration versus time. We have developed an algorithm to do this, and set conditions which must be true for the correction process to be perfectly accurate. Violation of these conditions worsens the accuracy of correction. Accounting for the hang-up feature improves the correspondence of the FSCV signal to the [DA] concentration over time and can lead to different conclusions about the results of experiments than if the FSCV signal towards the end of the measurement were taken to closely correspond to a bulk [DA] concentration, as it appears to.

Abstract Text

Liquid chromatography (LC) coupled with UV-absorption detection is a prominent analytical laboratory technique due to its broad applicability, high resolving power, and versatility. LC would be very useful for on-site environmental and clinical analysis, since measurements immediately after samples are collected would help in obtaining rapid and reliable results. Despite its popularity and wide use in the laboratory, portable LC systems are scarce. The main reasons for this are difficulties encountered in mobile phase use and disposal in the field, and re-engineering the high pressure pumping system and most commonly used detector (i.e., UV-absorption) to acceptable size, weight, robustness, and power usage. In this work, battery-operated (24 V DC) nano-flow pumps, capable of high-pressure gradient generation, were integrated with a miniaturized LED-based detector (260 nm) for environmental pollutant analysis, and with a portable laser-based detector (405 nm) for the diagnosis of hemoglobinopathies with high sensitivity. The gradient nano-flow pumps were specifically designed for capillary column use. Low detection limits were achieved due to proper light focusing, low stray light, and very low noise. Signals down to the ppb level were easily detected with a short-term noise level on the order of 10^{-6} AU.

Abstract Text

We report a battery powered ion chromatograph that weighs less than 3 kg with on-board rechargeable Li-ion batteries that provide power for 10 hours of operation. It is contained in an aluminum case measuring 30 x 25 x 16 cm. Separation relies on open tubular chromatographic columns which eliminate the need for high pressure pumps, drastically reducing weight and complexity. Eluent consumption is less than 100 μ L per separation. Eluent is supplied from a pressurized vessel connected to a compressed gas cylinder, similar to ones used to inflate bicycle tires, via a voltage-controlled electronic pressure controller. Flow rates are typically < 200 nL/min which allows a single 16-20 g gas cartridge to perform hundreds of separations. The flow rate is linearly proportional to applied pressure. A release valve provides for rapid reduction of pressure. Three low power miniature solenoids, which can operate up to 800 psi, provide variable volume injection capability and further reduce weight and size. Both pressure and injection times are used to control injection volume, typically in the pL – nL range, depending on the capillary size (typically 10-30 [micro]m) in ID. Typical column lengths are 30-75 cm and 100-150,000 plates/m are generated. Separation of 5 common anions takes less than 5 min, with the separation window itself being less than 2 min. The limits of detection are in the low [micro]M range. The design also includes a novel admittance detector design with full microprocessor control including GPS location data logging and storage. Additional configuration and data readout can be performed with a computer. Field performance data for operation in the Atacama Desert in Chile will be presented.

Abstract Text

X-ray fluorescence spectrometry (XRF) is well known as a nondestructive technique and for its rapid, simultaneous, and multi-elemental capabilities at concentrations ranging from 100% down to $\mu\text{g/g}$ (ppm). Although XRF does not have the accuracy and detection limits associated with Inductively Coupled Plasma Mass Spectrometry, its portability for positive material identification, hazardous waste screening and even for cultural heritage studies makes it uniquely attractive. Most portable XRF devices perform quantification based on fundamental parameters modeling that is specific to different modes of analysis. The primary goal of this study was to validate a "High Definition" X-Ray Fluorescence (HD-XRF) instrument developed specifically for field measurements related to assessing personal exposure to toxic metals through food, cosmetics, medicines and personal care products. Three HD-XRF units (HD-Mobile) were obtained from X-Ray Optical Systems (XOS), East Greenbush NY: one was an early prototype unit, the other two were full production models. The HD Mobile is a monochromatic micro XRF spectrometer that includes Doubly Curved Crystal optics to enhance measurement intensities. The unit is housed in a self-contained case for use in the field. Because the main use of the HDXRF is for analysis of samples with a light matrix, the plastic mode was used for quantification. Parameters such as accuracy, precision and detection limits were characterized in a laboratory setting using reference materials and standard solutions including: IAEA-413 Algae, NRC-CNRC TORT-2 Lobster Hepatopancreas, NIST SRM 1571 Orchard Leaves, IRMM BCR-627 Tuna Fish, NIST SRM-2976 Mussel Tissue, NRC DORM-2 Dogfish Muscle and IRMM ERM-CE464 Tuna Fish. Percent bias for the mean of elements such as As, Cd, Hg and Pb between days ($n = 5$) ranged from -9% to 10% for the prototype and -15% to 14% for the two production models. Five archived samples including herbal medicine products, ethnic spices and cosmetic products were analyzed with all three HDXRF units in the laboratory to compare their performance with "real" samples. Agreement between the prototype and two production models proved to be fit-for-purpose for the majority of the samples. The presence of the elements of interest as detected by HDXRF was confirmed by ICP-OES analysis of archived samples. In conclusion, these HDXRF units were shown to be suitable for the rapid screening of personal exposure to metals in the field.

Abstract Text

The concept of a remote chemical analysis system implies little to no user intervention after deployment. Additionally, inexpensive microfabricated sensors combined with low power instrumentation offer unique advantages for electrochemical sensing in the field. In order to combine these advantages, and to eliminate hands-on steps such as calibration and sample pretreatment, our group is developing a coulometric analysis three electrode cell that exploits Faraday's first law of electrolysis. In the stopped-flow, constant volume system, experimental studies using a novel coulometric stripping technique have produced linear relationships for the determination of Cu and Hg (LOD approximately 1.1 picomoles) that do not require a calibration step as a result of the known constant volume of the thin-layer cell (1.8 [micro]L).

The system instrumentation utilizes a microcontroller-driven, custom potentiostat with programmable gain control (sensitivity ranges between 0.1 nA/V and 100 nA/V) and automated sample loading using DC powered pumps/valves connected in-line with the sample and buffer flow paths (programmable flow rates of 1-1000 [micro]L/min). The microcontroller software under development allows for on-demand or periodic experiments (10 – 20 times per day, for example), local storage of experimental data (i.e. to microSD memory card) for later retrieval, and switching into low-power sleep mode between measurements. The software also periodically interrogates the potentiostat using a built-in dummy cell as a self-check. Additional features include a 12V (15 W) solar panel to charge a 2200 mAh lithium-ion battery that powers the system (approximately 35 mA current draw during a 60 sec experiment). A low-noise virtual ground technique is used to establish a split Vdd range of $\pm 5V$ that is used to power the instrumentation amplifiers included in the potentiostat circuit. Ongoing development includes lowering the noise floor for higher sensitivity, reduction of sleep-mode power consumption, and incorporation of a GSM modem for periodic transfer of data over existing cellular infrastructure.

Abstract Text

Nonspecific methods such as UV absorbance or fluorescence have been successfully used for the analysis of ppb concentrations of mercury in air and water. The unique amalgamation of mercury with gold and silver makes this possible. Air samples are collected and only the mercury is reacted with the gold surface. Any impurities are purged through, then the amalgam is heated to desorb the mercury which is measured by the detector.

We have used a very sensitive but nonspecific photoionization detector (PID) with a 10.6 eV lamp to measure mercury that has an ionization potential of 10.43 eV. The chemistry of the gold/mercury amalgam makes this method specific for mercury. The Permissible Exposure Limit (PEL) for Hg is 0.05 mg/m³ (0.408 ppm). Mercury permeation tubes were used to generate levels from 0.02 to 1 ppm. Preliminary data indicates a detection limit of > 10 ppb of Hg for the gold film photoionization detector (GFPID) analysis.

Water samples are analyzed using hydride generation with sodium borohydride to reduce the inorganic salts to elemental mercury that is efficiently detected by the PID. The EPA MCL for mercury in drinking water is 2 ppb. The detection limit for Hg in water by hydride generation GFPID was 0.2 ppb.

Abstract Text

For the last several years, we have been developing and characterizing 2d microplasmas on planar chips. More recently and to reduce fabrication costs, we used 3d-printing technology to make sugar-cube size, battery-operated microplasmas on 3d-chips.

Are these microplasmas any good for any analytical applications? To address this question and to demonstrate analytical capability and utility, we will discuss two applications. One involves the determination of the concentration of Zn in mm-long single stands of hair and the other of Pd in paint. Both of these were analysed as solids (i.e., without an acid digestion step), thus expediting analytical determinations. It is worth noting the if an ICP (Inductively Coupled Plasma) was used with a pneumatic nebulizer for sample introduction, acid digestion would be essential for both of these sample types.

Abstract Text

Accurate and reliable detection of different gases is required in many application areas, for example in industry, indoor and outdoor air quality, health and well-being, and defense and security. Also, high sensitivity and selectivity, rapid detection, and small instrument size are common criteria, especially when monitoring compounds that are harmful to humans.

Photoacoustic detection does not require long absorption paths and therefore it is possible to combine the high sensitivity with a small-sized detector. The use of optical cantilever microphone further enhances the sensitivity of the photoacoustic detection. When compared to more common capacitive microphones, optical cantilever microphone can achieve orders of magnitude higher sensitivity [1], which opens possibilities beyond the reach of the conventional infrared techniques.

In this study, different applications of cantilever-enhanced photoacoustic spectroscopy are investigated. The applications include, for example, indoor air quality measurement of different volatile organic compounds (VOCs), unknown gas identification, food process control, and forensic use and border control for drugs and explosives. In all of these applications, multi-gas detection with high selectivity and sensitivity is required.

Cantilever-enhanced photoacoustic cell was combined with a tunable infrared source, either an optical parametric oscillator (OPO) or a quantum cascade laser (QCL), to be able to scan the photoacoustic infrared spectrum and perform multi-component analysis. As QCLs and OPOs are becoming more common, they are available in greater number of wavenumber ranges, higher optical output powers, and are more and more affordable. Ppb and sub-ppb level detection limits were achieved with the combination of cantilever-enhanced photoacoustic cell and tunable infrared sources.

Abstract Text

The determination of tertiary alkyl amines using modern chromatography instruments has proven to be highly challenging due to the sticky nature of these compounds which causes significant issues with carry-over. Structural properties of the tributylamine (TBA) molecule were correlated to its problematic interactions within the flow path of the Agilent 7890A Gas Chromatograph and 5975C Mass Spectrometry Detector. TBA has a pKa of 10.9 and a high boiling point of ~214 °C. Though it is technically not a cation, when the nitrogen atom is protonated, it holds a strong positive dipole which ensures that it will occupy any active sites found in the instrument. Direct injections were made into a split liner with deactivated wool. An Agilent DB-5MS UI column was used for the separation due to its maximum operating temperature of 325 °C. TBA is a hydrophobic compound and the presence of having only one constricted site, at which hydrogen bonding can occur, limits the possibilities of using certain solvents for sample preparation and Solid Phase Extraction (SPE) clean-up. Samples were diluted in a pH 13 solution of ammonium hydroxide in acetonitrile. A Bond Elut CBA cartridge was used to extract TBA. To remedy the problem of carry-over, the MSD was operated in Selected Ion Monitoring (SIM) mode. A quantitative method for TBA, developed using GC-MS, is presented here. The LOQ was found to be at 0.25 ppm, and matrix spike recoveries were reproducible and between 96-115%. The average response factor RSD was reproducible, in the range of 4-8%.

Abstract Text

In order to more accurately model performance and critical properties of liquid fuels based on composition, detailed qualitative and quantitative information of the sample must be obtained. Currently one of the most comprehensive methods for fuel analysis is GCxGC-MS. Comprehensive GCxGC-MS couples two chromatographic columns with orthogonal selectivities to a fast Time-Of-Flight (TOF) mass analyzer. This approach enables direct analysis of complex organic mixtures providing detailed compositional information due to the inherent separation efficiency of a cryogenically modulated GCxGC. Since mass spectrometric detection is not quantitatively linear with respect to different compound classes due to differences in molecular ionization efficiencies, to obtain a more quantitative measurement, it will be necessary to establish compound class response factors. This was accomplished by configuring a secondary channel on the GCxGC-MS, such that the second column effluent is routed to a flame ionization detector (FID), which responds linearly to concentration. A three-way capillary flow splitter was installed into a GC with some modifications to the secondary column oven. This enabled the simultaneous collection of both FID and MS data channels, as shown in figure 1. This modification allows the collection of MS data that contains qualitative information about the sample compounds (compound identification) and the universal signal response of the FID will allow for analyte quantification. Quantitative MS measurements were thus obtained from a series of surrogate fuel blends with known compound abundances, and directly correlated with their FID responses. This provided the information necessary to establish response factors for each compound class. A secondary correction was also developed to account for changes in detector response with carbon number to produce class specific libraries of carbon number factors that will be used to improve fuel property modeling.

Abstract Text

Electron Ionization Gas Chromatography / Mass Spectrometry (EI GC/MS) is a powerful and information-rich technique for qualitative characterization and quantitative analysis of the compounds in a mixture. One of its most valuable functions is to provide the molecular weight of a compound. However, many compounds do not have a stable molecular ion under EI conditions and it is small or absent in the spectrum.

Cold Electron Ionization GC/MS (Cold EI GC/MS) can enhance the molecular ion abundance of most compounds while retaining the EI fragmentation pattern for spectral library searching.

The enhanced molecular ion intensity is achieved by supersonic expansion of the GC effluent into a molecular beam, where the analyte molecules are vibrationally and rotationally cooled adiabatically to ~10 - 30 K. When this vibrationally cold molecule is ionized by a 70 eV electron the final thermal energy is much lower than in EI, which ionizes a molecule at GC transferline temperature of several hundred °C. The reduced Cold EI internal energy produces much less fragmentation of the molecular ion. The ion source used in this work is of axial "fly-through" design, eliminating molecule and ion collisional scattering with ion source walls which could lead to additional fragmentation. This is demonstrated for compounds such as squalane, which shows a large molecular ion with Cold EI, but <1% by conventional EI.

When used in a novel q-TOF configuration the enhanced molecular ion increases sensitivity, selectivity, and information content.

Abstract Text

The goal of prep chromatography is to isolate specific compounds. Each project is a balancing act for the triangle of purity, yield and throughput. When picking the stationary phase for a prep chromatography project, the first thought has to be selectivity. If the stationary phase doesn't separate the desired material from the undesired material there is no hope for the separation. Even if there is some resolution, if the peak shape is very poor, it might be impossible to achieve the required project goals. Often pH is an effective tool for chromatography and can be used to adjust selectivity and peak shapes. Another powerful tool is using a core-shell media. Core-shell provides higher efficiency, improved sensitivity, and increased resolution when compared to what could be achieved with the same stationary phase on the same size fully porous media. The properties achieved by core-shell material will help significantly with the purity and yield aspect of a prep chromatographic method. The work presented here will demonstrate through several examples how core-shell media that can be used at high pH can be a powerful tool for the purification of pharmaceutical compounds.

Abstract Text

Liquid chromatographic methods, such as reversed-phase liquid chromatography and electrochromatography, are powerful and popular tools in the pharmaceutical industry. The past few years have seen more and more large molecule drugs, especially therapeutic monoclonal antibodies entering the market that was previously dominated by small molecule drugs.

Many important questions have to be re-considered as the analyte size changes from less than 1000 Da to 150,000 Da or more. In this presentation, an important question is addressed, which is, how accessible are the surfaces of common column materials to large analyte such as monoclonal antibodies.

We explored the answer experimentally by stacking monoclonal antibodies on the surface of three common liquid chromatography column materials, fully porous particles, core-shell particles and non-porous particles. The column materials are packed into UV-transparent capillaries under sonication to form homogenous packing. Fluorescently labeled monoclonal antibodies were injected into the packed capillaries with 5% acetonitrile in water with 0.1% Trifluoroacetic acid. Under such strong retaining condition, the IgG2s were pushed onto the surface of the packing material, forming a stacked plug. By comparing the length of the stacked plugs on different columns, we discovered that the surfaces of the core-shell particles and totally porous particles were largely inaccessible. Among the three, sub-micron non-porous particles provide the largest accessible surface area. It's therefor suggested that larger pores (than 300 Å) are needed for the characterization of monoclonal antibodies.

We also investigated sub-micron silica colloidal crystals for the analysis of monoclonal antibodies from unwanted contaminants by electrochromatography. Beside the larger accessible surface area, the narrower size distribution and faster mass transport of silica colloidal crystals lead to lower plate heights and increased resolution. Longitudinal diffusion is reduced with the plug-like flow profile in electrochromatography.

Abstract Text

Method development involves investigating a range of parameters to generate conditions for optimum separation. While there are many approaches to method development such as one-factor-at-a-time (OFAT), systematical protocols, and quality-by-design (QbD), the final goal is to develop a robust method that separates all components and generates an accurate result, time after time.

The arbitrary change of one factor at a time for method development (OFAT) is easy to perform, but typically does not result in a robust method. With a systematic approach, a predefined protocol is used, which typically incorporates scouting, screening, and optimization steps. Although this approach may result in development of a reproducible method, the most reliable separation conditions may not actually be identified. Analytical QbD approaches use statistical software to generate a design of experiments (DoE) to comprehensively study interactions of different factors to define a region of operating space with high method robustness.

In this work, we compare the development of a UPLC method for metoclopramide HCl and related substances using systematic protocol and analytical QbD. Both strategies also employed an integrated UV and orthogonal mass detection workflow to help automate and accelerate the peak identification and tracking process. We will compare results from both method development approaches and demonstrate that analytical QbD offers a thorough examination of variables and provides a measure of robustness which is integral to the final method.

Abstract Text

Tea, a popular drink with different varieties and flavors, is often considered as a medicinal alternative to fight against diseases. Empirical findings prove that tea drinks are able to provide many health benefits including antioxidation, anti-inflammatory, and netroprotective functions. In recent years, scientists found that the key ingredients contributing to tea's antioxidation benefits were catechins, a type of polyphenols that can eliminate free radicals inside organisms. To date, analytical methods employed high performance liquid chromatography (HPLC) have been applied to investigate copper induced oxidative stress in tea leaves and to investigate effects of water solution on extracting green tea leaves. However, many extraction (tea brewing) factors including temperature, solvent, and flavor supplement have not been thoroughly examined. Therefore, our project is to focus on determining the optimal extracting conditions for catechins from dry tea leaves and investigating how brewing parameter affect antioxidation functionality of catechins in tea drinks. Green tea extracts under different brewing conditions were analyzed by a reversed-phase HPLC method using a C18 column, and a mixture of methonal/water (20:80) as the mobile phase with a detection wavelength of 280 nm. Four major catechins in tea drinks were analyzed in 15 min. Preliminary data show that an introduction of ~0.5% NaCl to grean tea drinks increases the extraction of catechin from green tea leaves. The results from the Fenton reaction assay will be presented, as well.

This project is supported by California State Polytechnic University Pomona and the Goldstein Student Research Fellowship at California State Polytechnic University Pomona.

Abstract Text

Ion exclusion chromatography (IELC) has been used to effectively separate short chain aliphatic acids, primarily carboxylic acids often found in various drinks. Separations by IELC are commonly performed on strong cation exchange columns, in which the negatively charged sulfonate groups, making up the Donnan membrane on the stationary phase, will repel the negatively charged analyte ions, but allow the neutral species to penetrate the membrane and enter the pores with the occluded mobile phase. In addition to ion exclusion and steric effects, hydrophobic adsorption on the resin must also be considered as a potential aspect of the retention mechanism. In general, carboxylic acids with higher pKa values and more hydrophobic sites show longer retention. We have characterized for IELC a reversed phase column previously coated with a sulfonated surfactant. This surfactant modified ultra high-performance liquid chromatography (UHPLC) reversed phase column allowed for flexibility and customization of the column to the needs of the separation. A Kinetex XB-C18 reversed phase HPLC column (150mm x 4.6mm id, 2.6 μ m) was dynamically modified with sodium dodecylsulfate (SDS) for the separation of aliphatic and aromatic acids. The mobile phase was optimized to 1.84mM H₂SO₄ (pH 2.60) at 0.60 mL•min⁻¹, with a 20 μ L injection volume with UV detection at 200nm. Under these conditions, short chain aliphatic carboxylic acid mixtures, such as geometric isomers, fumarate and maleate, were efficiently separated with baseline resolution. Separation of aromatic carboxylic acids, such as o- and m-hydroxybenzoic acids, proved to be more challenging due to the complexity of the separation mechanism to include a strong hydrophobic effect. To improve separation efficiency of aliphatic and aromatic acid mixtures, we propose using a mobile phase modifier, such as methanesulfonic acid, or a shorter chain stationary phase modifying surfactant, such as C6 or C3.

Abstract Text

The incorporation of halogen atoms into the structure of active pharmaceutical ingredients (APIs) has become very important, it is assessed that 20 percent of all pharmaceutical drugs are halogenated. One of the most useful way to increase the bioactivity of an API is to introduce one or more fluorine atoms in the structure. Frequently dehalogenated impurities/by-product exist as side reactions during the production of the API may result in hydrohalogenation. These dehalogenated impurities often coelute with the major product of interest and also can persist through further synthesis steps. Further, the dehalogenated impurities are difficult to separate from the API. We have investigated number of chromatographic methods to identify optimum columns and conditions for separating dehalogenated impurities. The drugs evaluated in this study were aprepitant, atorvastatin, voriconazole, ezetimibe, paroxetine, risperidone, ciprofloxacin and ofloxacin. Cyclofructan, cyclodextrin, macrocyclic glycopeptide and zwitterionic based stationary phases were screened in the reversed phase, polar organic mode and HILIC to separate APIs from their des-fluoro analogs. Method optimization was performed for each drug.

Abstract Text

Encapsulated bonding technology (EBT) is a new approach to stationary phase end capping that provides exceptional inertness and excellent phase stability across a broad pH range from 1.5 to 11. This technology has previously been successfully applied to 2, 3 and 5 micron totally porous (non-core) packing materials, but has more recently been implemented for solid-core packings. The ability to use stationary phase chemistry (C18, phenyl-hexyl), organic modifier choice, and pH as variables in a systematic approach is a significant advantage for UHPLC and HPLC method development. The usefulness of such a method development strategy will be described and demonstrated with an appropriate example.

Abstract Text

In capillary chromatography, on-column porous frits are used to retain packed bed materials and allow for more reproducible and efficient separations. Shortcomings of current methods include bubble formation during particle sintering and irreproducible frit synthesis. Polymer frit synthesis can be initiated using UV radiation, but necessitates introduction of a fragile window within the capillary, whereas thermal radiation can be performed in the presence of the protective polyimide coating. Here, we report a new approach for frit fabrication employing thermal polymerization to form polymer frits within a fused silica capillary. Frits were synthesized in 3-(trimethoxysilyl)propyl methacrylate modified capillaries via free radical thermal polymerization using a sol-gel solution containing 2,2-azobisisobutyronitrile in the presence of glycidyl methacrylate, ethylene glycol dimethacrylate and porogenic solvent decanol. Thermal polymerization was initiated using a custom-built temperature controlled heating apparatus. Frit length was studied as a function of polymerization time and temperature. Frits synthesized at a lower temperature and longer time resulted in more stable frits compared to higher temperatures and shorter polymerization times. The breakdown pressure of frits was determined by identifying a deviation from linearity in the plot of backpressure versus volumetric flow rate. Thermal frits demonstrated similar stability compared to UV polymerized frits. Using zonal chromatography, the performance of C₁₈-packed capillary columns was compared for thermal versus UV-polymerized frits. This method offers short polymerization times, control of frit length, control of frit placement and improved capillary stability via retention of the polyimide capillary coating.

Abstract Text

We developed a software package entitled MetSign2 for analysis of stable isotope assisted metabolomics (SIAM) acquired on high resolution mass spectrometry. A significant feature of SIAM data is the overlap of isotopic peaks generated by isotopologues as well as co-eluting metabolites. MetSign2 first deconvolutes the mass spectra into isotopic peaks. Metabolites were then tentatively assigned based on m/z value and the isotopic peak profile. MetSign2 further deconvolutes the overlapped isotopic peaks using a linear regression model, assuming the intensity of isotopic peak is additive and can be represented by a linear combination of overlapped isotopic peaks. By solving the linear regression model, the weights (i.e. the contribution from each isotopologue) are obtained. To prevent negative values of weight, an iteratively linear regression process is employed, in which the isotopologues with negative weights are considered as noise and removed from the list of candidate isotopologues in an iteration. However, some of the deconvoluted isotopologues may be noise due to the match of their m/z values. To determine the threshold of weights obtained from the linear regression model, metabolites recorded in KEGG, LIPID MAPS and HMDB were used to generate overlapped isotopic peaks, with 2%, 5%, 7% and 10% of Gaussian white noise added to the abundance of each isotopic peak, respectively. The linear regression model was trained using these simulated data and the optimal threshold of the weight value was determined as 7.5×10^{-7} .

The algorithm was implemented in Matlab 2010b and tested with mixtures of compound standards and biological samples. Our initial tests demonstrate that MetSign2 is able to remove ^{13}C natural abundance contribution and uncover the true ^{13}C enrichment in detected metabolites. Figure 1 shows the comparison result of ^{13}C isotopologues of compound ATP between before deconvolution and after deconvolution.

Abstract Text

Type 1 diabetes is caused by autoimmune destruction of insulin-secreting beta-cells found in the islets of Langerhans of the pancreas. Severe cases can be treated by islet transplantation. However, islets used for transplantation can undergo a great amount of oxidative stress during the isolation process, which could have profound effects on islet viability and potency. Metabolomics provides a powerful tool for investigating stress-induced alterations in cellular pathways by enabling the quantification of a wide range and amount of metabolites. Liquid chromatography-time-of-flight mass spectrometry is a useful metabolomics technique because of its high sensitivity and selectivity.

Previous metabolomics studies have typically been conducted with clonal beta-cells due to their ease of access and specificity for beta-cell metabolism. However, because clonal cells are derived from a cancer line and as such may favor pathways involved in cell growth, corroboratory data from native islets is necessary. One challenge is that islets vary widely in size, so beta-cells within an islet may be exposed to varying concentrations of stimulants, leading to a more variable metabolic profile and potentially poor reproducibility of results.

We have developed a sample preparation method for the reproducible measurement of ~70 metabolites within whole islets through optimization of islet number, extraction method, and extraction solvent. Analyses were performed using a hydrophilic interaction liquid chromatography/anion exchange (HILIC/AEX) column or a reverse phase column coupled to a TOF-MS to measure polar metabolites and lipids, respectively. We then applied this method to study the effects of hydrogen peroxide treatment on islets as a model of oxidative stress. Several key metabolites were found to be significantly altered by this treatment. Future work involves investigating whether these metabolites can be used as markers of islet viability/potency for transplantation purposes.

Abstract Text

A MALDI MSI methodology was developed to analyze and visualize the distribution of glycolytic and oxidative skeletal muscles fibers. Soleus (SOL), extensor digitorum longus (EDL), and gastrocnemius (GAS) muscles from 6-month old rats were used for this study. SOL is mainly composed of oxidative type I muscle fibers, EDL is mainly composed of glycolytic type II fibers, and GAS is composed with a mixture of both type with regionalization of oxidative fibers.

Tissue sections were obtained at 10 μm thickness at $-25\text{ }^{\circ}\text{C}$, and thaw mounted atop glass slides. Serial sections were used for immunofluorescence staining and positive and negative ion mode MSI analyses. For positive ion mode, 0.5 M 2, 5-dihydroxybenzoic acid (DHB) in methanol was used as the matrix, whereas 10 mg/mL 9-aminoacridine (9AA) in 70:30 (v:v) ethanol:water was used for negative ion mode. The matrix coated tissue sections were analyzed by a Thermo LTQ XL with a $\sim 100\text{ }\mu\text{m}$ laser spot size.

Differences were observed from the comparison between the averaged mass spectra recorded from each muscle. Principal component analysis (PCA) was also performed. Separation between muscle group sample points was observed from the 2-D scores plot. The loadings plots were analyzed for significant m/z values of each sample group; m/z values with different localization were observed in MS images. In negative ion mode, fructose-bisphosphate (m/z 339) showed higher relative intensity in SOL and oxidative GAS, whereas inosine-monophosphate (m/z 347) showed higher relative intensity in EDL and glycolytic GAS. In positive ion mode, phosphatidylcholine (PC) (18:1/18:1) showed higher relative intensity in SOL and oxidative GAS, whereas anserine (m/z 241) showed higher relative intensity in EDL and glycolytic GAS. Overall, this study showed the different metabolic profiles in oxidative and glycolytic muscles, and demonstrated the ability to visualize the tissue structural information with minimal loss of chemical information.

Abstract Text

A highly sensitive platform was developed to determine anionic polar metabolites by coupling capillary ion chromatography with high resolution accurate mass spectrometry. This method provided separations of isobaric sugar monophosphates, sugar diphosphates, and organic acids using a capillary format anion-exchange column optimized for high resolution and efficient separations of organic acids using supermacroporous, 4- μm particle resin particles. The analytes were detected by an orbitrap mass spectrometer resulting in mass accuracy <1 ppm and fmole on column sensitivity.

This method was applied to metabolomic profiling of metabolic biomarkers for oral squamous cell carcinoma (OSCC) metastasis, 3-paired OSCC cell lines (UM1, UM5, CSC) with wild-type controls. Cap IC demonstrated outstanding separation and peak shape for anionic polar metabolites with increased sensitivities [greater than]100-fold as compared to RPLC and HILIC methods. Differential analysis revealed significant changes in energy metabolism pathways.

Abstract Text

The studies reported herein describe the performance of 1-aminopyrene (AP) and AP-derived group of uniform materials based on organic salts (GUMBOS) as novel matrices for matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS) analyses of peptides. A number of solid phase salts of AP, i.e. GUMBOS, are synthesized of variable hydrophobicity simply by changing the counterions. The primary aim of this study is to investigate the performance of these GUMBOS as well as AP as new MALDI matrices on the basis of their hydrophobicity for the analysis of hydrophobic as well as hydrophilic peptides. A clear trend was observed between the signal intensity of hydrophobic peptide and hydrophobicity of matrices. The hydrophobic matrix materials are more effective for hydrophobic peptides and, similarly the most hydrophilic peptide displayed great intensity in the most hydrophilic matrix. A mixture of hydrophobic and hydrophilic peptides demonstrated the variation in signal intensities in different AP and AP based GUMBOS, and these signal intensities directly depend upon the hydrophobicity of the matrix. The performance of these materials in terms of reproducibility is also compared with that of α -cyano-4-hydroxyl benzoic acid (CHCA), which is a widely used matrix for peptide-mass fingerprinting in proteomics. These materials showed good signal intensity for hydrophobic peptides with good reproducibility.

Abstract Text

Physalis angulata is a weed used medicinally for several diseases including infertility in both males and females, prevention of miscarriage and management of asthma, throat swelling, muscular stiffness and pain, rheumatism, gonorrhoea, diarrhoea, malaria and skin disorders. In order to correlate the constituents of the whole plant with these medicinal uses, the essential oil was extracted and analyzed by gc-ms. The whole plant was air-dried and the essential oil extracted into hexane by hydrodistillation using a Clevenger apparatus. Collection was in two modes; single collection over four hours and hourly collection over three hours. Analysis was on Agilent gc-ms (7890A/MSD 5975C) fitted with HP 5MS column using a temperature program of 80 deg.C (2min) increased at 5 deg./min to 120 deg.(2min) increased at 2.5 deg./min to 240 deg.(6min). The major constituents were tetradecanal /E-2 tetradecene 1-ol (15-16%), 2-pentadecanone, 6, 10, 14 trimethyl (23-30%), cis-vaccenic acid (11.8-20.6%) and 9,12-octadecadienoic acid methyl ester (4.2-6.0%). Other constituents include caryophyllene oxide (2.6%) in the first hour fraction, 9, 12, 15 octadecatrienoic acid (Z, Z, Z)- (0.9-1.2%) and cis/trans-13-octadecenoic acid methyl ester (1.3-2.0%). Small quantities of phytol, hexadecanoic acid and the methyl ester were also present. Caryophyllene oxide is anti-inflammatory, antibacterial and anti-fungal, is an analgesic, exhibits repellency against malaria vector and has been used for the prevention and treatment of cancers. Phytol is anti-inflammatory and is useful in the management of arthritis and tumors and has been proposed as an active ingredient in asthma plants. Long chain unsaturated fatty acids such as cis-vaccenic acid exhibit anti-inflammatory, antibacterial and anti-fungal activity. Thus the constituents of the essential oil lend support to some of the uses of the plant in Alternative medicine.

Co-Author(s)

Abstract Text

Dogs can reliably distinguish by sniffing between healthy and ill people suffering from cancer. These obviously existing volatile cancer markers have long been searched for, but have not yet been detected.

In cancer tissue, high levels of nitric oxide (NO), nonvolatile thiols and nonvolatile nitrosothiols (SNOs, being a synthesis product of both) have been described as typical. Taking this into consideration, volatile nitrosothiols (vSNOs) generated from volatile thiols that are omnipresent in malign tissue and NO are proposed to be the source of the characteristic smell of cancer.

Derived from the structures of volatile sulfur compounds repeatedly found in the breath emission of humans (e.g. thiols, sulfides and disulfides), with typical carbon structures based on methyl-, ethyl-, 2-propyl- and propenyl- (allyl) groups, the corresponding vSNOs were synthesized and stabilized for weeks as n-decane solutions (see poster for syntheses and analyses of vSNOs).

To prove that the smell of cancer consists of vSNOs, a dog was trained with an artificial odor mixture composed of the four vSNOs structured as mentioned above. In succeeding sniffing tests, this dog was reliably able to find cancer tissue in amongst non-cancer tissues without ever before having sniffed cancer. This is the first time that a dog training procedure using artificial fragrances has enabled a definite and secure detection of cancer. These results are strong hints for vSNOs as cancer markers. But their detection remains difficult due to their fast decomposition rate (e.g. during enrichment) and until now has been unsuccessful in vivo even when handled with consideration by cryo-sampling and low temperature GC.

Abstract Text

Mycobacterium avium spp. *paratuberculosis* (MAP) is the causative agent for Johne's disease, an intestinal infection in ruminants, which results in economic losses of at least 200 million US-dollars per year. Fast diagnostic of MAP infection is difficult because of slow growth of the pathogen. This study was intended to detect MAP specific patterns of volatile organic compounds (VOCs) in headspaces over in vitro cultures by means of two different micro-extraction techniques.

239 cultures from three different MAP-strains, grown on five different media, were examined. VOCs were extracted from headspace (20mL) of in vitro cultures by means of bidirectional needle-trap-micro-extraction (NTME, 160 samples), or solid-phase-micro-extraction (SPME, 79 samples), respectively. GC-MS was used to identify and quantify extracted VOCs.

113 VOCs, alcohols, alkanes, alkenes, aldehydes, ketones, sulfides, esters, furans and aromatic compounds were detected in ppbV-/high-pptV-levels. 51 of 96 substances detected through NTME and 18 of 82 substances detected through SPME had significantly different concentrations in cultures compared to blank media. Specific VOC patterns could be attributed to different MAP strains and to density of bacterial growth. 17 VOCs were only detected by means of SPME and 31 VOCs only by NTME. 13 of the differentiating VOCs were found by means of NTME and SPME.

VOCs emitted from MAP cultures revealed characteristic patterns. As sensitivity can be improved by increased sampling volume, NTME is better suited for comprehensive VOC-profiling. For some substances, SPME provided additional information. Smart combinations of micro-extraction and GC-MS can be used to detect and characterize mycobacterial growth in cultures.

Abstract Text

Macroautophagy is the process by which cellular debris and excess protein is degraded in living cells, maintaining homeostasis. Dysregulated macroautophagy results in the accumulation of unnecessary protein and cellular debris, and has been linked to pathologies including myopathy and muscle wasting. Proteomics is essential to investigate the pathways behind the dysregulation of macroautophagy. Unfortunately, conventional proteomic strategies cannot distinguish between the proteomes of multiple cell types co-existing in a tissue. Mass cytometry is an emerging technology that measures cellular markers on the surface or within single cells that allows for detection and quantification of upwards of 30 separate cellular targets labeled with isotopically pure heavy metals. The instrumentation combines the high mass accuracy and low limits of detection that are characteristic of ICP-MS, with the single cell analysis capabilities of flow cytometry. Because of the shape and size of muscle fibers, this technique has not been used for the analysis of muscle fibers. In this presentation it will be shown that both intra and extracellular markers of macroautophagy, previously identified by proteomics, can be detected and quantitated in individual mouse muscle fibers, using mass cytometry. Immunofluorescence microscopy has been used to identify antibodies appropriate for use in mass cytometry. Mass cytometry data will be evaluated using SPADE analysis, and fibers with similarly expressed markers will be grouped. This analysis will allow for the discovery of relationships between cellular markers of macroautophagy. Ongoing work on this project includes labeling appropriate antibodies, and titration mass cytometry experiments.

Abstract Text

Imaging mass spectrometry, a powerful label-free imaging technique with high sensitivity and selectivity, has been increasingly applied in biological and medical research. *Drosophila melanogaster* and *C. elegans* have relatively simple nervous systems but possess high order brain functions, many that are similar to humans. Therefore, these have been used as common model systems in biological studies. In our work, multimodal imaging techniques including ToF-SIMS and MALDI have been utilized to image the fly brain and the worm in order to investigate the effects of stimulant drugs on the brain's chemical structure and the basic chemical anatomy of the extremely small worm.

From ToF-SIMS analyses, different distributions of various molecules, particularly eye pigments, fatty acids, diacylglycerides, and phospholipids have been found spatially across the fly brain. In *C. elegans*, interesting pattern of lipid heterogeneity has been uncovered. Statistical analysis of the fly data with PCA shows that the amounts of several lipids, fatty acids and diacylglycerides in the central brain are altered by drug administration. Tandem MS has been performed to elucidate the structures of molecules affected by the drug. In MALDI analyses, we have explored different sample preparation methods including the use of Au and Pt nanoparticles (NPs), and sublimation to gain improved spatial resolution and sensitivity. Low mass molecules, particularly eye pigments, diacyl-glycerides, and intact lipids, were detectable using Au NPs. In contrast, Pt NPs and sublimation with DHB offered the possibility to detect high mass molecules including intact lipids and peptides with m/z up to 1800 Da. Both types of NPs provided better spatial resolution (20 μm) compared to sublimation. The orthogonal SIMS and MALDI methods provide complementary chemical structural information making them very useful for biological studies on invertebrate models.

Abstract Text

Inflammatory bowel disease (IBD) is a widespread GI tract disease. It affects 1.4 million people in the US and 2.2 million people in Europe. IBD can be triggered by an abnormal immune system response. The exogenous antigens activate T-cells, releasing cytokines from the intestinal epithelium. These cytokines can significantly increase pro-inflammatory cytokines, such as the TNF- α and cyclooxygenase (COX), lipoxygenase (LOX) enzymatic mediating mechanisms are triggered. The pro-inflammatory prostaglandins including 6-ketoprostaglandin F_{1 α} , thromboxane B₂, 8-isoprostaglandin F_{2 α} , and prostaglandins F₂, E₂, and D₂ can be used as biomarkers of the COX pathway during the inflammatory response in IBD. Meanwhile, biomarkers from LOX pathway include leukotrienes such as leukotriene B₄, C₄, D₄ and E₄ and hydroxyeicosatetraenoic acids (HETEs) such as 5-HETE and 15-HETE. Our goal was to develop a LC-MS method to monitor the change of these biomarkers in microdialysis sample to study the roles of LOX and COX enzyme activity in the inflammatory response in IBD. LC separation was obtained by a Phenomenex Kinetex XB-C18 column (100 mm \times 2.1 mm i.d., 1.7 μ m particle sizes) with binary solvent gradient elution. Solvent A consisted of water and 5 mM formic acid. Solvent B consisted of acetonitrile and 5 mM formic acid. The two-step linear gradient was: 0-18 minutes solvent B increased from 25 to 80%, and then remained at 80% for 7 minutes. MS results were acquired by a Thermo ESI ion-trap mass spectrometer. The microdialysis probe was implanted into the rat colon. Ringer's solution was perfused to extract these biomarkers and then the dialysate was analyzed by the LC-MS method. All the 12 analytes were detected with good LOD, from 1-5 ng/L. The regression coefficients (R^2) from the calibration curve (1-50 ng/L) were over 0.999 for PGs and 0.98 for LTs and HETEs.

Abstract Text

The cytoplasm is a dynamic environment that plays an important role in cellular metabolism. Sequential enzymes of several metabolic pathways are known to exist within close proximity, perhaps due to phase separation induced by macromolecular crowding within the cytoplasm. This has been described as the basis for microcompartmentalization and the subsequent colocalization of biomolecules may provide a means of regulation within a metabolic pathway. Aqueous solutions of structurally distinct polymers or a polymer and a salt phase separate over specific weight percentages. Enzymes and substrates preferentially partition to one of the phases, thus increasing local concentration while total volume remains constant. The common sequential enzyme pair of glucose oxidase and horseradish peroxidase was introduced into a polyethylene glycol (PEG):citrate biphasic system. Enzyme partitioning and product formation was monitored by fluorimetry while a mathematical model was used to elucidate the effects of compartmentalization by describing the reaction rates within each phase with respect to partitioning. Results indicate that the interface is influential for product formation when substrates and enzymes are localized in different phases and also suggest that complex reactions within heterogeneous media can be quantitatively described with such models.

Abstract Text

The developments and wide applications of nanomaterials in the past decades have increased dramatically, drawing people's attention to their potential adverse impacts on the environment and human health. Titanium dioxide (TiO₂) nanoparticles (NPs) are manufactured worldwide and widely used in many fields. Although many studies have demonstrated the cytotoxicity of TiO₂ NPs, the mechanism is not well understood and needs to be further investigated. It is anticipated that when cells are exposed to external stimuli, such as high concentrations of NPs, the changes of cellular activities, such as differentiation, gene expression, metabolism, and others, may alter the intercellular and extracellular pHs. Due to the heterogeneous characters of cells, the pH change among different cells maybe different upon exposure to the same concentration of TiO₂ NPs. Therefore, monitoring pH at single cell level is utmost important to understand the response of each individual cell to the change of the environment. In this study, a newly developed micro-pH probe has been applied to measure the pH profile of cell surface at single-cell level. The effects of different sizes of TiO₂ NPs on pH changes at cell surface with different time domain and space domain were investigated. Results showed that pH of cell surface decreases continuously after dosed with TiO₂ NPs and the decreasing rate of pH of cells correlates well with the distance between cells and the TiO₂ NPs. The detail experimental conditions, results, and discussions will be presented at the conference.

This research is supported by National Institutes of Health (NIH).

Abstract Text

The organic ligands surrounding metal nanoparticles (NPs) not only provide stability and control growing during the synthesis but also, creates a flexible platform for sensing volatile organic compounds (VOCs). In this work we chemically synthesized surfactant (tetraoctylammonium bromide)-coated Au NPs and assemble them as films for the detection of VOCs via distinct changes in plasmon band, interparticle distance, and film structure. For instance, changes in distance between NPs upon VOCs have been usually speculated on the basis of indirect results such as changes in film current or plasmon band. Here, we performed in-situ GISAXS and SAXS experiments in order to unambiguously monitor interparticle distance and film structure upon measured concentrations of polar (ethanol) and non-polar (toluene) vapors. Results show distinct film behavior depending on both; the nature of the analyte vapor and organic alkyl chain. In this presentation I will discuss the importance of film flexibility provided by the organic matrix during VOCs sensing. I will show how the organic alkyl chains are responsible of film restructuring, changes in distance between NPs, and distinct plasmon shift towards red and blue depending on the polarity of the vapor analyte.

Abstract Text

A facile approach for shape-controlled synthesis of gold nanoparticles (Au NPs) using 5-hydroxyindoleacetic acid (5-HIAA) as the reducing agent has been reported. Au NPs of various shapes (triangles, hexagons, and semi-spheres, etc.) were prepared by varying the ratio of chlorauric acid and 5-HIAA, temperature, and reaction time. A detailed characterization was performed using ultraviolet-visible (UV-Vis) spectroscopy, scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FTIR) and Raman spectroscopy. The as-prepared AU NPs exhibited excellent surface-enhanced Raman scattering (SERS) properties, which make them extremely attractive for the development of SERS-based chemical and biological sensors.

Abstract Text

Predictable performance of immobilized proteins on many surfaces is a required condition to functional scaffold materials for potential applications in biosensing, tissue engineering, and proteomic platforms. We have utilized polydiacetylene liposomes as an immobilization scaffold for evaluating the behavior of substrate-enzyme reaction activities. Liposomes composed of polymerized 10,12-pentacosadiynoic acid and dimyristoylphosphatidylcholine were used for immobilization of enzyme and substrates at the bilayer. The resultant protein or enzyme covalently bound to liposomes interacted with free Trypsin (Rh-TRY) or fluorescein-BSA (FI-BSA) forming Liposome-Protein-Enzyme (BiPE) or Liposome-Enzyme-Protein (BiEP) complexes respectively. The subtle biological interactions occurring at the bilayer surface were monitored by using electronic absorption spectroscopy, fluorescence anisotropy (FA), and spectral imaging. Both colorimetric response (CR) and FA confirmed enzymatic reaction for BiEP and BiPE. CR increased to 35% and FA decreased from 0.29±0.001 to 0.04 suggesting enzymatic cleavage of bound protein into bulk solution. The fluorescence imaging confirmed the enzymatic cleavage of BSA which showed the fluorescein emission intensity decreased ~60% after one hour of enzymatic reaction. In the second case, BiE generated CR 8% which increased to ~25% after the addition of free FI-BSA probably due to stress imposed by enzyme-protein interactions at the conjugated bilayer. It was discovered that BiPE imposed a much larger stress on the bilayer compared to BiEP. Ultimately, we show that the interactions between enzyme and substrate at the bilayer can provide useful information, and it acts as a model system for potential creation of novel technologies as promising biomolecules-liposomes hierarchical complex structure.

Abstract Text

The photoreversibility of molecular machine-attached onto anisotropic nanostructures have been studied using optical spectroscopy. For the first time, we have observed an unprecedented 21-nm shift of localized surface plasmon resonance (LSPR) peak of gold nanoprism upon cis to trans isomerization of azobenzenes. The observed shift was a combined effect of energy transfer across the nanostructure and azobenzene molecule and increased in the dielectric environment of the nanostructure. We also investigate the mechanism underline large LSPR peak shifts by fine-tuning the distance between azobenzene and gold nanoprisms. Understanding such mechanism will aid in designing of highly efficient sensing platforms for future optoelectronic device fabrication.

Abstract Text

In this work, glassy carbon electrodes (GCE) modified with Self-Assembled (SA) films of polyaniline (PAni) and carboxylic acid functionalized multiwalled carbon nanotubes (MWCNT-COOH) were developed and applied to determine de pesticide 2,4-D. Three different SA films were produced, with 20 alternated layers of PAni or its composite with 5 percent in mass of MWCNT (PAni 5% MWCNT) and with an alternated layer of Polystyrene Sulphonated (PSS). The scanning electron microscopy results (MEV) showed the presence of MWNT that was more evidenced into the PAni/MWCNT/PAni/PSS film. The cyclic voltammetry (CV) results showed an increase of the peak current characteristic of the conducting polymer (PAni) with the increase of the MWCNT proportion. The PAni/PSS film was able to detect 2,4-D by the increase of the current signals even in aqueous media with pH 7,0.

Abstract Text

Monolithic nanoporous gold nanoparticles are of great interest due to the unique 3-dimensional bicontinuous nanostructures with large surface area, tunable plasmonic resonance and high-density hot-spots. Recently we have also demonstrated their potential applications in surface enhanced spectroscopy, photothermal conversion and plasmonic sensing. In existing applications, nanoporous gold nanoparticles have been employed as dense particle arrays fixed on glass or Si substrates. In other words, little has been done in developing colloidal nanoporous gold nanoparticles as a platform to form various nanocomposites with other nanomaterials. In this presentation, we show that by tuning the pore size, small gold nanoparticles can be loaded into the porous structure or attached at the surface of nanoporous gold nanoparticles to form nanoporous gold nanocomposites. The strong plasmonic coupling not only originates from the interaction between nanoporous gold nanoparticles and small gold nanoparticles, but also between small gold nanoparticles. The plasmonic resonance can be easily tuned in both visible and NIR spectral ranges by changing the diameter of attached gold nanoparticle sizes. In addition, potential applications of nanocomposites in surface-enhanced Raman scattering and plasmonic sensing will be discussed.

Abstract Text

Resistive pulse sensing with two nanopores in series is used to measure size and mobility of individual hepatitis B virus (HBV) particles as they self-assemble in real time. A nanochannel with two nanopores in series is milled in glass by a focused ion beam to bridge two V-shaped microchannels. The assembly product is driven through the nanochannel by application of a positive potential, and two decreases in ion current are measured for each transiting species. HBV forms two icosahedral capsids, a 90-dimer capsid with T = 3 symmetry (32-nm diameter) and a 120-dimer capsid with T = 4 symmetry (35-nm diameter), which are discriminated by their relative ion current displacement. Current displacement is proportional to capsid volume, and the 3-nm difference in outer diameter between T = 3 and T = 4 capsids is easily resolved. Capsid velocity is determined from the transit time between pore one and pore two and is used to calculate electrophoretic mobility. Virus assembly is initiated by mixing HBV dimer with a high salt buffer, and assembly is monitored over minutes to hours. Under normal reaction conditions, T = 4 capsids are the dominant product (90%) and resistive-pulse sensing easily differentiates between a T = 4 capsid and a T = 3 capsid, which often unresolved by conventional measurement techniques such as light scattering. Our single-particle counting method reveals differences in the assembly kinetics of T = 3 and T = 4 capsids.

Abstract Text

The use of supercritical CO₂ mobile phases or convergence chromatography (CC) is an attractive alternative to liquid chromatography that provides different selectivity, low solvent usage, and high efficiency separations. To fully take advantage of the potential efficiency gains, greater linear velocities are desired. Furthermore, the analysis of polar analytes by supercritical fluid chromatography (SFC), a normal phase technique, can require a high percent of organic co-solvent for elution. Therefore, the analysis of polar analytes by SFC requires robust instrumentation that can accommodate high flow rates and high solvent viscosities.

To fully realize the benefits of convergence chromatography, it is important to screen a wide range of variables during method development, including organic co-solvent composition, column temperature, column dimension, flow rate, and applied back-pressure. Each of these variables impacts not only the chromatographic separation, but also the overall speed and efficiency of analysis. Increasing the linear velocity to aid in throughput will also increase the overall system pressure. This phenomenon is especially noticeable for SFC methods requiring a higher percentage of organic co-solvent and is compounded further if a complex separation requires the use of longer columns which also generate an increase in system pressure.

Combining convergence chromatography, with instrumentation that has an elevated allowable system pressure, we were able to test a wider range of parameters during method development, ultimately leading to faster, higher efficiency separation methods. Specifically, polar compounds which require high amounts of organic co-solvent for column elution were now run with increased flow rates resulting in more efficient separations and higher sample throughput.

Abstract Text

Quality Control (QC) Laboratories are continually looking for ways to improve efficiency and reduce sample turn-around-time. With this goal in mind the latest advances in Supercritical Fluid Chromatography (SFC) were leveraged for the separation and quantitation of active ingredients in Health, Beauty and Nutrition Products that were previously determined by HPLC and UPLC methods. Method Equivalency was demonstrated by comparing results obtained for 6 sample preparations analyzed by each technique through statistical analysis via a two, one-sided t-test (TOST) at the 95% confidence interval. Nine QC methods were converted that resulted in several efficiency benefits: instrument run time was reduced by 79%, the number of mobile phase solvents was reduced by 82%, the volume of mobile phase required was reduced by 95% and the number of analytical columns was reduced by 78%. Additional benefits were realized by utilizing the column manager and pump module which removed the need to manually switch columns and solvents between analytical runs allowing for the automated sequential testing of different sample sets. Based on the results obtained from this evaluation the recent advances in SFC make it a competitive choice to HPLC and UPLC methodology.

Abstract Text

Brominated vegetable oil (BVO) is often used as a weighting agent, or a solubility-transmitter for citrus oils and other lipophilic compounds¹ in soft drinks and beverages. The US FDA has established a BVO limit at 15 ppm in finished beverages, while many countries in Europe, Asia, South America, and Australia, have banned its use in beverages. Analysis of BVO is rarely reported. Gas chromatography with mass spectrometry (GC-MS) has been proposed recently for the analysis of BVO in soft drinks and cocktail syrups^{2,3}. This GC-MS method requires tedious derivatization (or saponification) of BVO, and has a long run time (about 50min). UltraPerformance Convergence ChromatographyTM (UPC2[®]) is a state-of-art supercritical fluid chromatography (SFC) that provides exceptional efficiency and speed of separation⁴. It has been applied to a wide range of compounds, including VO, and has shown great benefits in selectivity, throughput, and ease-of-use⁵. This work demonstrates a rapid and simple analysis of BVO in soft drinks and beverages using UPC2-MS. BVO was extracted and analyzed directly without any derivatization. The chromatography total run time was 9 min. The analytical method performance (limit of quantitation or LOQ, repeatability, linearity, and recovery) as well as the analysis of BVO in soft drinks and beverages are presented.

Abstract Text

Advancements in SFC instrumentation with specifically designed column chemistries have provided a more robust chromatographic solution. With the new technology, we have also improved the traditional SFC method development strategy, which often took a brute force screening approach. Extensive libraries of column chemistries and multiple combinations of modifiers and additives are no longer necessary to develop successful SFC separations. Using novel, sub-2 μm UPC² achiral chemistries coupled with ACQUITY UPC² instrumentation, we have created a simplified method development strategy by implementing a single column scouting run. Resulting selectivity and peak shape from our 2-Pic chemistry will then direct the user to further optimize or select another specific chemistry and/or specific co-solvent to meet the separation criteria. Research used to design the strategy shows which methanol based co-solvents provide the largest impact on each new chemistry and how chemistry/co-solvent combinations compare to each other. ACQUITY UPC² technology provides a complete system platform that allows users to quickly develop robust methods by accessing a wide selectivity space with exceptional peak shape and separation performance.

Abstract Text

Bioanalysis and drug metabolism studies are critical parts of the drug development process. The aim of these studies is to identify and quantify drugs and their associated metabolites in biofluids such as plasma and urine. Typically reversed-phase chromatography coupled with mass spectrometry is often the analytical technique of choice utilized in the analyses due to the specificity and sensitivity of the technique. However, due to the complexity of the biofluid samples accurate and precise measurements can become challenging due to poor chromatographic peak shape, insufficient chromatographic resolution from matrix components and incompatible sample compositions.

Recent advancements in the field of super critical fluid chromatography (SFC) have lead to the development of sub 2 micron chromatographic separations coupled mass spectrometry operating under positive ESI mode. In the work presented here the applicability of SFC for both chiral and achiral bioanalysis is shown. The orthogonal separation selectivity compared with reversed-phase separations and tolerance for high organic sample compositions will be discussed. This work further presents a critical evaluation of the influence of mobile phase and make up flow modifiers on the sensitivity and selectivity of probe pharmaceuticals analyzed under SFC/ESI positive mode MS conditions.

Abstract Text

Separations via supercritical fluid chromatography (SFC) continue to proliferate as an environmentally friendly separation technique, particularly in format similar to that of packed column liquid chromatography (LC). Stationary phases typically used in HPLC have been explored in SFC. Amide-based columns, where a polar group is embedded in the hydrophobic backbone of a reversed phase type material, provide alternate selectivity towards more polar compounds. These types of phases have not been studied much under SFC conditions. This study has the objective evaluating a C18-amide stationary phase using SFC. The amide column is compared with bare silica and C18 phases. The system was held at supercritical pressure and temperature with a mobile phase composition of carbon dioxide and a co-solvent. The linear solvation energy relationship (LSER) model was used in an attempt to understand the behavior of these materials, relating the retention factor of selected probes to specific chromatographic interactions. Preliminary results show that the C18-amide stationary phase posses combine interactions, as one would expect. The hydrophobic interactions are favorable; however, the electron donating ability of the amide group also shows a large positive interaction. Details of the chromatographic evaluation will be discussed.

Abstract Text

Countless lives have been saved due to widespread blood banking efforts since the advent of blood transfusions and introduction of effective storage conditions. However, managing the supplies of stored blood products continues to be an administrative challenge. Presently, stored red blood cells (RBCs) are considered to be viable for 42 days, but there is strong evidence that blood from different donors does not degrade at the same rate. Observational studies have suggested that these variations are responsible for a variety of post-transfusion illnesses. It would therefore be advantageous to assess the condition of stored blood rapidly and accurately without needing to sample the contents of the bag. When stored in a plastic blood bag, RBCs are known to undergo a multitude of chemical, physiological, and morphological changes over time. Many of these age-related changes (for example, loss of hemoglobin or a decrease in metabolic regulators) produce chemical species that can be characterized using Raman spectroscopy. This study clearly demonstrates that the Raman spectrum of stored RBCs changes as a function of storage age, most notably with specific bands related to the oxygenation state of hemoglobin and supernatant spectra that offers insight into small molecule externalization. Chemometric methods reveal the biochemical components that have previously been associated with ageing. The presented data will show that Raman spectroscopy has promise as a tool for monitoring RBC storage.

Abstract Text

Soft tissue injuries are painful, disabling, and costly. While actual tendon and ligament ruptures are rare, sub-rupture strains and sprains present substantial clinical problems. We have provided the first evidence that overload failure of soft tissues such as tendons is governed by a novel mechanism: discrete plastic failure of collagen fibrils in a series of kink-like structures that develop along the fibril's length. FTIR spectrochemical imaging is one of several techniques that we use to characterize normal, stressed and overloaded tendon. A recent optics upgrade to our thermal source FTIR microscope (Agilent Cary 670/620, 64x64 Focal Plane Array detector) enabled rapid acquisition of spectrochemical images with an effective geometric pixel size (~1 micron edge) at the sample plane. Rapid ex vivo tissue imaging is done in-house, with images collected over larger areas, in less time (minutes), with comparable quality and resolution to the best synchrotron source FTIR imaging capabilities. Image files, initially processed with the Agilent ResPro software, are exported to Matlab™ where the distribution of integrated absorbance peak values is modelled using a Gaussian mixture with two components. The model components for each peak are used to classify each spectrum into the model-appropriate groups. Spectra with alike classifications are averaged to identify differences within the sample. Matched-pair samples are assessed spectroscopically (FTIR) and visually (SEM), so that overload-induced differences in spectra can be directly related to alterations in the tendons' collagen fibril nano-architecture. We will present analysis and implications from our first results on normal and overloaded tendons, prepared with and without prior decellularization.

Abstract Text

Gold microhole arrays are a highly sensitive plasmonic substrate, which can be easily produced by either colloidal lithography or photolithography. We previously reported improved sensitivity by three fold for an IgG bioassay using SPR in Kretschmann configuration and microhole arrays. The micrometric features of microhole arrays lead to the excitation of propagative and localized surface plasmons. In this work, the localized electromagnetic field is exploited for metal enhanced fluorescence (MEF). The design of a SPR-fluorimeter allowed the simultaneous detection of both SPR and fluorescence signals in a labelled protein bioassay. A simultaneous detection of correlated fluorescence and SPR signals will lead to more reliable and sensitive immunoassays. We investigated the MEF phenomenon and optimized the microhole arrays parameters by changing both thickness and hole diameter to obtain maximal enhancement in both SPR and MEF. Up to three-fold fluorescence signal enhancement was obtained for rhodamine 6G deposited on microhole arrays, in comparison to standard thin gold films. As a proof of concept, we used a PSA sandwich-immunoassay and were able to detect both SPR and fluorescence signal. Thereby, we envision bioanalysis using an hour-long procedure on an instrument the size of a lunch box.

Abstract Text

The degradation of carbofuran a frequently carbamate derivative pesticide that is considered a priority pollutant was investigated. This work has been conducted to study the factors (temperature, UV-rays, direct sunlight and pH) affecting on biodegradation of carbofuran pesticide by irradiated fungi . The residue of carbofuran was analyzed by high performance liquid chromatography (HPLC). The results showed that calculated half-life times of carbofuran were 121.95, 102.87 and 36.00 hours at 25, 35, 45 °C, respectively when exposed to different temperatures. The statistically half-life times for carbofuran was 15.14 hours after exposure to UV-rays as a thin film in a glass surfaces. The results clearly showed that the photodecomposition of carbofuran occurred after one hour of exposure to sunlight. The percent loss for carbofuran was 78.70 % after one hour of exposure to sunlight. The results also demonstrated that no carbofuran was detected after 4 days from exposure to pH 9 at 45 °C.

Abstract Text

Batteries and cell phone batteries cause a serious environmental problem today, by presenting in its Constitution and health harmful metals to the environment such as mercury, lead, copper, zinc, cadmium, manganese, nickel and lithium. Classified as class I, hazardous waste, once used, most batteries are thrown in common waste. Studied matrices are landfill waste, garbage, compost manure and sewage sludge. The mud did not show toxic metal concentrations below those required by Brazilian legislation for the use of agricultural waste. The residue of landfill garbage compound showed high levels of Zn, Pb, Cd, Ni, Cr, Mn, Cu and the toxic metals that contaminate the soil, water courses and water table, reach the flora and fauna of the surrounding regions. Through the food chain, these substances come to humans, may cause intoxications, depending on the dose absorbed.

Abstract Text

Nitrogen in soils is important for the evaluation of organic matter and the calculation of the amount of fertilizer to be added by providing information regarding the deficiency or excess of nutritional elements important for plants growth. Nitrogen content is important in determining the quality of various types of crops for feeding and processing, as well as for N-cycle and N-fixation monitoring in agricultural and environmental research. Nitrogen and Carbon analysis in soils gives information pertaining to the deficiency or excess of nutritional elements. For this reason the use of an accurate instrumental analytical techniques is required. As the demand for improved sample throughput, reduction of operational costs and minimization of human errors is becoming every day more notable, it is very important apply a simple and automatic technique which allows the fast analysis with excellent reproducibility. The FLASH 2000 Analyzer, using typically Helium gas carrier and based on the dynamic flash combustion of the sample, copes effortlessly with the wide array of laboratory requirements such as accuracy, day to day reproducibility and high sample throughput. However as in the last years there is a possible worldwide shortage and large cost increasing for Helium, it is necessary to test as alternative gas, Argon which is readily available. This paper presents data on Nitrogen and Carbon determination in soils and plants reference materials with different Nitrogen and Carbon concentration to show the performance of the system using Argon as carrier gas and the reproducibility of the results obtained.

Abstract Text

Se deficiency in dairy cows can cause serious problems such as retained placentas at calving and high somatic cell counts in milk, which in turn reduces milk quality and quantity and increases the risk of mastitis. Se deficiencies in newly born calves and lambs can result in ill-thrift, brought about by reduced eagerness to suckle milk and white muscle disease. It is therefore common place to supplement for these deficiencies with inorganic minerals such as sodium selenite. However, ruminants are less able to absorb inorganic Se (<50% absorbed) compared with organic forms. In addition, the inorganic form of Se is less readily converted into milk Se than its organic counterpart. It is therefore important to be able to determine the Se status of ruminant feeds.

It is a challenging task to quantitatively analyse selenium species in livestock feed. Five selenium species have been investigated in this study. The extraction procedure from livestock feed samples and the separation of the five selenium species is investigated and optimised. HG-AFS technical is used for the detection of Se signals with detection limits between 0.13 and 0.43 ng (3s).

Abstract Text

In the past, there have been several major dioxin and polychlorinated biphenyl (PCB) contamination incidents in food and feed industries such as the Belgium crisis in 1999. This event and other major accidents in Europe demonstrated the importance of monitoring/removing dioxins/PCBs in food and feed. Currently, activated carbon (AC) is the most widely used agent to adsorb dioxins and PCBs in the feed industry. However, the main mechanism for AC adsorption is the planarity effect. In other words, non-dioxin like PCBs (the two phenyl rings of the PCB congeners are not coplanar) cannot be effectively removed by AC (<30% removal). In addition, due to the limited selectivity, AC treatment typically requires elevated temperature (70-80 °C) and special conditions like low pressure (50 mbar) or countercurrent supercritical CO₂ extraction.

Here, a molecularly imprinted polymer (MIP) adsorbent for dioxins/PCB was prepared using a non-covalent fragment imprinting technique. MIP particles were synthesized in methylene chloride/methanol mixture by using 1,2,3,4,5-pentachlorobenzene (PenCB) as a template, 2,4,6-trimethylstyrene (TMS) as the functional monomer, and ethylene glycol dimethacrylate (EGDMA) as the cross-linker. The MIP showed an excellent affinity towards dioxins and PCBs (including non-dioxin like PCBs) in aqueous solution, and the adsorption efficiency is 1.2 ± 0.3 mg kg⁻¹. All dioxin and PCB congeners (10 ng) were nearly completely removed (less than our detection limit) by 3 mg MIP treatment within 30 minutes at room temperature.

Abstract Text

Metabolomics provides an alternative to supplement compositional analysis for substantial equivalence assessment of genetically modified crops. Therefore, understanding of biological variation in metabolites due to multiple factors such as environment (growing location), genetic modification, planting season is of great importance. In this study, two common maize sample sets from the year of 2012 (180 samples) and 2014 (90 samples) were selected, including 5 genetically diverse non-GMO DuPont Pioneer commercial maize hybrids grown at six North America locations. GC/MS and LC/MS were used as complementary analytical platforms to detect a wide range of compound classes. Genedata software was used for data pre-processing and integration. A total of 157 and 139 metabolites were detected in forage and grain samples by GC/MS, while 657 and 256 metabolites were detected in forage and grain samples by using LC/MS positive mode and negative mode combined. Univariate and multivariate statistical analyses were utilized to evaluate the main effects and interaction of environment, genotype, and planting season on the maize metabolome. The results showed that the environment had far more impact than genetic background, which were consistent with previous findings. Moreover, seasonal effects within each location were greater than genotype effects. 30% to 63% of the metabolites in forage samples, and 19% to 65% of those in grain samples, were significantly altered between the two seasons, compared to less than 10% of the metabolites affected by genetic modifications.

Abstract Text

Acid-base equilibrium is related to almost all process occurring in soil. The bioavailability of nutrients for plants, for instance, depends on the solubilization of mineral nutrients in the soil solution, a pH-dependent process. The determination of pH in soil solutions is usually carried on by potentiometric measurements. The soil solutions are prepared from extractions of some soil components with water or CaCl₂ solution. In this proposal a new, simple and direct method for soil pH determinations is proposed using laser induced breakdown spectroscopy (LIBS). Sixty samples presenting different textural composition and having their pH previously determined by pH electrode were considered. LIBS spectra were recorded for each sample in pellets format, using a laser pulse energy of 115 mJ. The laser operated at 532 nm, 4.4 ns pulse duration, and 10 Hz repetition frequency. Intensities of thirty-three emission lines from LIBS spectra, corresponding to emission of Al, Ca, H and O, were used to delineate a partial least square model, which was validated using ten folds cross-validation. The pH values predicted by the proposed model showed a strong correlation with reference values (R= 0.83) and a prediction mean absolute error of 0.3 units of pH. These results highlight the LIBS potential for other determinations beyond the sample elemental composition. Considering soil analysis, the proposed method encloses the possibility of pH determination in addition of nutrients and contaminants using a single LIBS measurement.

Abstract Text

A suitable reverse phase HPLC (RP-HPLC) analytical method was implemented for the quantitative extraction and determination of "active ingredient A" in experimental samples from a very complex soil matrix. During the green house study, soil samples were collected at different time points, expressed in days.

The RP-HPLC separation was carried out by reverse phase chromatography on Zorbax Eclipse C8 column (3.0 x 150 mm, 3.5[μm]); a gradient run using mobile phase A: MilliQ water + 0.01% formic acid, mobile phase B: acetonitrile + 0.01% formic acid; flow rate= 0.5 mL/min; injection volume 5 [μL] and UV-VIS detection at 260nm. The accuracy was calculated, the percent recovery was 98-101% and reproducibility was found to be satisfactory. The calibration curve for "active ingredient A" was linear from 2.5 to 250 [μg/mL], where the limit of detection and limit of quantification were 1 and 2.5 [μg/mL], respectively. The inter-day and intraday precision was found to be within limits. The present analytical method is accurate, precise and it was successfully applied to analyze these research samples.

Abstract Text

Gamma-aminobutyric acid (GABA), four carbon non-protein amino acid, is proposed to be a signaling molecule in response to various abiotic stresses in plants. Salinity and drought are important environmental stress factors that negatively affect plant survival and productivity. The aim of this study was to evaluate the effects of drought and salinity on GABA in Phaseolus vulgaris L. plants. GABA content was determined by HPLC (Agilent 1200) with a modified method. Pre-column derivatized samples were separated with RP-HPLC on a C18 column and UV detection (330 nm) with flow rate 1 mL min⁻¹ and 5 µL injection volume. High salinity increased GABA levels compared with drought stress conditions. However GABA content was decreased with the effect of combined stress conditions. According to our results we can suggest that GABA metabolism is strongly related with primary metabolism products, also drought and salinity stress conditions. We further evaluate the effects of different environmental stress factors on GABA metabolism in different plants.

Abstract Text

Cell surface proteomics has seen momentous developments in the past two decades but still faces major challenges in location verification of identified cell surface proteins (CSPs). Recent approaches focus on modification/labeling of CSPs by chemical reagents followed by mass spectrometric analysis of labeled CSPs. Popular biotinylation reagents have shown some intrinsic disadvantages such as internalization in the cell cytoplasm, poor recovery of biotinylated proteins, presence of endogenous biotin and non-specific interactions between avidin and proteins. In our study, silica coated iron oxide (Fe₃O₄@SiO₂) superparamagnetic nanoparticles (MNPs) of 100~150 nm were utilized to prepare an impermeable and magnetically separable cell surface labeling reagent. Sulfo-N-hydrosuccinimidyl (NHS) ester group was conjugated to the surface of Fe₃O₄@SiO₂ MNPs via a disulfide bond to facilitate removal of the magnetic nanoparticle moiety after separation. The surface exposed amine groups of *Saccharomyces cerevisiae* were modified at physiological pH on ice to preserve the native structure of CSPs. Electron microscopic analysis of MNPs conjugated to the *S. cerevisiae* cell surface confirmed the impermeable nature of sulfo-NHS ester Fe₃O₄@SiO₂ MNPs. The labeled CSPs were easily separated by using a magnet and eluted from MNPs by cleaving a disulfide bond. The LC-MS/MS analysis of labeled peptides revealed 30 surface proteins located on solvent exposed surface of the *S. cerevisiae*. The sulfo-NHS ester modified Fe₃O₄@SiO₂ MNPs offers benefits such as impermeability, quick magnetic separation of labeled peptides and labeling under physiological conditions.

Abstract Text

Magnesium and its alloys are receiving increased interest in the field of biodegradable materials because of their good metallic strength, light weight, low toxicity and rapid corrosion rate in aqueous solutions. Various magnesium alloys have been developed in order to better control their corrosion rate, but due to the lack of standard procedures in testing the corrosion rate in vivo and in vitro, few systematic studies have been reported. We have developed the capability for monitoring in real time the Mg corrosion process in vivo for corrosion products using a H₂ sensor. We also established a protocol for in vivo corrosion studies to obtain the surface composition of explanted Mg alloy by surface spectroscopies such as XPS; the distribution of corrosion products in the tissue surrounding an implant and in critical organs of test animals using bioanalytical techniques involving extraction and ICP-MS.

Abstract Text

Volatile nitrosothiols (vSNOs) are presented as a compound class that should be taken into consideration for cancer disease markers in breath and from tissue emissions. Methyl-, ethyl-, 2-propyl- and allyl-SNOs have been synthesized in a two phases reaction between an aqueous layer covered with n-decane. The reaction is carried out with the corresponding thiols and sodium nitrite in the presence of oxalic acid. The reaction solution turns into red due to the production of the colored vSNOs. The evolving and decomposition of the vSNOs in the reactor system has been monitored by online-MS/MS of the headspace gas of the reaction solution. Spectra of the vSNOs among educts and decomposition products have been recorded by loop injection on fast GC/MS at sub ambient temperatures. Storing the reaction mixtures as diluted n-decane solutions in air tight diffusion devices allows handling them for weeks without decomposition and to train sniffer dogs. The behavior of sniffer dogs has shown that the proposed vSNOs seem to be very similar or even identical to cancer odor emission. Details of the synthesis, pictures of the reaction solutions, analytical runs and construction parts of the diffusions devices are presented.

Abstract Text

Circulating tumor cells (CTCs) show great potential for cancer diagnosis as well as guiding cancer treatment. However, the rare number of CTCs in peripheral blood hinder its application, making its detection and analysis a big challenge. Antibody-based CTC isolation method has been proved to be one of the most efficient method for CTC enrichment in patient blood. Microfluidic device with micropost array in microchannels, a popular device used for antibody-based CTC isolation, gives high CTC capture efficiency and purity due to its specific geometry. However, how CTCs interact with such a microfluidic device under different flow conditions remain unclear. We report here cancer cell distribution around microposts under different flow conditions. Homogenous human acute lymphoblastic leukemia cells (CCRF-CEM) were used as target cells in this study. We used high affinity aptamers as an alternative to antibodies for cell capture. Flow rates and post shapes were studied as the parameters that affect flow condition. While higher flow rate decreased cell capture efficiency, cell captured locations around microposts also changed, leading to higher ratio between cells captured around the front half of a micropost vs cells captured around the back half of a micropost. As comparison with experimental result, simulation based on COMSOL was conducted. A 2D model was set up to model a section of a microchannel with a micropost array. The detailed results and comparison will be presented in this paper.

Abstract Title **Alkylated Porous Poly (styrene-divinylbenzene) Particles: A Superior Phase for Analytical and Preparative Oligonucleotide Separations**

Primary Author Derek A. Jensen
Hamilton Company

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s)

Abstract Text

Synthetic oligonucleotides are typically purified using ion-pair reversed-phase HPLC. One problem for preparative scale separations has been the restriction of mass transfer within the porous network or exclusion of larger molecules from the pores altogether. Use of elevated temperatures (> 60 [degree]C) improves mass transfer, leading to improved resolution and peak shape, however, silica-based C18 (ODS) columns have diminished lifetimes under such conditions. Instead, columns based on poly(styrene-divinylbenzene) (PS-DVB) have been attractive alternatives due to their superior thermal (>100 [degree]C) and pH stability (pH 1-13). However, predecessor PS-DVB beads suffer from poor mechanical stability and lower efficiency compared to ODS.

In this study, a porous, mechanically-stable (> 5,000 psi) C18-functionalized PS-DVB-based column has been evaluated for analysis and preparative scale purifications of trityl-off DNA oligonucleotides. Resolution and loading for the C18-alkylated PS-DVB column was superior to both unmodified PS-DVB and organic/inorganic hybrid silica-based C18. The thermal stability of the new polymeric support permits use of elevated temperatures (up to 100 [degree]C) to further enhance efficiency. Long (> 60mer) DNA oligonucleotides could be separated from n-1 truncated sequences in 10 minutes with single nucleotide resolution.

Abstract Text

Misuse of growth hormones and steroids have become a recurring problem amongst professional and amateur athletes. Not only performance-enhancing drugs undermine ethical issues in competitive sports but also present serious health threats to the abuser. Recombinant human growth hormone (rhGH), a 22 KDa polypeptide, is a banned substance by the World Anti-Doping Agency and much effort by international researchers has been focused onto developing tests that can reveal its presence or anabolic effect. A number of detection tools such as mass spectroscopy (MS) and enzyme-linked immunosorbent assay (ELISA) have been developed to monitor the level of these drugs in blood as a reliable measure of doping; however, these tests suffer from either lack of sensitivity or laborious work. In this study, the diagnostic potential of a Surface Plasmon Resonance imaging (SPRi) in combination with semiconducting nanoparticles (NanoSPRi) or without was assessed for measuring hGH in serum and was compared with commercially available ELISA kits. Our results strongly suggest that SPRi and Nano-SPRi encompass many advantages over ELISA.

Abstract Text

Proteins exist in a highly ordered, folded state. This highly ordered structure of a protein is integral to the efficacy and safety of the protein-based bio therapeutic. Conformational changes of proteins by solvent induced unfolding may result in conformational changes, even if not completely denatured. As a protein begins to unfold, the hydrodynamic radii of protein species change. Different proteins are susceptible to solvent induced unfolding to a different extent. The change in the conformation due to solvent induced unfolding is possible to be identified by the associated volume changes by size-exclusion chromatography and can be detected by the change in the intrinsic fluorescence of the tryptophan containing proteins. Larger the molecular exclusion limit, expectedly it is easier to monitor the volume changes associated with the unfolding, provided the conformation of the unfolded state is stable under the chromatographic conditions of analysis. Here we report the study of the stability of proteins and antibodies in solvents containing guanidine hydrochloride or urea. A 3 μm particle size, 30 nm pore size SEC column with 2500 kDa molecular weight exclusion limit is used for the separation and intrinsic tryptophan fluorescence of the proteins and antibodies is used for the detection by fluorescence detector.

Abstract Text

The mission of the National Institute of Environmental Health Sciences (NIEHS) of the National Institutes of Health is to discover how the environment affects people in order to promote healthier lives. To realize this mission the NIEHS supports a wide variety of fundamental and applied research, including the development of technologies and approaches that can more precisely measure environmental exposures at the level of the individual and characterize how different individuals respond to those exposures with respect to disease risk. Through the Small Business Innovative Research (SBIR) and Small Business Technology Transfer (STTR) programs, NIEHS supports small businesses to develop new tools for exposure assessment, including wearable sensor devices to quantify exposures to multiple environmental exposures in real time with location information. Other exposure assessment approaches include remote sensing technologies and devices that combine analyte detection with other lifestyle factors including physical activity and physiological responses to changing exposure conditions. NIEHS also supports the development of assays and biomarkers to characterize individual responses to environmental stressors, novel methods for measuring internal concentrations of environmental agents, remediation technologies for hazardous sites, and computational approaches to use data from toxicology studies to link chemical exposures to pathway alterations and disease outcomes. Priorities for SBIR/STTR research and technology development for NIEHS will be presented and the application and review process for NIH SBIR/STTR grants will be discussed.

Abstract Text

Many bioconjugate nanosystems have been developed in analytical chemistry, medicine and pharmacy. Gold nanoparticles (AuNP) are most commonly used in nanotechnology and a number of bioconjugation techniques to advance properties of these nanoparticles has been proposed. The choice of proper bioconjugation approach is a very important issue because it directly affects the orientation, accessibility, and bioactivity of biomolecules immobilized on nanostructures [1]. The aim of this study was to synthesize magnetic gold and polymeric nanoparticles and modify them with antibody molecules or enzyme glucose oxidase in order to develop multifunctional nanoparticles for biomedical application. Magnetic-AuNP (M/AuNP) are suitable for protein immobilization and practical applications in biomedicine. The same surface modification methods as that used for AuNP functionalization can be used; it is very simple to separate M/AuNP from the solution; functionalized nanoparticles are free of reagents used for modification. Advanced properties of M/AuNP will be discussed. Poly(pyrrole-2-carboxylic acid) (PCPy) particles were synthesized in aqueous media by chemical oxidative polymerization of pyrrole-2-carboxylic acid monomers using H₂O₂. PCPy particles were of 50 – 100 nm in diameter. These particles were modified with glucose oxidase (GOx) via primary amine groups after activation of the PCPy carboxyl groups. The stability of GOx was tested electrochemically. After 18 days the electrochemical signal of electrodes modified with nanoparticles retained 46.3% of the initial activity.

Abstract Text

Tissue engineering through directed growth of cells on a biological scaffold has tremendous potential to transform human medicine. A key challenge lies in removing cells and immunogenic material from a donor organ while maintaining scaffold properties that will promote growth of newly seeded autologous cells. Another challenge is to understand how reseeded cell types interact with each other and with the scaffold. We examine both the decellularization and recellularization processes using proteomics on samples from vocal folds, livers, and lungs.

We analyzed decellularized scaffolds and identified, with in-depth coverage, remnant cellular proteins that may be unfavorable, and extracellular matrix (ECM) proteins that may be crucial determinants of directing constructive tissue remodeling. Quantitative analysis of change in individual protein abundance through the decellularization process was performed. The observation that the decellularized scaffolds still contain many cellular proteins, although at decreased abundance, indicates that elimination of DNA does not assure adequate removal of all cellular material, underscoring the need for incorporating proteomics into the decellularization evaluation toolbox.

As for recellularization, using vocal fold mucosa (VFM) as model system, we compared different reseeding approaches, developed a novel strategy employing SILAC to differentiate between proteins that were already in the scaffolds and newly synthesized ones, thereby assessing the active protein synthesis and in vitro remodeling of the ECM. The VFM is an attractive model for matrix remodeling studies because it contains an exquisite ECM that is finely tuned for biomechanical transfer of aerodynamic energy to acoustic energy during voice production. Our study analyzes, for the first time, the dynamic relationship between matrix and growing cells, providing biological system-wide insight into the tissue regeneration process.

Abstract Text

Multipurpose contact lens solution (MPS) preservatives have been suggested to cause corneal injury. To determine the validity of this assumption, the molecular-level interactions of common disinfectants in soft contact lens MPS and the corneal epithelium using an in vitro model were assessed. A liposome-based model of the corneal epithelial surface was developed and used to assess the interactions of polyhexamethylene biguanide (PHMB), and polyquaternium-1 (PQ-1) on membrane components and the effects of PHMB and PQ-1 on membrane integrity. Membrane integrity was assessed by measuring the liposome transition temperature using the lipophilic fluorescent probe 6-dodecanoyl-2-dimethylaminonaphthalene (Laurdan). Laurdan is a fluorescent probe that detects changes in membrane phase properties through its sensitivity to the polarity of its environment in the bilayer. Variations in the membrane water content cause shifts in the Laurdan emission spectrum, which are quantified by calculating the generalized polarization (GP). Laurdan fluorescence can then be used to distinguish differences in the membrane order and fluidity by measuring the temperature dependent Laurdan GP. It was found that PHMB improved membrane integrity through interactions with the membrane surface observed as an increase in Laurdan GP and an increase the membrane transition temperature. In contrast, PQ-1 had no effect on membrane integrity as observed by no change in Laurdan GP or the membrane transition temperature. However, upon PQ-1 addition interactions between the membrane surface and PQ-1 caused liposomes to aggregate significantly and precipitate from solution leading to the conclusion that PQ-1-to-liposome bilayer interaction is destructive on a larger scale.

Abstract Text

According to the World Health Organization (WHO), breast cancer is the most fatal form of cancer for women worldwide and attributes to 16% of all female cancers. Although there have been many advances in early detection and treatment, a cure is yet to be discovered. Immunotherapy, which is designed to induce or enhance immune response, is being explored as an alternative to current therapies, including surgical resection, chemotherapy, and radiation therapy. While vaccines are most commonly used prophylactically for several infectious diseases, this study attempts to explore the benefits of a therapeutic cancer vaccine. Here, we will aim to formulate and evaluate a therapeutic breast cancer vaccine using a microparticulate delivery system. The whole cell lysate (WCL) of 4T07 murine breast cancer cells will be incorporated in an aqueous polymer matrix and spray dried with a Buchi B-290 mini spray dryer to formulate an enteric protected vaccine microparticle. The total protein concentration of the WCL will be determined by Bio-Rad DC total protein assay. Additional cell based assays, including MTS cell cytotoxicity assay, phagocytosis studies, and various immune response studies, will be used to evaluate the efficacy of the particulate vaccine. This approach can potentially be translated to a future clinical setting, wherein the patient undergoes surgery and their tumor cells can be used for an individualized particulate vaccine, which can be administered therapeutically to avoid relapse.

Abstract Text

Photothermal therapy (PTT), as a minimally-invasive therapy, has generated a great deal of interest to kill cancer. Better targeting of photoabsorbers to tumors, has become a new concept in the battles with cancer for improved treatment efficacy and reduced side effects. In this study, the bombesin analog (BBN), with binding ability to all GRP receptor subtypes, was bound covalently with gold nanorods (GNRs) via the nanothink acid as a linker and coated with PEG to increase stability and biocompatibility. The interactions were confirmed by UV-vis and FT-IR spectroscopy. Cytotoxicity study showed biocompatibility of GNR-BBN-PEG conjugate. The cell binding and internalization studies showed high specificity and internalization of GNR-BBN-PEG towards breast cancer cells. The in vitro study revealed destroying of breast cancer cells exposed to new agent and 830 nm continuous wave laser irradiation for 3 min at 80 mW. The biodistribution study showed significant accumulation of GNR-BBN-PEG in breast tumor in mouse model. The in vivo photothermal therapy showed the complete disappearance of xenographted breast tumor in mouse model. The results showed considerable potential of new nanodrug to selective killing of cancer cells in mouse model.

Abstract Text

Molecular recognition-based separation techniques have received much attention in chemistry and biology because of their high selectivity for target molecules¹. Cholesterol, chosen as a target molecule of molecular imprinted membranes investigated in this study, is a major ingredient of the plaque that collects in the coronary arteries and causes coronary heart diseases². Cholesterol imprinted poly(2-hydroxyethylmethacrylate-co-methacryloylamidotryptophan) [p(HEMA-co-MATrp)] membranes were prepared by UV irradiation. Functional monomer MATrp was synthesized by the reaction of L-tryptophan and methacryloyl chloride. 2,2-azobisisobutyronitrile (AIBN) and toluene were used as initiator and pore maker, respectively. Cholesterol imprinted membranes were characterized by elemental analysis, FTIR and SEM. Adsorption experiments were performed in batch experimental set-up in methanol or intestinal mimicking solution. Stigmasterol and estradiol were used as competing molecules in selectivity tests. Obtained some results were as follows: According to the elemental analysis results, with the increase in the amount of functional monomer MATrp in the polymerization medium, incorporation of MATrp was increased. Specific surface area of NIP and MIP particles were found as 13.7 m²/g and 36.5 m²/g, respectively. Template molecules were removed from the membrane in the ratio of 82-88%. Imprinted membranes were 1.96 and 2.13 times selective with respect to the stigmasterol and estradiol, respectively. Imprinted membrane showed negligible loss in the cholesterol adsorption capacity after ten adsorption-desorption cycles with the same adsorbent.

Abstract Text

Raman spectroscopy can provide a molecular-level signature of the biochemical composition and structure of cells with excellent spatial resolution and could be useful to monitor changes in composition for early stage and non-invasive cancer diagnosis, both ex-vivo and in vivo. The high wavenumber region (2,800–3,600 cm^{-1}) provides more specific information based on N-H, O-H and C-H vibrations and can be used to identify changes, for example, in lipidic content. It is known that ethanol has a strong effect on the cell membrane, which could directly affect changes in the membrane and cytoplasm lipidic structure and content. In this study, we demonstrate the potential of using the high-wavenumber spectral region of the Raman spectrum to discriminate between oral cells lines treated and non-treated with 1% ethanol. The in vitro Raman spectra were analyzed by the area under the curve as a discriminate method. In this region we discriminated comparing the vibrational modes of CH₃/lipids and OH-confined water bands. Also we were able to demonstrate the effects of ethanol in the cell membrane by using dynamic molecular analysis. These results show the importance of the effects of ethanol for cancer-induced in oral mucosa, which is not completely clear in literature.

Abstract Text

Oral and Pharyngeal cancers are the sixth most common worldwide. 90% of intraoral cancers are squamous cell carcinomas (SCC). They are associated with high morbidity and mortality rates with a 5 year survival of 50%. Oral SCC is often preceded by dysplastic changes in the epithelium and a host of molecular changes such as the inactivation of p53 and overexpression of EGFR and cyclin D1. Cyclin D1 is overexpressed in a number of carcinomas such as breast, oesophageal, ovarian, hepatocellular, colorectal, and head and neck carcinoma. Cyclin D1 overexpression has been associated with increased metastasis and poor prognosis. Raman spectroscopy can be used to determine the biochemical composition of a sample, where each peak corresponds to certain vibrations in molecular bonds. The aim of this study was to investigate Raman spectroscopic profiles and cyclin D1 expression levels in oral cancerous cells. An oral squamous cell carcinoma cell line, SCC4 was used for the study. The cells were synchronized using thymidine and the percentage of cells in each cell cycle phase was determined using flow cytometry. A fluorescently tagged secondary antibody was used to detect the expression of cyclin D1 in the cells. In parallel Raman spectroscopy was carried out on the synchronized cell populations. The results showed that cyclin D1 expression varied at different stages of the cell cycle, with higher expression in G1 and G2/M phases of the cell cycle compared to S phase. Raman spectroscopy could separate the different phases of the cell cycle which we were able to show using unsupervised PCA and linear discriminant analysis utilizing leave one out cross validation.

Abstract Text

Melatonin played an important role in Alzheimer's disease as an antioxidant and as a neuroprotector. This study focused on development of the novel sensitive substrate of Fe₃O₄@Ag core-shell magnetic nanoparticles for melatonin detection. Fe₃O₄@Ag nanoparticles were synthesized, and their surface morphology and structure were characterized using TEM. The sensitivity and reproducibility of the substrates were tested by detecting rhodamine 6G (R6G), a common SERS probe molecule. More importantly, this substrate showed big advantages of extraction and enrichment of low concentration R6G samples which could further lower the detection limit. This study provides a potential method for analysis of trace amount of melatonin in complex biological samples by combining separation and detection.

Abstract Text

Resource-poor settings have trouble treating diabetes with glucometers because test strips are either unavailable or unaffordable. Some regions receive donated equipment, but each strip type is only compatible with one type of meter. If the donations are not the same every time or are not consistent, they do not meet the need of the patient. A meter without its specific type of strip cannot be used. We have designed a system to help resolve these issues using modified ink-jet printing to create affordable test strips that can be read by a colorimetric glucometer. We fill color cartridges with enzyme and dye solutions and print them onto filter paper backed by contact paper. The filter paper allows for separation of the red blood cells from the plasma in the blood sample, and the contact paper provides wet strengthening for the strips. The reaction between the enzymes and dye (Glucose Oxidase, Horseradish Peroxidase, and 2,2'-Azino-Bis(3-Ethylbenzthiazoline-6-Sulfonic Acid) creates a linear relationship between the absorbance measurement of the test strip and the glucose concentration. We have designed a meter from easily sourced parts that reads the absorbance and calculates the glucose concentration. The strips would be able to be manufactured in resource-poor settings, alleviating the dependence on donations. They are much more affordable as well, costing \$0.013 apiece to produce, opposed to the average \$1 cost of strips currently on the market. Future work will involve testing using human blood and eventually distribution in Tanzania via our partnership with Madaktari Africa.

Abstract Text

Antimicrobial peptides kill bacteria by disrupting the bacterial cell membrane and it is therefore difficult for bacteria to develop drug resistance. They have been widely researched to be used as new antibiotics and to be immobilized on surfaces to produce effective antimicrobial coatings. In this study, we immobilized an antimicrobial peptide, MSI-78, onto a self-assembled monolayer (SAM) surface via click chemistry. Two mutants, MSI-78 with an azido functionality on either N- (nMSI-78) or C-terminus (MSI-78n), were clicked to alkyne terminated SAMs. Sum frequency generation (SFG) vibrational spectroscopy was applied to characterize the structural information of the surface immobilized MSI-78 via different termini. SFG results showed that both immobilized peptides adopt an alpha-helical structure, but with different orientations, with nMSI-78 standing up and MSI-78n lying down on the surface. Coarse grain molecular dynamics simulations were used to validate the SFG data and provided more detailed understanding on the peptide-surface interaction. The antimicrobial activity tests indicated that the “standing-up” peptides interact with bacterial cells much quicker than the “lying-down”. Such antimicrobial surfaces prepared using immobilized MSI-78 with click chemistry were found to be easy to prepare, store and very stable. We believe that this study provides fundamental insights into how to rationally engineer peptides and substrate surfaces to produce optimized abiotic/biotic interfaces for antimicrobial applications and beyond.

Abstract Text

The objective of this study is to investigate the efficacy of either individual or combined doses of idebenone, carnosine and vitamin E in ameliorating some biochemical indices in liver of nano-sized Titanium dioxide (n-TiO₂) intoxicated mice. Nano-anatase TiO₂ (21nm) was administered as a daily oral dose of 150 mg/Kg for 2 weeks followed by the aforementioned antioxidants daily either individually or in combination for 1 month. N-TiO₂ induced a significant elevation in serum levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST) and hepatic oxidative stress biomarker malondialdehyde (MDA) associated with a significant reduction of glutathione (GSH) level, however the hepatic inflammatory markers [Tumor necrosis factor- α (TNF- α) and Interleukin -6 (IL-6)] were augmented by n-TiO₂. Caspase-3 level along with Bax gene expression were also enhanced while Bcl2 was down regulated. COMET assay showed DNA damage post n-TiO₂ administration. Moreover, mRNA gene expression observed a significant elevation in nuclear factor kappa beta (NF- κ B) and nuclear factor relation-2 (Nrf2). Histopathological examination of hepatic tissue reinforced the previous biochemical results. Co-treatment with either idebenone, carnosine, vitamin E alone or in combination ameliorated the deviated parameters with a variable degrees against n-TiO₂ toxicity in mice. In conclusion, our findings suggest that the different treatments exert a therapeutic protective effect in n-TiO₂ toxicity by decreasing oxidative stress, mRNA gene expression and hepatic tissues DNA damage.

Abstract Text

Cancer treatment currently focuses on radio-, chemo- and immune-therapeutic techniques; however, these treatments also show toxicity toward normal cells. Considering the massive side effects on patients from these treatments, it is essential to develop new techniques that are selective toward cancer cells. Recently, a new group of compounds, i.e. a Group of Materials Based on Organic Salts (GUMBOS), have been designed and are being studied for various applications. These solid phase ionic liquid mimics are also organic salts; however, their melting points make their applications much wider. Synthesis of a range of hydrophobic to hydrophilic GUMBOS was accomplished through anion variations and relative hydrophobicity was measured using octanol-water partition coefficients. Bio-spectroscopic technology was then used for determination of cytotoxicity using cell viability bioassays. Interestingly a trend between cytotoxicity and hydrophobicity was observed with the Rhodamine-6G GUMBOS. Experimental evidence shows that toxicity of the Rhodamine-6G dye towards cancer cell lines as well as normal cell lines are quite different. In this regard, hydrophobic GUMBOS formed nanoparticles which are selectively toxic towards cancer cells with lowered toxicity towards normal cells. Previous research shows that Rhodamine-123, a derivative of Rhodamine-6G, and Crystal Violet are also toxic to cancer cells. This research has advanced to investigating the trend of cytotoxicity and hydrophobicity of Rhodamine 123 and Crystal Violet using the previously determined GUMBOS strategy.

Abstract Text

Pancreatic cancer is one of the deadliest cancers with a mean survival time of few months: 4-8 months for more than 80% of patients. The main reasons of this poor prognostic are the absence of specific symptoms and the lack of biomarkers, leading to a late detection. Aptamers are single stranded DNA oligonucleotides which bind to their target with good specificity and high affinity. They are generated through a process name cell-SELEX (cell based Systematic Evolution of Ligands by EXponential Enrichment). The principle of SELEX is the evolution of an initial random library of 10^{15} DNA sequences through successive rounds until the binding sequences (10^6 sequences) are enriched and a panel of aptamers is generated. Once generated, those probes need to be characterized in term of binding affinity, specificity as well as the potential to get internalized. The main advantage of cell-SELEX is the generation of a probe to recognize a whole cell instead of a specific protein removing the need of knowing the target before starting the selection and leading to the discovery of new biomarkers. In this study, these probes have been developed to recognize pancreatic ductal adenocarcinoma and they have been characterized. In brief, the generation of new molecular probes to recognize pancreatic cancer cells is required in order to detect and treat more efficiently this disease.

Abstract Text

Carnitine palmitoyltransferase 1 (CPT1) catalyzes the rate-limiting step in long chain acyl-CoAs's transport from cytoplasm to the mitochondrial matrix. There are 3 CPT1 isoforms: CPT1A is mainly in liver and it is located in the outer mitochondrial membrane (OMM). CPT1B is located in the OMM of muscle and brown adipose tissue and CPT1C is expressed in brain and testes, and its location is ER. Their structures are not described as they have not been crystallized yet. Studies about their quaternary structure using chemical cross-linking methodology suggest that CPT1A self-assembles into an oligomeric complex of trimers, which associates into a dimer to yield hexamers. Nothing is claimed about CPT1C's disposition in the ER.

Our objectives are:

- (1) Confirm CPT1A's conformation in the OMM.
- (2) Define if CPT1C adopts the same polymeric organization as CPT1A.
- (3) Study CPT1A-CPT1C's interactions in contact sites between mitochondria and ER.

To achieve these objectives, we designed recombinant CPT1 proteins bound to fluorophores in the C-terminal region. Different tones of fluorophores were used: turquoise (Turq2) and yellow (SYFP2). We obtained four plasmids: hCPT1A-Turq2, hCPT1C-Turq2, hCPT1C-SYFP2, hCPT1A-Turq2-hCPT1C-SYFP2. We confirmed their correct sequence by sequencing all the constructs. We also found the best transfection conditions for the chimeric protein's expression in HEK293A cells. Analysis of the transfections by confocal microscopy confirmed their correct protein expression. Transfected cells are ready to be analyzed by AFRET technology to obtain the distances between fluorophores and determine CPT1A and CPT1C's structures and interactions. AFRET's assay is being carried out by Pilar Lillo's group in Rocasolano Biological Physicochemical Institute (Madrid).

Our future work is immunoassay with endogenous CPT1A and CPT1C and study in which pathological conditions CPT1C migrates to OMM.

Abstract Text

Chemotherapeutic Drugs with Low aqueous solubility, High systemic toxicity, Lower cellular entry, and Instability at physiological pHs. However the advantages of cancer nanotechnology Nanotechnology may also be useful for developing ways to eradicate cancer cells without harming healthy, neighboring cells. Scientists hope to use nanotechnology to create therapeutic agents that target specific cells and deliver their toxin in a controlled, time-released manner. Highly selective targeting to cancer cells without harming healthy cells; Nanosystem can do much more than deliver treatment. NIR spectral region is ideal for in vivo imaging. Multifunctional nanosystem offer more powerful outcomes for cancer therapy. They can do much more in an all-in-one system: 1) assist in imaging inside the body; 2) recognize precancerous or cancerous cells; 3) release a drug that targets only those cells, and 4) report back on the effectiveness of the treatment. Gold Nanorods Conjugated with Doxorubicin and cRGD [cyclo(Arg-Gly-Asp-D-Phe-Cys)] for Combined Anti-cancer Drug Delivery and PET Imaging Synthetic scheme for the multifunctional GNR-DOX-cRGD-64Cu nanocarriers.

It is expected that most DOX conjugated onto the system would not be released prematurely into the bloodstream (pH 7.4) before reaching the targeted tumor sites, yet provide a sufficient amount of drug to effectively kill the cancer cells once the nanosystems are internalized and enter the endocytic pathway, thereby greatly enhancing the therapeutic efficacy while reducing the undesirable side effects.

The level of cellular up-take of the GNR nanocarriers or free DOX directly correlated with cytotoxicity. Increasing cell uptake using cRGD peptides conjugated onto the GNR nanocarriers to target α V β 3 integrin on tumor cells can directly increase cellular destruction.

Abstract Title **The Determination of Mercury in Unstabilized Hydrocarbon Liquid Streams by Vaporization-Amalgamation-Atomic Fluorescence Spectrometry**

Primary Author Matthew A. Dexter
P S Analytical

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Peter B. Stockwell, Warren T. Corns

Abstract Text

Unstabilised hydrocarbon liquid streams such as unstabilised condensate present particular challenges for sampling and determination. If the liquid sample is depressurised, a portion of the sample is vaporised, producing a two phase sample for determination. Mercury can be associated with both the gas and liquid portions of the sample. Conventionally, determination of liquid process streams which are gas-liquid mixtures when depressurised is difficult due to the need to characterise two separate phases and combine the results.

This poster describes a novel offline auto-injection system designed to introduce the sample to the analyser at process pressure to avoid the issues associated with depressurisation. Sample is collected into a sample vessel (or “bomb”) at process conditions. The vessel is then connected to the auto-injection system where it is pressurised with nitrogen to ensure it remains 100% liquid. A pressurised sample flows through an injection valve, where aliquots of sample are introduced to the vaporisation chamber of a pre-concentration unit, operated in conjunction with an amalgamation-atomic fluorescence spectrometry analyser.

This poster further describes a similar online implementation, using ATEX/IECEx zone 1, certified equipment. The system can be configured for up to eight sample streams. Filtered sample is delivered at process pressure to an injection valve, where aliquots of sample are introduced to the vaporisation chamber of a pre-concentration unit and amalgamation AFS analyser. Both the Pre-concentration unit and analyser are located in purged enclosures.

Results will be presented for demonstrating both the offline and online approaches.

Abstract Text

In order to accurately assess battery safety in a particular application, a safety evaluation needs to use realistic application scenarios including power drain, charge modes, duty cycle, and so on. Adiabatic calorimeters accurately provide “worse case” or “real life” measurements which is why they are commonly used in safety applications to study and prevent runaway reactions. In addition, the ability to safely and accurately measure the heat changes associated with the charging and discharging process is key to battery management system (BMS) design and for correct thermal management. Isothermal Calorimetry, on the other hand, is the best approach to get this information for large lithium ion batteries used in EV applications as other approaches simply do not scale appropriately for these larger systems. Cycling a cell inside a calorimeter can provide information on the efficiency of the battery and the effect of added connections and other support electronics, such as the BMS, to larger modules and packs. This poster will compare both Adiabatic and Isothermal Calorimetry methods as applied to lithium ion battery characterization with regards to their safety and performance aspects.

Abstract Text

Formic acid (HCOOH) has been considered a promising fuel in power technologies, for its low toxicity, low crossover, good electrical conductivity, high open circle potential, and availability from biomass. However, effective electro-oxidation of HCOOH requires the use of highly efficient anodic catalysts. We report here the syntheses of four palladium (Pd) based nano-materials and their catalytic activities towards the electrochemical oxidation of HCOOH. The first and second Pd nano-sized catalysts were prepared by chemical reduction using NaBH_4 of PdCl_2 mixed with graphite nano-particles (GNP) (~10 nm) and graphite powders (C) (20-50 nm), respectively. The as-prepared Pd/GNP and Pd/C catalysts were casted on glassy carbon electrodes (GCE) with Nafion separately, and used for HCOOH oxidation. The Pd/GNP catalyst prepared from 1 to 4.2 molar ratio of PdCl_2 over GNP showed a broad electrochemical oxidation peak at $\sim +0.30$ V vs Ag/AgCl (3.0 M KCl) in 0.10 M HCOOH-0.10 M H_2SO_4 . However, when the molar ratio of PdCl_2 /GNP and PdCl_2 /C changed to 1/1.7, the particles showed greater stability with oxidation peaks at $\sim +0.13$ V for Pd/GNP and $\sim +0.18$ V for Pd/C nanocatalysts, respectively. The morphology (SEM images) and energy-dispersive X-ray spectroscopy (EDX analysis) were also reported for both the catalysts. Additionally, 20 wt% Pd nano-materials on three different carbon based support materials (GNP, Vulcan XC-72, and Ketjen Black) were synthesized. The prepared catalysts were compared with the commercial 20 wt% Pd/activated carbon for formic acid electrooxidation using Hg/Hg $_2$ SO $_4$ (satd. K $_2$ SO $_4$) with a 0.025 mg Pd/cm 2 of GCE as catalytic load. The stripping peaks at $\sim +0.05$ V vs Hg/Hg $_2$ SO $_4$ (satd. K $_2$ SO $_4$) were also explained in terms of change in scan rates as with slower scan rates (10 mV/s and below) the peak disappeared which corresponds to the reduction of PdO to Pd. Furthermore, the reference electrode was changed from Ag/AgCl (3.0 M KCl) to Hg/Hg $_2$ SO $_4$ (satd. K $_2$ SO $_4$) as the typical formic acid oxidation behavior was not observed which is under investigation.

Abstract Text

Hydrogen measurement is critical to the control of a number of modern refining and chemical processes. Wide spread deployment of hydrogen measurement has been impeded by harsh process conditions that rapidly degrade common low cost hydrogen sensors. In this paper we present a novel sensing technology that overcomes these limitations and explore some of the applications that are thus enabled.

Abstract Title **TD-NMR Combined with Chemometrics Analysis: An Alternative Tool for Monitoring Diesel Fuel Quality**

Primary Author Poliana M Santos
UTFPR

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Åsmund Rinnan, Luiz A Colnago, Marcos Monteiro, Renata S. Amais

Abstract Text

Time domain Nuclear Magnetic Resonance (TD-NMR), based on low cost benchtop instrument, has become an attractive alternative for traditional analytical methods due to the ability to analyze samples with little or no sample preparation, fast data collection and capability to serve as inline measurements. These advantages result in time and cost savings and higher analytical throughput. In this context, the aim of this study was to apply TD-NMR combined with chemometrics analysis to classify and predict quality parameters of Brazilian commercial diesel samples. Diesel samples were provided by the Center for Characterization and Development of Materials (CCDM, São Paulo, Brazil). Cetane index, density, flash point and temperature achieved during distillation to obtain 50% of the sample distilled (T50) reference values were obtained according to the Brazilian standard methods (ABNT NBR). TD-NMR experiments were evaluated in the SLK 100 TD-NMR benchtop instrument (Spinlock Magnetic Resonance Solution, Argentine) equipped with a 0.23-T permanent magnet. ^1H transverse relaxation times, T_2 , were performed using Carr-Purcell Meiboom-Gill (CPMG) pulse sequence with a τ pulse width of 6.4 μs , time between echoes of 2 ms, 1000 echoes and a recycle delay of 1.5 s. Soft independent modeling of class analogy (SIMCA) and partial least squares regression (PLS) was applied to generate classification and calibration models, respectively. SIMCA models exhibited tight and well-separated clusters, allowing the discrimination of the diesel samples based on the sulfur content: 10 (S10), 500 (S500) and 1800 (S1800) mg kg⁻¹. PLS models showed good agreement between the real and predicted values, with high coefficients of correlation ($r > 0.98$) and low standard error of prediction (SEP). These results support the application of TD-NMR to evaluate the quality of diesel, providing simple, rapid and non-destructive method for the petrofuel industry.

Abstract Text

In this work, several experiments for characterization of the main wastes generated by sugar and ethanol productions from sugar cane (*S. officinarum*) were conducted. Such wastes (bagasse, filter cake and vinasse) were sampled from two sugar cane mills located in a radius of 170km from Araraquara, Brazil. Analytical and thermoanalytical techniques such as ultimate analysis, determination of higher heating value (HHV), X-ray diffractometry (XRD), infrared spectroscopy (FTIR), atomic absorption and emission spectrophotometry (AAS and AES, respectively), vis-spec, thermogravimetric analysis and differential thermogravimetric analysis (TGA-DTG), differential thermal analysis (DTA) and differential scanning calorimetry (DSC) were employed. In TGA-DTG and DTA, dynamic atmospheres of synthetic air and N₂ were used. DSC curves were conducted in a static air atmosphere. Despite similar organic constitution, differences in HHVs and in thermal behavior were observed due to high contents of inorganic matter detected in filter cake and vinasse. Thus, a higher amount of ash was generated when such wastes were heated in relation to bagasse. Among samples of the same waste from different sugar cane mills, changes in their constitutions were detected, mainly regarding to metals concentration (Ca, Cr, Fe, Mn, Ni and Pb). Therefore, for a same waste, different thermal behaviors were observed for each sample in terms of displacement of peaks to lower temperatures and maximum thermal decomposition rates.

Abstract Text

Thermogravimetric analysis (TGA) is an analytical technique in which changes in physical and chemical properties of materials are measured as a function of temperature and/or time. TGA is commonly used to determine selected characteristics of materials that exhibit either mass loss, or gain, due to decomposition, oxidation, or loss of volatile material, such as moisture. Common applications of TGA are materials characterization through analysis of characteristic decomposition patterns and determination of combustible materials and combustion residues. Macro TGA systems that use gram-size samples have been used for a couple of decades for monitoring industrial processes. The larger sample sizes allow more accurate mass measurements and a representative sample for characterization of heterogeneous materials. Flue gas desulfurization (FGD) solids are industrial byproducts that have been monitored using macro TGA systems. Compounds reported to have been successfully measured include free moisture, moisture in hydrates, gypsum, lime, $\text{CaSO}_3 \cdot 0.5\text{H}_2\text{O}$, and CaCO_3 . The actual measurement of $\text{CaSO}_3 \cdot 0.5\text{H}_2\text{O}$ in FGD solids is questionable and is the subject of this study.

A LECO TGA701 macro TGA system and elemental analysis data were used in a study to characterize the components in various FGD solids. Pure materials, and their mixtures, were first analyzed with the TGA701. Pure $\text{CaSO}_3 \cdot 0.5\text{H}_2\text{O}$ is not available and was not used in the study. The study of pure materials and mixtures demonstrated the accuracy of the TGA701 in characterizing the compounds. In most of the previously reported macro TGA studies of FGD solids, lime is not reported as one of the components in FGD solids. The TGA reaction profiles for lime and $\text{CaSO}_3 \cdot 0.5\text{H}_2\text{O}$ decomposition occur in the same temperature range. This study sheds new light on this subject.

Abstract Title **Viscosity Reduction of Heavy Crude Oils Using Hydrogen or Methane as Reducing Agents**

Primary Author Laura O. Aleman-Vazquez
Instituto Mexicano del Petroleom

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Jose L. Garcia-Gutierrez

Abstract Text

Heavy crude oils are an important part of the world reserves of liquid hydrocarbons. In offshore fields, where the production of these crude oils is limited by their high viscosities, viscosity reduction via crude oil upgrading is not feasible due to the size and cost of the facilities for hydrogen production or for high-carbon-content residues handling. In this work, we evaluate the alternative of using methane as reducing agent instead of hydrogen in the mild thermal cracking of a heavy crude oil.

Experiments were carried out in a pilot plant at 713 K and 56 bar. The flows of heavy crude oil (12.7 °API, 1101 cSt @ 333 K, 48.4 vol. % total distillates to 811 K) and hydrogen or methane were controlled using mass flow controllers. The distillation curves of the heavy and upgraded crude oils were determined by the ASTM D7169 GC-Simulated Distillation method, the viscosities by the ASTM D-7042-04 method (Stabinger viscometer) and the sediments contents by the ASTM D-4807-05 method.

For the test using hydrogen as reducing agent, total distillates yield to 811 K in the upgraded crude oil was 64.4 vol. %, viscosity was 57 cSt and sediments content was 0.4 wt %. For the test using methane, total distillates yield was 62.0 vol. %, viscosity was 115 cSt and sediments content was 0.8 wt %.

These results show that hydrogen is appreciably more effective than methane for preventing the polymerization of heavy molecules in the free radicals reactions in thermal cracking.

Abstract Text

Recent column manufacturing improvement and new application specific designed stationary phases for GC PLOT columns make it possible to look at separations in new ways. Separations that have historically required more than one column and/or multiple methods can be simplified by taking advantage of recent improvements in Plot column technology. Approaching challenging separation from a new prospective is leading to successful single column solutions on these phases.

The separation of hydride impurities in Arsine, Phosphine, Propane and Propylene are promising using Pora Plot U columns showing excellent separation and low level detection by GC-ICP-MS. Using new detection and separation tools to revisit long standing challenges such as trace level analysis of arsine in phosphine matrices is bearing fruit. Example chromatograms highlighting peak shapes and low level detection illustrate the power of revisiting long standing challenges with better analytical tools.

Primary Author Remko van Loon
Agilent Technologies

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Coen Duvekot

Abstract Text

Oil and gas exploration require the analysis of dissolved natural gas in mud samples from the well within short run times. This poster highlights the use of a Micro Gas Chromatograph for rapid, accurate mud logging analysis. Gas chromatography is proven to be an accurate and sensitive technique for the characterization of individual hydrocarbon gases to combine in lithology reports for the mud logging field. Critical information is obtained for making decisions on additional drilling or production of the well.

A system equipped with two analytical channels is used for on-line analytical testing of drilling fluid sample. Each column channel is a complete GC containing an electronic carrier gas control, micro-machined injector, narrow-bore analytical column and micro thermal conductivity detector (TCD). Dissolved gases, collected from the drilling fluid samples using a semipermeable membrane, are analyzed on both analytical channels in just over 30 seconds.

Miniaturization has resulted in a small, shoe-box size, instrument dimensions that makes it easy to integrate into on-site control cabins or explosion proof enclosures. Moreover, industry standard 19-inch rack configuration further simplifies integration into mud logging operations.

Co-Author(s) Bin Chen, Peter B. Stockwell, Warren T. Corns

Abstract Text

Adsorbent materials are widely used in the oil and gas sector to remove mercury from gas and liquid feeds. Similarly, adsorbent materials are also used in the treatment of waters and waste waters to remove mercury, arsenic and selenium, amongst other contaminants. The performance of these adsorbent materials varies significantly with the physical and chemical nature of the material itself and with the composition and flow rates of the fluid stream being cleaned.

There is a significant requirement within the industry to test and demonstrate the performance of adsorbent media, from both the suppliers of the media and the end users. Generation of the required breakthrough curves is time consuming and potentially labour intensive. The use of a suitable automated test system facilitates the collection of suitable data to demonstrate/test the performance of materials.

Working with standard modules, with bespoke components where required, test bed systems have been developed for a range of applications. Systems can work with either gaseous, aqueous or hydrocarbon liquid. In all cases the bed flow rates are precision controlled with mass flow controllers or metering pumps and the media volume recorded. Analyte concentrations are automatically measured at the inlet, mid-bed and outlet points, with multiple parallel bed streams accommodated to reduce total testing time. A range of additional criteria can also be met, including wide concentration ranges and addition of other contaminants.

This poster describes bespoke systems for testing adsorbent materials in gaseous, aqueous and hydrocarbon liquid media, presenting breakthrough curve data for various adsorbents.

Abstract Text

The presence of even small amounts of elemental sulfur in natural gas is known to facilitate corrosion in distribution lines, increasing the costs of maintenance and concerns over safety. If the sulfur travels through the system to the final user, the environmental and health problems can be severe. The sulfur fumes can cause irritation of the eyes, nose, and respiratory tract. Elemental sulfur can react with O₂ to form SO₂, which can cause vascular damage in the brain, heart and kidneys, as well as imbalance the enzyme system. It is clear the importance of finding a way to detect and quantify elemental sulfur in the natural gas. Over the last couple years, we have been working on a new approach to fulfill this need: a regular sample cylinder is used as a base for a simple mechanical trap to collect the sulfur from a known amount of gas. This cylinder is washed with a known volume of a solution of triphenylphosphine and n, n-dimethylformamide in a blend of aromatic solvents, to get the sulfur in a stable organic compound: (C₆H₅)₃PS. This solution has been analyzed with a series of analytical methods, the results of which have been presented previously. In working with our customers on this technique, we have considered the possibility that the sulfur tends to concentrate in the liquid phase associated with the natural gas, and is pushed through the process with it.

In this work, we present the results of this investigation and the latest advances to a definitive method.

Abstract Text

Diesel fuels are known to generate reactive and potentially harmful compounds upon combustion. In an attempt to compare the profiles of pollutants emitted from Yanmar power generator fueled with diesel and biodiesel blended with different biomass-derived additives, Tedlar™ bag samples of emissions from different fuels were analyzed by GC-MS with a pre-concentrator outfitted with a glass bead trap and a Tenax™ TA trap. The emission samples were also introduced into a 10-meter gas cell for quantitative determination of carbon monoxide, formaldehyde, methane, and ethylene by FTIR spectrometry. The FTIR and GC-MS techniques are complementary to one another because the former technique allows the measurement of C1-C2 compounds at the 0.1-100 ppmv levels and the latter is more suitable for analysis of C3-C12 compounds at the 0.1-100 ppbv levels.

Biodiesel fuels produced with both sodium hydroxide and barium hydroxide catalysts were also compared in terms of their emission profiles as well as their biodiesel yields. Experimental variables of alcohol-to-oil ratio, reaction time, reaction temperature, and catalyst concentration will be presented. The FTIR tests showed significant reduction in the emission of carbon monoxide and formaldehyde for oxygenated biodiesel based on fatty acid methyl esters and glycerol-derived oxygenated additives. Likewise, the production of long-chain aliphatic aldehydes and alcohols along with ketones with less than six carbon atoms were significantly reduced in biodiesel and glycerol-derived additives.

Abstract Title **Trace Detection of Carbon Monoxide in Hydrocarbon Feedstock Processing Using Continuous-Wave Cavity Ring-Down Spectroscopy (CW-CRDS)**

Primary Author Florian Adler
Tiger Optics

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Elyse Baroncini, Erika Coyne

Abstract Text

Tiger Optics has developed a new generation of cavity ring-down spectrometer – the CO-^{rekt}™ – for measurement of carbon monoxide, and other gases, in hydrogen. The analyzer is packaged in a NEMA enclosure to allow efficient purging, satisfying Class I, Division 2 regulations, and thus is suitable for operation in hazardous locations. It has been quickly embraced as a gamechanger in the hydrocarbon feedstock world, as it overcomes costly and potentially dangerous issues associated with incumbent technology. Specifically, the device is insensitive to vibration, free of drift, solid state and automatically self-calibrating.

Detection of carbon monoxide in hydrogen is required in a wide range of applications, including process monitoring in HyCO and Steam Methane Reformer (SMR) plants. Such plants mainly serve refineries and chemical industries, and, therefore, need to produce high purity H₂ to protect their customers' processes. Continuous, online monitoring of CO is especially critical as it poisons the catalytic beds used to manufacture pure H₂.

Continuous-Wave Cavity Ring-Down Spectroscopy (CW-CRDS) is a field-proven analytical technique for trace gas detection that directly derives the absolute optical loss due to molecular absorption inside the cavity from a simple time-based measurement, independent of laser intensity noise and environmental conditions. CW-CRDS provides an ideal analytical solution that is fast, sensitive, accurate yet extremely robust and simple to operate.

Performance data will be presented illustrating sensitive detection limits of 100 parts-per-billion of CO in H₂ and showcasing the analyzer's wide dynamic range of up to 2000 parts-per-million. Furthermore, the analyzer responds within seconds of a CO excursion event, making it an ideal choice for monitoring process upsets.

Abstract Text

India is rich in coal bed methane resources but still lacks in methane development technologies. To begin understanding this prospective source, in the present investigation, microbial methane production was examined from bituminous, subbituminous and lignite coals obtained from Jharia coal mines in India. Microbial populations were enriched over a period of 21 days on various methanogenic specific substrates including the three ranks of coal. Maximum methane production (49%) was obtained on Methanosprillum sp specific medium (sodium acetate and isopropanol) supplemented with subbituminous coal at 65°C and pH 6.8. Phylogenetic analyses of 16S rRNA gene sequences from the selected CBM65 consortium revealed a syntrophic association between a hydrogenotrophic methanogen Methanoculleus thermophiles and fermentative bacteria Comamonas sp. The results of this study shed light on the fact that Jharia coal mines are methanogenically active and offer a prospective source for coal bed methane extraction. Also, considered among the richest source of methane in India this data will help in determining the potential role of methane emitted from this site in influencing the global carbon cycle.

Abstract Text

Oil shale is a fine grained sedimentary rock that contains a solid mixture of organic chemical compounds called kerogen. Oil shale was formed from the organic debris millions of years ago. When heated by natural geothermal heat these shales produce liquid organic products by thermal decomposition.

With the conventional oil resources being quickly depleted, there has been a great boom on the exploration and production of shale oils around the world. One of the traditional methods for identifying shale oil deposits is vitrinite reflectance (VR), which uses light reflectance as an indicator of maturity in hydrocarbon source rocks. However, this technique has several disadvantages, including analysis being subject to human error, low/absent reflectance values in some of the oil shale deposits, etc. Several previous studies indicated that Raman spectroscopy of carbonaceous materials can be used for measuring the thermal maturity. In this study, oil shale samples from Texas were analyzed with a fast imaging confocal Raman microscope and demonstrated that Raman imaging provides a non-biased chemical metric for fast identifying thermal maturity (and oil content) of the oil shales. In addition, Raman imaging also identifies, with high speed and accuracy, the presence of different minerals in the oil shale samples, including calcium carbonate (calcite), quartz, and clay minerals among others. Knowledge of the presence or absence of these minerals in oil shale is essential for efficient oil extraction in drilling operations by the new technique of hydraulic fracturing.

Abstract Text

Elemental and isotopic analysis is a key tool for characterising coal material. Using the automated Flash 2000 Elemental Analyzer interfaced with a Delta V Isotope Ratio Mass Spectrometer (IRMS), rapid, accurate and precise Carbon, Nitrogen, Hydrogen, Sulfur, and Oxygen elemental and isotopic data can be obtained. The elemental data combined with the relative heat value calculation allows an assessment on quality of the coal whereas isotope ratio values allow an evaluation of material provenance and diagenetic processes.

The EA system is based follows the Dumas combustion principle and allows simultaneous CHNS determination in a single analysis run and the Oxygen determination by pyrolysis in a second run. The Heat Value and the CO₂ emission trade are calculated automatically by the dedicated software. The combustion method is described in ASTM D5373-02, which was followed here.

In this paper we present elemental and isotopic CHNS/O data, Heat Value and a CO₂ emission trade calculation on a range of coal samples and demonstrate the reproducibility on the EA and EA – IRMS data.

Abstract Text

While hydraulic fracturing (fracking) has made shale gas accessible and economical, large quantities of wastewater are produced over the lifespan of a well: drilling and fracturing a Marcellus shale well requires approximately 14,000-17,000 m³ of water. Within one year of well completion, 10-25% of the water returns to the surface as a concentrated brine. Although 55-80% of this returned water is reused for other wells, a substantial amount of wastewater is leftover. These large wastewater volumes have prompted the need for appropriate management and monitoring techniques. Current methods for water analysis are not designed for fracking formulations, thus new approaches are needed to assess and maintain environmental compliance and safety as these valuable natural resources are utilized.

To meet these demands, microfluidic tools are being designed, built and applied. These offer the advantages of low cost, simplicity, stability and high adaptability for widespread distribution. Our devices can be interfaced with multiple detection methods, including colorimetric detection using stand-alone, low-cost hardware and the optical hardware on smartphones. Detection of constituents such as bromide, strontium and barium are of particular interest because they are characteristic of the wastewater generated by Marcellus shale gas extraction. Detection can serve as an early indication of wastewater leaks—a crucial tool for preventing source water contamination. Additionally, rapid detection of these elements can be useful for tracking the movement of produced waters, an important process for ensuring safe wastewater disposal. We will present recent outcomes from our work on quantification of fracturing fluid indicators.

Abstract Text

In recent years, there has been a marked increase in hydraulic fracturing or “fracking” in order to recover natural gas from deep beneath the earth’s surface. As a result of this drilling, there has also been a rise in the concern of gases escaping during the “fracking” process and contaminating nearby water sources. In order to test for the possible dissolved gas contamination, most laboratories refer to a standard operating procedure entitled “RSK-175”. This procedure calls for static headspace sampling of the water samples and calculating the amount of dissolved gas using Henry’s Constant. However, as RSK-175 is standard operating procedure and not a formal method, interpretations can vary. In order to address this issue, a formal method is currently being written by American Society for Testing and Materials (ASTM) Committee D-19. This application will test for the dissolved gases using the procedures established in the ASTM method.

Abstract Text

Dye-sensitized solar cells (DSSCs) are low cost, third generation solar cells. In order for DSSCs to be competitive with current technology, the efficiency of DSSCs must be improved. The photosensitizing dye plays a critical role in DSSCs by absorbing photons from sunlight and transferring electrons to generate current. In this regard, a new class of materials known as a Group of Uniform Materials Based on Organic Salts (GUMBOS) and nanoparticles derived from GUMBOS (nanoGUMBOS) is evaluated as photosensitizing dyes in DSSCs. GUMBOS are solid organic salts that are composed of bulky organic ions with a melting point in the range of 25-250°C. The properties of GUMBOS can be tuned by varying the cation and anion, resulting in a unique material possessing characteristics of both ions. NanoGUMBOS retain the beneficial properties of both GUMBOS and nanomaterials. In this study, GUMBOS were synthesized using porphyrins dyes that contain different central metal atoms as anions, and their optical and electrochemical properties were studied using ultraviolet-visible absorbance spectroscopy, fluorescence spectroscopy, and cyclic voltammetry. NanoGUMBOS were prepared by reprecipitation to yield uniform particles between 50 – 100 nm in size. The solar efficiency was investigated using GUMBOS and nanoGUMBOS of differing composition.

Abstract Text

Porous silicon (pSi) exhibits strong, visible photoluminescence (PL) at room temperature. One negative aspect of as-prepared, H-passivated pSi (ap-pSi) is that the PL is unstable. One approach to stabilize the pSi PL and simultaneously impart chemical functionality to the surface is oxidation to create oxidized porous silicon (ox-pSi) and subsequent silanization with an organically modified silane (e.g., (RO)₃Si-R').

Direct application of candidate silanizing agents to ox-pSi can be rapidly carried out by contact pin-printing (CPP) methods. Towards this end, we have prepared microarrays by CPP using two common silanes: 3-aminopropyltriethoxysilane (APTES) and butyraldehydetriethoxysilane (BATES). Initially, fabrication of high density microarrays proved difficult because of significant feature "spreading". A combined PL and IR imaging study allowed us to determine the root causes of the spreading. We then developed and evaluated new strategies to mitigating feature spread. In the end, although APTES is by far the more popular silane for surface modification and secondary grafting, it may be far less suitable for CPP on ox-pSi if the goal is to form high density microarrays.

Abstract Text

Food and pharmaceutical packaging materials are complex multicomponent structures that are designed to fulfill many requirements. They must be durable enough to permit products to be transported great distances. They must block the ingress of moisture, ultraviolet radiation, microbes, and gases to prevent product spoilage and contamination. The packaging must also facilitate sale of the product through compatibility with the printing processes deployed to inform or attract the consumer of the product. FTIR, FTIR Microscopy, Photoacoustic step-scan and Raman microanalysis techniques have been used for years to characterize these materials. This paper will explore the benefits and weaknesses of these methods including the hardware and software tools needed. Guidance on which technique is the most appropriate for different analysis scenarios will be presented.

Abstract Text

Poly-L-lactide (PLLA) is a biocompatible, biodegradable, semi-crystalline and optically active polymer that is widely used as an implant and artificial cell scaffold material. The degree of crystalline character of PLLA influences its electromechanical properties such as elastic modulus and piezoelectric character. From its amorphous state, PLLA can be made more crystalline by drawing the polymer at a temperature above the glass transition, but below its crystallization temperature. Cold-drawing the PLLA to higher draw ratios increases its piezoelectricity and rigidity, two important considerations in the development of improved implants and biodegradable matrices. In the work presented here, a non-destructive and non-contact optical method for characterizing tailored PLLA substrates using Raman imaging and Raman polarization microscopy is described. The method utilizes a novel chemometric method to generate image contrast based on the degree of crystalline character. The image results enable a preliminary understanding of differences in bond orientations across the spatial extents of the sample and differentiated sample regions that are more crystalline from those that are more amorphous. A complete description of the optical method is presented along with a theoretical description of the chemometric technique.

Abstract Text

The possibility of large enhancements in the radiative rates of emitters placed inside a cavity has been known since the middle of the last century (E.M. Purcell, Phys. Rev. 69,681). We have recently shown that very large Purcell enhancements can also be achieved for Raman processes when high-finesse Fabry-Perot microcavities are employed. In the case of Purcell enhanced Raman scattering (PERS), the spontaneous Raman emission rate is inversely proportional to the cavity mode volume. In the case of Purcell enhanced CARS (PECARS), the anti-Stokes emission rate is inversely proportional to the square of the cavity mode volume.

The PERS effect was demonstrated for the 1,388 cm^{-1} Raman transition of CO_2 in CO_2 -air mixtures in a high-finesse (50,000) microcavity having mirrors with 40 μm radius of curvature and cavity length near 30 μm . The cavity length was adjusted to be resonant with both the pump laser wavelength near 867 nm and the Stokes wavelength near 985 nm. Under these conditions, the Raman emission from the cavity was found to be 2×10^7 stronger than that estimated for free space. Approximately a factor of 3,000 increase was from the intracavity build-up of the pump laser power, and another factor of 7,000 attributable to the Purcell enhancement.

Experiments were also performed to investigate PECARS on the same CO_2 Raman transition. The results show that similarly large Purcell enhancements should be possible for the anti-Stokes emission. The implications of PERS and PECARS as new spectroscopic techniques, including the possibility of single molecule detection, will be discussed.

Abstract Text

The use of a coupled Rheometer and Raman spectrometer for obtaining comprehensive insight into a materials behavior is presented.

Rheology is the analytical method of choice to correlate the absolute flow and deformation characteristics of a given product with its behavior towards a certain processing or application step. However, Rheology as an integral method only yields answers on the bulk of the investigated sample towards certain absolute shear or deformation conditions. It does not give any insights into what is actually happening on the molecular level during a certain processing step.

Raman spectroscopy has shown its ability as a powerful, effective and non-invasive method for chemical analysis. Coupling a Rheometer with a Raman spectrometer provides direct information about the molecular reaction kinetics and the mechanical properties. This is extremely useful for studying the crystallization behavior of polymer melts during processing. It can also provide insight for [i]in-situ[/i] characterization and monitoring which can be challenging when working with on-line techniques as only relative flow fields are characterized.

Finally, the coupling gives the researcher the advantage of maximizing and synchronizing the information gathered from a single measurement as well as enabling transient information on their materials during fast processing conditions.

In this contribution we present results obtained with the brand new combination of a Thermo Scientific HAAKE MARS rheometer with a Thermo Scientific DXR spectrometer. Details of this unique new set-up as well as selected results including shear and temperature induced crystallization will be presented.

Abstract Text

Heavy metals and associated compounds are potentially the most toxic elements for the environment. Generally, these metals are very toxic for living organisms, being dangerous to human health when present in drinking water and food. Various biological effects of heavy metals have been described; at the molecular level they decrease the activity of certain enzymes. The mechanism of enzyme inhibition by heavy metals is based on the interaction of metal ions with exposed thiol- or methylthiol groups of protein amino acids, often forming the active site of enzyme. Mercury is a very harmful pollution compound because of its great volatility and of its possibility to easily combine with many organic compounds, resulting in organomercury derivatives. These compounds are toxic and able to concentrate in living bodies, especially fishes, which become improper for human consuming. A fast spectrometric kinetic method for mercury(II) ions determination based on their property to inhibit glucose-oxidase activity is presented. The measurement of enzyme activity was based on enzymatic reduction of benzoquinone to hydroquinone and on the measurements of the initial rate of hydroquinone absorbance increase at 290 nm. A calibration curve for Hg(II) concentrations was obtained in the 0.05–1.0 µg/mL range, with a detection limit of 0.015 µg/mL and a relative standard deviation of 2.7%. The analysis time was 2 min. Determination of mercury in a real sample was in good agreement with the declared mercury concentration.

Abstract Text

The measurement of Airborne Molecular Contamination (AMC) in clean rooms requires highly sensitive detection methods as typical AMC amount fractions are at nmol/mol level and below. In the last decades cavity based spectroscopic methods such as CRDS and CEAS have been introduced which can reach such level of sensitivity. However the number of species that can be detected with a single instrument is inherently limited by the cavity mirrors. Within the EMRP project MetAMC (Metrology for Airborne Molecular Contamination) VSL develops an instrument which is suitable to detect a large number of species yet at high sensitivity. The instrument is based on the well-known photoacoustic technique. The required sensitivity is obtained by using a high power, yet compact mid-infrared light source developed by Taiwanese partner. To handle reactive and adsorbing AMCs the measurement cell is designed of glass and a special sampling system has been constructed. The instrument will be discussed in detail and initial results will be presented.

Abstract Text

Nickel Carbonyl and Iron Carbonyl are highly toxic vapors and pose a human health hazard at concentrations as low as several PPB in air. This paper will present an FTIR based sensor for Nickel Carbonyl and Iron Carbonyl that achieves a limit of detection of these components below 1 PPB. Furthermore, the FTIR is not confused by interferences that often lead to false alarms with conventional chemiluminescent sensors. Components like Nickel and Iron Carbonyl when released in air are often accompanied by significant concentrations of Carbon Monoxide which is also measured by the FTIR. The FTIR based sensor does not require any consumables, calibration gases or zero and span verification. Since Nickel and Iron Carbonyl are so highly toxic, a high reliability combined with effective diagnostics that will indicate the occurrence of malfunction is essential.

Abstract Text

Some endocrine disruptors, such as active substances of some medicines, are known to be concentrating in the environment due to the inefficiency of conventional wastewater treatments to remove these residues. The catalytic photodegradation of these contaminants is a promising solution to the elimination of these compounds but requires further optimisation. The new technologies are first assessed in the laboratory for some pollutants or photodegradation markers and, if proved efficient, applied to more complex systems.

This work presents a strategy to develop reliable detailed models of the quantification of the efficiency gain of the catalytic photodegradation of methylene blue. Methylene blue was chosen since it is a very popular compound for assessing and comparing the efficiency of photocatalytic degradation processes. These models are used to report the photocatalytic gain with uncertainty to allow the comparison of results of different tests performed in the same or different laboratories, and to minimise determination uncertainty. The uncertainty was evaluated using the so called "bottom-up" approach. The methylene blue was determined by UV/Vis spectrometry at various wavelengths. To reach a relative standard uncertainty of less than 2 %, concentration of methylene blue after photodegradation larger than 5 mg L⁻¹ need to be determined. This uncertainty allows the reliable determination of variations of efficiency gain larger than 8.4% [1].

This work was supported by Fundação para a Ciência e Tecnologia (FCT) under project PEst-OE/QUI/UI0612/2014 and PEst-OE/QUI/UI0536/2014.

Abstract Title **High Speed WDS Spectrometer for SEM Provides Rapid Id of Overlapped Peaks from Minor and Trace Constituents (WDS) / Materials**

Primary Author John Konopka
Thermo Fisher Scientific

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Brian R. Strohmeier, David Rohde, Keith Thompson, Martin Long, Simon Nunn

Abstract Text

Energy Dispersive X-ray Spectroscopy (EDS) is the easiest and fastest way to perform x-ray spectroscopy in an SEM. However, several x-ray line overlaps are too close to resolve by this technique. This is particularly true if one or more elements are present in low amounts or if only low energy lines are available. Wavelength Dispersive X-ray Spectroscopy (WDS) provides much higher resolution and can easily resolve most overlaps but traditional WDS instruments require well trained, dedicated operators and are relatively slow.

A novel WD spectrometer has been designed which brings the benefits of WDS to the typical SEM/EDS laboratory. The use of direct drive motors with no gears belts or pulleys make it extremely fast and precise. It can change focus from one x-ray line to another in under a quarter second. No utilities are needed for operation besides electricity. It eases the need for training by automating most of the decisions normally made by the operator. A hybrid x-ray optic focuses x-rays onto the resolving crystal providing improved soft x-ray sensitivity and greatly reducing size restraints on the SEM mounting port. The result is a very fast WD spectrometer that can attach to most SEMs and is almost as easy to use as EDS.

The typical SEM operator can use this device to apply the high resolving power of WDS to peak identification during EDS analysis obtaining energy scans in just a few minutes which greatly amplifies the abilities of the SEM/EDS laboratory.

Abstract Text

Over the last decade, considerable attention has been given for microchip electrophoresis in analytical science because of its many advantages including feasibility of miniaturization, minimal sample/solvent usage and speed. As part of a senior level problem-based learning analytical course, an assay that involved microchip electrophoresis (ME) was developed by undergraduate students. The problem that was assigned is as follows: both natural and synthetic antioxidant supplements are becoming popular among human beings because of their ability to retard the activity of pro-oxidants. A newly established company is seeking for a fast, cost effective assay, which can be performed without a highly equipped conventional laboratory. After a comprehensive literature search, the students chose microchip electrophoresis with amperometric detection for assay development. The assay focused on the most commonly consumed antioxidants: ascorbic acid, cysteine and glutathione. Two commercially available antioxidant supplements were used to demonstrate the capability of the method. Separation was carried on PDMS microchips using a 10 mM phosphate buffer containing 0.5 mM SDS as the surfactant at pH of 7.4. Detection was accomplished amperometrically at a Pt electrode. Calibration plots were prepared. The calculated antioxidant concentrations were then compared with the results obtained with LC-UV. Substantially reduced analysis times were obtained with ME relative to LC.

Abstract Title **Comparison of Soxhlet and Accelerated Solvent Extraction (ASE) for Leachable and Extractable Analysis of Packing Material**

Primary Author Hua Yang
Thermo Fisher Scientific

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Kate Comstock, Linda Lopez

Abstract Text

According to the regulations and guidelines set by the U.S. Food and Drug Administration (US FDA), the European Medicines Agency (EMA) and other regulatory agencies, extractable and leachable information must be included in applications for medical devices and container closure systems packaging human drugs and biologics.

The Product Quality Research Institute (PQRI) Leachables and Extractables Working Group have recommended incorporation of multiple extraction techniques that employ vigorous extractions using multiple solvents of varying polarity in Controlled Extraction Studies. However, traditional Soxhlet or reflux techniques recommended by PQRI are labor intensive (>24 h/sample) and consume a large quantities of solvent (>150 mL/sample). The accelerated solvent extraction (ASE) technique is an automated extraction technique with many advantages, including more efficient extraction, reduced extraction time (<0.5 h/sample), reduced solvent use (<30 mL/sample), and more flexibility in solvent selection. It is a powerful technique to reliably extract compounds from polymeric materials.

In this study, direct comparison of Thermo Scientific™ Dionex™ ASE™ 350 and Soxhlet were conducted. A polypropylene pill bottle and a transdermal patch pouch were extracted with 2-propanol and n-hexane using the Thermo Scientific™ Dionex™ ASE 350 system and Soxhlet, respectively. The extracts were analyzed using a Thermo Scientific™ Dionex™ UltiMate 3000 LC system coupled with a Thermo Scientific Q Exactive™ Hybrid Quadrupole-Orbitrap™ Mass spectrometer.

Compared to Soxhlet, ASE delivers comparable or more efficient extractions using less time (<0.5 vs. >24 hr per sample) and less solvent (<30 vs. >150mL per sample). Extractions using multiple solvents of varying polarity are necessary in Controlled Extraction Studies, because different solvents can provide additional information on extractables.

Abstract Text

Interest in chromatography using aqueous-organic mobile phases high in organic content (aqueous normal-phase, ANP, HILIC) has continued to build in recent years.[1, 2] In this mode of chromatography analyte retention increases monotonically with an increase in the organic component of the mobile phase. In previous studies, significant contribution of stationary phase chemistry toward the manipulation of retention and selectivity in ANP has been demonstrated.[3] The aim of this continuing study was to further enhance our knowledge of retention mechanisms that dominate in this interesting and useful mode of chromatography.

Ion exchange has been shown to contribute significantly toward retention and selectivity in HILIC separations. Solute descriptors important for chromatographic processes involving ion-exchange such as ionization constants (pK_a/pK_b) are often only available as measured in aqueous environments. When operating in HILIC mode, one deviates significantly from the aqueous environment and thus from these aqueous-based descriptors. It is therefore important to better understand the ionization state of the analytes and stationary phases in the HILIC environment. In this study, the influence of high organic content on basic and acidic pK_a values as well as mobile phase pH dependence is explored. The impact of the descriptor variation is related to real chromatographic separations providing enhanced understanding, prediction and control over HILIC separations.

Abstract Title **Using Area-Under-the-Curve (AUC) as a Tool for Validating the Hypoglycemic Effects of Sida acuta Ethanolic Leave Extract in Experimental Diabetes**

Primary Author Grace E. Ukpo
University of Lagos

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Ajibola Azeez, Steve O. Ogbonna, Teddy S. Ehianeta

Abstract Text

Sida acuta, a tropical plant, is used in traditional medicine to control of diabetes. The heterogeneity of diabetes has placed a demand on the search for newer hypoglycemics. Thus the hypoglycemic effect of *Sida acuta* leave extract in alloxan-induced diabetes relative to a standard drug (metformin) was evaluated and the predictability of Area under the Curve (AUC) as a tool for monitoring the hypoglycemic potential of hypoglycemic agents established

Diabetic rats with blood glucose levels (BGLs) > 200 mg/dl were screened for the study following a 72hrs post-alloxan induction (150mg/kg/i.p). The baseline BGLs were determined prior to *S. acuta* extract and metformin treatment. Treatment with extract and standard drug were administered as follows: group II (induced only); group III (induced + metformin 2.57mg/kg/p.o); group IV (induced + *S. acuta* 200mg/kg/p.o); group V (induced + *S. acuta* 400mg/kg/p.o); group VI (induced + metformin + *S. acuta* 200mg/kg/p.o) and group VII (induced + metformin + *S. acuta* 400mg/kg/p.o). BGLs were observed at 0hr, 1hr, 3hr, 6hr, 24hr, 48hr, 72hr, 7days, 14days and 21days. Statistical analyses were carried out using graphpad prism 5.0. Mean BGLs were compared using the student paired t-test and ANOVA ($p < 0.01$) and the AUCs determined from pharmacokinetic plots.

Relative to baseline and control groups, a significant decrease in BGLs was observed ($p < 0.001$) in the treatment groups. The percentage decrease in BGLs trends as *S. acuta* 200mg/kg (86.25%) > metformin (80.90%) > *S. acuta* 400mg/kg (73.50%) > metformin + *S. acuta* 200mg/kg (54%) > metformin + *S. acuta* 400mg/kg (41.90%). The % reduction in AUC followed the same trend, thus establishing evidence of reduced glucose in the physiological milieu.

Sida acuta (200mg/kg) showed a better hypoglycemic property than Metformin. The AUC best correlated with hypoglycemia and thus can be used to monitor BGLs and validate the significant anti-diabetic potentials of *Sida acuta* ethanolic extract.

Abstract Text

UHPLC using UV or MS detection is now a routine technique in most analytical laboratories. The development of instruments and LC columns in the recent years improved the performance of fast and highly resolved separations significantly. Fused Core and sub 2 micron particle columns now enable the full performance of a UHPLC system with a maximum of sensitivity and chromatographic efficiency. Mobile phase impurities and the ion suppression effect are still pose concerns for the most common ESI source.

The results presented in this poster show the positive effect of a sample clean-up step prior to LC-MS analysis. Complex sample matrices, such as food samples, often cause ion suppression by co-eluting components, such as sugars or phospholipids. As, demonstrated in this poster, this issue can be resolved by using high purity additives.

Abstract Text

Candida albicans is a major human fungal pathogen, causing a variety of infections, ranging from superficial to life-threatening [1]. Recent evidences suggest that the majority of disease produced by this pathogen is associated with biofilms growth. Microbial biofilms can be defined as communities of surface-attached microbial cells firmly encased in a layer of extracellular matrix (ECM). The biofilm lifestyle confers resistance to antimicrobials, and prevents access by host inflammatory cells and can also alter host metabolism [2,3]. Currently, wide ranges of anti-biofilm strategies have emerged, their focus include increase the permeabilization of biofilm in order to antimicrobials can penetrate deeper of this microbial community [3]. This study has evaluated the effectiveness of a supramolecular polymer together with the antifungal fluconazole against *C. albicans* biofilm. Supramolecular polymer hydrogel were derived from stearic acid and the aminocarbohydrate meglumine that self-assembled in aqueous phase through hydrophobic interactions and hydrogen bonds. This supramolecular gel can disrupt the ECM that is considerate a principal resistance mechanism of biofilms, once hamper the antimicrobial penetration. The incubation (24 hours) of mature *C. albicans* biofilms with the polymer (4%) associated with fluconazole (65 µg mL⁻¹) promoted ~ 70% inactivation of these fungi, while only the antifungal at same conditions inhibited ~ 40% of *C. albicans*.

Abstract Text

Due to the high cost and time frame associated with drug development, methods for improving efficiency while simultaneously reducing overall expenditure are critical. A specific area focused upon for the reduction of materials is in vitro pharmacokinetic (IVPK) models. The goal of such models is not to completely eliminate animal models but to work in tandem to eliminate costly animal studies by utilizing IVPK models. Current IVPK models, such as the hollow fiber chamber reactor, are able to successfully mimic in vivo PK curves but at a large cost due to large quantities of media and synthesized drug. Here, microfluidics are employed, due to the reduced volumes, i.e., milliliter or microliter, to investigate the potential of developing an IVPK device. Initially PDMS, a staple of the microfluidic community for decades, was explored as a platform for the IVPK model. While the absorbance (C_{max} of 2 μM) and elimination (half-lives of 0.5, 2, 4, and 8 hours) portions of the curve could be observed, the two could not be monitored on the same device due to the fragility of the membrane separating the channel from the well after flow times of 8 hours. PK curves were also lacking reproducibility owing to the single use nature of the PDMS devices. A 3D-printed platform resulted in a rugged reusable device, which is amenable to such automated infrastructure as plate readers and auto samplers. The reproducible curves produced with the 3D-printed device allowed for a mathematical prediction model for both the half-life and C_{max} .

Abstract Text

The modernization of official monographs continues to be a key initiative at USP after the formal implementation in 2013. The key benefit of the modernization scheme is the evaluation of the identity, strength, and purity of drugs. A summary of the accomplishments, current status and future direction of monograph modernization will be presented. Important issues and challenges affecting modernization of monographs as well as strategies to include some over-the-counter (OTC) drug monographs will be presented and discussed.

Abstract Text

Estrogens are classically female reproductive hormones while they also regulate reproductive processes in males. The effects of estrogens are mediated by estrogen receptor (ER), which belongs to the superfamily of nuclear receptor, and it contains ER α and ER β two subtypes. [sup]1[/sup] Since ERs have been found to be related to many different diseases, including osteoporosis and breast cancer, they have drawn a lot of attentions by medicinal chemists in the past decades. [sup]2[/sup] Thus selective estrogen receptor modulators (SERMs) have been developed, which are widely used in clinical for the regulation of ERs in different tissues, such as Tamoxifene (1) and Raloxifene (2). Since the existing SERMs show some serious side effects, a lot of different core structure ligands were synthesized and evaluated, e.g., pyrazoles (3), furans (4), pyrroles (5), and even more complex benzo[b]oxepines (6) and so on. These compounds showed good to excellent binding affinities to ERs depending on different substituents on the core, and some ligands possess certain subtype selectivity.

As a sustaining interest in developing novel core structure compounds as ER ligands, [sup]3[/sup] in this presentation, we will report our latest efforts to develop a novel series of phthalaz-(2H)-one core derivatives as ligands for estrogen receptor. The binding affinities of these compounds are moderate and most of them were selective for ER α . Reporter gene assays reflect that they are ER α agonist and ER α antagonist. Molecular modeling suggests these ligands have a similar binding pattern as estradiol, which might be responsible for their agonism.

Abstract Text

Sustained releases tablets of Diltiazem hydrochloride were formulated by employing hydroxypropyl methylcellulose (HPMC K100 M) and the sustained release behaviour of the fabricated tablets was investigated. Sustained release matrix tablets containing 120 mg Diltiazem hydrochloride were developed using different drug: polymer (HPMC K100 M) ratios. Tablets were prepared by wet granulation technique. Formulation was optimized on the basis of acceptable tablet properties and in vitro drug release. The resulting formulation produced robust tablets with optimum hardness, consistent weight uniformity and low friability. All tablets but one exhibited gradual and near-complete sustained release for Diltiazem hydrochloride (96-100%) at the end of 24 h. The results of dissolution studies indicated that formulation B5 (drug to polymer 1:1.25) was found to be most successful as it exhibits drug release pattern very close to theoretical release profile. A decrease in release kinetics of the drug was observed on increasing polymer ratio.

Abstract Text

Laser Induced Breakdown Spectroscopy (LIBS) is an ideal analytical technique for in situ analysis of any elemental composition. In this work, we have performed a comparative study of the quantitative and qualitative analysis of atomic and molecular emission from LIBS spectra. In our experiments, a mixture of SrCl₂ and Al₂O₃ in powder form was used as sample. The atomic emission from Sr and molecular emission from SrCl₂ and SrO observed in LIBS spectra were analyzed. The optimum laser energy, gate delay, gate width for selected atomic lines and molecular bands are determined from the spectra recorded at various experimental parameters. The optimum experimental conditions were used to collect the calibration data for the selected atomic and molecular emission spectra and use to determine the limit of detection (LOD) of Sr. The details of the results of these measurements will be presented.

Abstract Text

Recently, the photoacoustic effect has been utilized to allow 3D imaging in turbid media (e.g. living tissue). To date, most work has used hemoglobin as an endogenous agent for biomedical imaging, though some work has been done in developing exogenous contrast agents. However, few chemical reporter molecules have been identified for conducting imaging based on local properties (e.g. pH, temperature,). We present the development of a pH reporter molecule for measurements in turbid media, including living tissue, and focus on the properties required to permit well-behaved chemical measurements.

Abstract Text

The present study was carried out to investigate the antibacterial activities of 2-aminophenol Schiff bases and metal complexes. The increasing microbial resistance to existing antiseptics and disinfectants has necessitated the search for new compounds with potential effects against pathogenic organisms. Both developed and resource-poor countries are faced with the burden of healthcare-associated infections. The risk of infection with multidrug-resistant organisms can be overcome with the use of disinfectants in homes, veterinary and hospital environments. There is therefore a need to synthesize and investigate new antiseptics and disinfectants on a range of microorganisms. In line with this, novel copper(II) complexes with Schiff bases derived from substituted benzaldehydes and 2-aminophenol have been synthesized using condensation method.

The compounds were fully characterized using elemental analysis, atomic absorption spectroscopy, infrared spectroscopy, ¹H NMR, electronic absorption spectroscopy and thermal gravimetry analysis. The Schiff bases and their metal complexes were screened for *in-vitro* antibacterial activities against 6 human pathogenic bacteria; *Escherichia coli* (ATCC 8739), *Staphylococcus aureus* (ATCC 6538), *Pseudomonas aeruginosa* (ATCC 19582), *Bacillus cereus* (10702), *Enterococcus faecalis* (ATCC 29212) and *Klebsiella pneumonia* (ATCC 10031). Sodium hypochlorite was used as a reference compound. The result showed that Schiff bases exhibited moderate inhibitory activity against the tested microorganisms similar to sodium hypochlorite. The Schiff base metal complexes exhibited higher antibacterial activity compared to sodium hypochlorite. Our results show that these complexes can be employed as active ingredients in development of broad spectrum antiseptic agents.

Abstract Text

A series of Benzimidazole derivatives synthesized were found to exhibit excellent antimicrobial properties. The formation of bioactive heterocyclic analogues was confirmed using IR spectrophotometer (Bruker alpha-t). The titled heterocyclic analogues were formed by condensation of two intermediates, which was confirmed using vibrational frequencies of the functional group(s). Thus Vibrational Spectroscopy plays a vital role in determining the formation of drug like molecules and thus can be used as a tool for determining the structure in drug discovery process.

Abstract Text

Optofluidics is a scientific instrumentation manufacturer that makes systems for analyzing small scale particles in solution. Our technology enables single submicrometer particle Raman spectroscopy, to chemically identify and characterize small particles in solution with applications to biopharm quality control. In addition, it also enables surface analysis of single submicrometer particles to determine surface functionalization success and nanoparticle coating analysis/ stability, with applications to nanomedicine and nanoparticle formulation. Unlike traditional light scattering and spectroscopy systems, we use chip based optics to take on the challenge of transcend particle analysis beyond the traditional "sizing" paradigm.

Abstract Text

Ketoconazole (KTZ) is a highly effective broad spectrum antifungal agent. Several methods for the assay of KTZ have been reported, including potentiometric methods that are approved standard methods in the British Pharmacopeia (BP) and United States Pharmacopeia (USP). Intensive investigations were performed to assay KTZ using different spectrophotometric methods. Recently, EPR spectroscopic analytical methods have been used to monitor radical formation through the chemical oxidation of KTZ in the presence of Cerium(IV) in acid media. The method was shown to be precise, accurate, specific, and fast for quantitatively determining the KTZ concentration in tablet or cream formulations. This method is precise, fast, and consumed less reagents compared to the other reported methods. However, special sample preparation and large quantity of KTZ are required. In the present study, a new inexpensive two-electrode cell for use in in-situ electrochemical-electron paramagnetic resonance (EC-EPR) spectroscopy techniques was developed and utilized for the analytical determination of Antifungal drug ketoconazole (KTZ). A schematic illustration of the EC-EPR setup is given below. The developed method relied on monitoring the peak-to-peak EPR signal intensities obtained from KTZ-radical species that were generated electrochemically at disposable graphite pencil electrode (GPE) surfaces. Optimization of the EC-EPR parameters enabled KTZ radical detection at a concentration and with a volume that were one order of magnitude lower than the corresponding concentrations and volumes tested using chemical oxidation analysis techniques.

Abstract Title **Ultraviolet Visible and Infrared Spectroscopy as a Tool for Characterization and Classification of Colombian Propolis**

Primary Author Guillermo Salamanca-Grosso
Universidad del Tolima

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Laura M. Reyes-Méndez, Mónica P. Osorio-Tangarife

Abstract Text

Propolis is a natural and sticky, resinous, material collected by bees from different botanical materials and exudates found on plant wounds, mixed with own substances from mandibular and hipofaryngeal secretions, and transformed in order to be used for sealing different holes in the hive, to clean the comb cells or to hygienist hives. The studies of propolis are usually associated with the identification and determination of their biogeographic origin. Usually instrumental analysis is necessary for evaluations and characterization of this natural product. The object of this research has been focused on UV-Vis and infrared spectroscopy as a tool for classification of Colombian propolis from different biogeographical zones. Twenty-three samples of crude propolis were extracted with ethanol 96^o, determining the performance in the soft extract in each removal. The infrared and UV-VIS spectroscopy spectrum were measured and registered. Organoleptic properties and spectral properties were used in for the characterization and classification of the types of Colombian própolis. Propolis spectra with 320 nm have total flavonoid content low tan 2 g /100 g. Propolis spectra having a plateau as UV maxima between 320 and 395 nm exhibit a total flavonoid content approximately of 5 g/100 g; spectra samples having 295 nm, show total flavonoid between 5 and 10 g/100 g. IR (cm⁻¹) spectra show signals for C-H bonds of aromatic compounds, in the region of 3300–2700 range, carbonyl group, (C=O) with a strong absorption in (1820–1660); O-H band group found at (3300–2500); C=C band was as a weak absorption (1650); Aromatic ring as general gave rise weak absorption in (1650–1450). Additional procedures for classification demand the use of chemometric analysis.

Abstract Title **Physicochemical and Quantitative Analysis of Ten Brands of Ofloxacin Tablets Obtained from Mushin Area, Lagos State, Nigeria**

Primary Author Aderonke A. Adepoju-Bello
University of Lagos

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Abiodun G. Ayoola, Hannat T. Akanbi

Abstract Text

Ofloxacin is a synthetic chemotherapeutic agent used to treat severe and life threatening infections. It is a fluroquinolone antibiotic with broad spectrum of activity. This study aimed at evaluating some physicochemical parameters and quantitative quality of ten brands of ofloxacin tablets randomly obtained from some pharmaceutical stores in Mushin Area, Lagos state.

The physicochemical tests carried out include uniformity of weight, hardness, friability, disintegration and dissolution while the Ultraviolet/Visible spectrophotometric method was adopted for the quantitative analysis.

The dissolution rate and disintegration time were determined in simulated gastric fluid (SGF). Similarity factor (f₂) was used to assess bioequivalent between the innovator brand and the other brands.

The results indicated that all the ofloxacin brands complied with the official specification for uniformity of weight, friability, and disintegration. However, the dissolution profiles in 0.1N HCl (SGF) showed that brand F failed to attain 80 % dissolution in 30 min, despite the fact that it passed the quantitative test. Brands F, G and J has similarity factor less than 50 % compared to the innovator brand (brand A). This shows that brands F,G and J are not similar with the innovator brand. The UV spectrophotometric assay of ofloxacin tablets revealed that two brands (B and G) contained less than 90 % of labeled chemical content. This suggests that chemical equivalence does not indicate bioequivalence.

In conclusion, 100% of the samples passed the physical tests while 80% of the samples passed the quantitative assay and 70% passed the similarity test.

Abstract Text

Drug stability studies, including chemical, physical, and microbiological stability, is mandatory for development of pharmaceutical active ingredients and products. No significant changes (e.g. appearances, drug contents, impurities, polymorphisms, sterility, etc.), which impact pharmaceutical quality, safety and efficacy, should be observed during the drug shelf-life. Methods for stability studies must be stability-indicating to enable the determination of drug substances and the quantitation of degradation products upon exposure to various stress conditions (e.g. thermal stress, hydrolysis (acid, alkaline, neutral), photolysis and oxidation).

Two stability-indicating capillary electrophoretic (CE) methods were developed for the stability study of anti-diabetic drugs, metformin (MET) and gliclazide (GCZ). For MET and its major degrade (CGN), capillary zone electrophoresis (CZE) was proposed in 40 mM citrate buffer (pH 6.7) using a fused-silica capillary with an effective length of 60 cm and an inner diameter of 50 μm , injection at 50 mbar for 5 s at 30 $^{\circ}\text{C}$ with a voltage of 15 kV and photodiode array detection (PAD) at 214 nm. For, GCZ and its impurities (gliclazide impurities B (GZB) and F (GZF)) were separated using 10 mM phosphate buffer (pH 7.0) containing 15 mM sodium dodecyl sulfate on a fused-silica capillary with an effective length of 40 cm and an inner diameter of 50 μm , injection at 50 mbar for 5 s, temperature of 25 $^{\circ}\text{C}$, a voltage of 20 kV and PAD at 225 nm. Both methods were validated and applied to establish stability profiles, degradation kinetics (e.g. rate constants, half- and shelf-lives) and pathways of both drugs.

Abstract Text

To determine the optimal interactions between flavonoid ligands and Benzodiazepine Receptor (BzR) on GABAA, 4D-QSAR analysis was applied using CoMCET method. The electronic properties were used as the 3D descriptors created by ETM. GA (genetic algorithm) was performed to analyze these descriptors roles in all activities and to construct a model that would be able to predict binding affinity for a wide range of molecular structures. Model validation was carried out by applying LOO-CV in addition to external validation. Using a Pha model together with five partial atomic charges as descriptors, a QSAR model of nonlinear equation was established, then the Q2 and R2 possessing fairly high values of 0.806 and 0.761, respectively were calculated. The analysis of docking suggested good theoretical affinity and pharmacophoric points of the new compounds to the enzyme GABAARs/BZR. Docking analysis was in harmony with the QSAR analysis.

Abstract Text

Memantine, amantadine and rimantadine are amantadane drugs that act as an N-methyl-D-aspartate antagonist. Memantine and amantadine are neuroprotective agents, which are used for treatments of Alzheimer's and Parkinson's disease, respectively. Additionally, amantadine and rimantadine are antiviral drugs that are used in combination with oseltamivir for treatment of influenza. Analysis of these drugs can be problematic due to the lack of chromophores or fluorophores in their structures. Although several analytical methods have been proposed, including liquid chromatography-mass spectrometry (LC-MS), spectrofluorometry and gas chromatography-MS (GC-MS), simpler, faster and more cost-effective methods are still required. This study aimed to develop a fully automated procedure for the analysis of the drugs using in-line derivatization capillary electrophoresis with photometric detection. Standard solutions of the drugs were directly injected into the capillary then were in-capillary derivatised with a short plug of fluorescence tag fluorescamine, which was injected before the sample. Separation was carried out in 150 mM borate buffer (pH 9.5) using a 50 μ m i.d. capillary with an effective length of 50 cm, with a voltage of 25 kV, temperature of 25[degree]C and the detection wavelength at 305 nm. The fluorescent product migrate at 5.3 min and was baseline separated from interference. The product formation increased linearly ($r^2 > 0.98$) to the amount of the analyte. Simultaneous separation of all products and application for real samples are under investigation. The method offers advantages in term of short analysis time and a low sample and chemical consumption, which can be beneficial to pharmaceutical analysis.

Abstract Text

In April, 2012 the United States Pharmacopoeia (USP) proposed that Chapter 231 be replaced with two new Chapters which outline ICP-OES/ICP-MS methods to determine a group of metallic contaminants in pharmaceutical products and supplements. The methods that have been summarized in General Chapters <232>, <233> and <2232> are undergoing final revision with a proposed implementation in December, 2015. Chapter <232> specifies the list of elements and their toxicity – Personal Daily Exposure (PDE), and outlines the method of analysis per maximum daily doses of the drug within specific drug delivery categories – oral, parenteral (intravenous injection), inhalation and large volume parenteral. The objective of the chapter <2232> is to limit the amounts of four of the most toxic potential elemental contaminants in finished dietary supplements: arsenic, cadmium, lead, and mercury (the “Big Four”). Many papers and articles have presented data from analysis of a single specific drug or supplement (based on the recommended dosage) using the new USP Method. However, it is common for people to take several medications and supplements daily. This poster presents data from an experiment to sum the USP 232 elements found in a hypothetical mix of a few common drugs and popular supplements that one person might take daily. It utilizes the tools outlined in USP Chapter 233 - sample preparation by closed vessel (microwave) digestion and analysis by ICP-MS.

Abstract Text

An enteric-coated tablet formulation was developed for a BCS Class II compound with a layer of acid-resistant polymer coating to prevent drug release under acidic conditions. The active pharmaceutical ingredient (API) has poor aqueous solubility (<1 [micro]g/mL) across a wide pH range. To develop the two-stage dissolution method as per USP <711>, we used a micro dissolution apparatus to perform solubility testing and screen different dissolution media. The in situ, real-time dissolution profiles were collected by a UV fiber optic spectrophotometer. After the dissolution media were selected, a Distek Symphony 7100 with dissolution apparatus I & II was employed to screen and optimize other dissolution method parameters. Among the several surfactants studied, SLS was selected since it results in good solubility of the API from pH 1.2 to 6.8, and provides satisfactory release of the core tablet. However, the direct application of SLS in acid media will cause slow dissolution of the enteric coating material. To solve this challenge, the final dissolution method was developed as a 2-tier method with media additions, with an initial acidic media stage, followed by a stage using pH 6.8 phosphate buffer. This dissolution method demonstrated that the enteric-coated tablet has minimal release under acidic conditions and full release at pH 6.8, which met the USP requirements for a delayed release formulation.

Abstract Text

Adenosine-5'-triphosphate (ATP) supplements are a relatively new trend in the health and exercise industry, but the notion of a secondary source of energy outside of a normal diet is not new. It is well known that many of the dietary supplements on the market are unregulated. In fact the FDA estimates that up to 70% of supplement companies do not adhere to basic quality standards which can result in health complications. Due to the nature of the marketing taking place with respect to ATP supplements, it is important to determine the purity and accuracy of the ingredient labels because many of the ATP supplements also contain its hydrolysis products including adenosine-5'-diphosphate (ADP), adenosine-5'-monophosphate (AMP) and adenosine. Quantitative analysis of two commercial ATP supplements (Douglas labs and Hammer nutrition) was performed using capillary electrophoresis with UV detection. The four analytes were separated and detected using a run buffer consisting of 20 mM pH 7.48 phosphate buffer at 485V/cm field strength. It was discovered that each Douglas Labs ATP-20 tablet contained an average of 11.59% ATP, as well as 0.3% AMP and 0.2% ADP by weight. Adenosine was quantitated by microchip electrophoresis with electrochemical detection and was present at a concentration of 0.4% by microchip capillary electrophoresis. Hammer Nutrition PeakATP tablets contained a proprietary form of ATP that could not be quantitatively analyzed.³¹P NMR spectra also confirmed the presence of ADP and AMP in both commercial supplements.

Abstract Text

The Joint United Nations Program reported the estimate of people living with HIV was 33.4 million in the world in 2008[1]. Indinavir is a common drug used in HIV therapy. Recent studies have revealed the drug-drug interaction between venlafaxine immediate-release formulation and indinavir[2]. It was reported that interaction of racemic mixture of venlafaxine significantly decrease serum concentrations of indinavir by 28% thereby possibly lowering the therapeutic benefit of indinavir in HIV-treated patients. If a drug-drug interaction alters the balances of (-) and (+) enantiomers, it is possible that the other therapeutic actions of antidepressant such as efficiency in patients with chronic pain syndromes could be affected. The only way to rule out this type of drug-drug interactions is the assessment of the potential changes in (-) and (+) enantiomer serum concentrations of venlafaxine and its metabolites O-desmethylvenlafaxine, which is marketed as Pristiq®[3-4], and is about three times more potent than Vx in inhibiting norepinephrine(NE) presynaptic neuron reuptake[4].

In this study, a pharmacokinetic assay based on micellar electrokinetic chromatography-electrospray ionization-tandem mass spectrometry (MKEC-ESI-MS/MS) is under development to simultaneously separate the two enantiomers of both VX and ODVX. To achieve the simultaneous baseline enantiomeric separation of VX and ODVX in short analysis time, some MKEC parameters such as head groups of the surfactant and buffer pH etc. have been optimized. We are now at the stage of method validation and application to the patient plasma samples.

Abstract Text

The development of medical physics in Russia recent years was associated with the attention of medics to physical characteristics of biological objects - tissues, blood, physiological liquids etc. The evaluation methods of biological objects structure - cells of human organism, bacteria, etc are developed. In this regard, there is a growing interest to devices and equipments to assess the physical characteristics of drugs, promising for use in the treatment of diseases. For example, the rheological characteristics of the skin medications are important. It is known that the standard methods of viscosimetry require a large volume of liquid and this is often inconvenient.

The possibility of application in dermatology the device constructed by Russian hematologists for the evaluation rheological properties of blood, suspension of erythrocytes and plasma are presented here. In this device the time of expiration of any biopolymer, viscous component or mixed drug solutions are registered automatically. Probe volumes of sample elastic - viscous biologically active fluid is equal to 250 microlitres. This is more economical than forehead methods for samples of the developed drugs in the treatment of skin. As the models of viscous drugs for skin were selected the water solutions of glycerin with concentrations ranging from 10 to 80 % of glycerin; these fluids comes in many pharmaceuticals. The series of porous membranes from polycapramide, which are more sensitive to viscous properties of flowing liquids, were chosen as the models of the skin. The diameter of pores was 0.22 - 0.65 μm , the surface structure of membranes was determined by atomic force microscopy. The results of obtained relations between the glycerin concentrations and the flow dynamics of viscous fluid through the porous films as skin model are presented.

Abstract Text

Hot Melt Extrusion (HME) has become increasingly adopted for the formulation of new chemical entities (NCE) to overcome solubility and dissolution rate issues. An important application of HME is the development of novel pharmaceutical applications such as co-extrudates. In which, a multi-layered extrudate is created by simultaneous hot-melt extrusion of two or more materials through a single die.

Raman imaging can be an excellent analytical technique to characterize the co-extrudates due to its sensitivity, speed, spatial resolution and highly detailed chemical information it can provide. In particular, the resulting images can be used to confirm the migration of the active pharmaceutical ingredient (API) between different layers.

Here we present the complete process of producing a co-extrudate in laboratory scale and applying Raman imaging technique to monitor the quality of the final product. Critical process steps and associated analytical parameters will be discussed in-depth.

Co-Author(s)

Abstract Text

The absorption and fluorescence behavior of a rigorously purified phenylalanine ionic liquid, L-Phenylalanine ethyl ester bis(perfluoroethanesulfonyl)imide are studied in the neat condition. The ionic liquid was prepared using a metathesis reaction between lithium bis-(perfluoroethylsulfonyl) imide (LiBETi) and L-Phenylalanine ethyl ester hydrochloride. The ionic liquid was obtained as a highly viscous and clear liquid at room temperature. The water content of the IL was determined using Karl Fischer titration. The possibility of racemization in the synthesized ionic liquid was evaluated using circular dichroism. NMR spectroscopy was used to determine its purity and its thermal properties were evaluated using thermal gravimetric analysis (TGA) and differential scanning calorimetry (DSC). The ionic liquid was found to be stable up to 292°C with a melting point of 95°C. The fluorescence emission of the neat CIL shifted to longer wavelengths as the excitation wavelength was increased. This is attributable to the existence of energetically different excited state species. The work involves studying the CIL's viscosity and ability for column coating. It is used to analyze its ability to discriminate between various chiral analytes.

Abstract Text

Different chemometric models were applied for the quantitative determination of betamethasone dipropionate (BMD), clotrimazole (CT) and benzyl alcohol (BA) in ternary mixture using their UV spectral data, namely, Partial Least Squares (PLS) and Artificial Neural Network (ANN). The effect of Genetic Algorithm (GA) as a variable selection tool was evaluated by comparing the results obtained from the PLS and ANN models with and without variables selection. The applied chemometric models were PLS, ANN, GA-PLS and GA-ANN. A calibration set composed 15 mixtures and a validation set composed of 12 mixtures were both constructed according to a 3-factor 5-level experimental design. The proposed methods were successfully used for the determination of BMD, CT and BA in pure powder form and in pharmaceutical preparation and the validity of the proposed methods was further assessed by applying the standard addition technique.

Abstract Title **EDXRF Method for Ultralow Level Sulfur in Gasoline Analysis to Comply with US EPA Tier 3 Ruling**

Primary Author Kim Russell
Analytical Instruments Marketing

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s)

Abstract Text

US EPA's Tier 3 Ruling reduces allowed sulfur concentrations in gasoline from an average of 30 mg/kg to an average of 10 mg/kg, beginning in 2017. Refiners, importers and biofuel blenders of gasoline will be required to perform sulfur analysis at these ultra-low levels to report compliance throughout the supply chain. The Ruling also enacted use of a PBMS (Performance Based Measurement System) approach to allow reporting laboratories new flexibility regarding the sulfur test method they may use. Use of consensus group (e.g. ASTM) standardized test methods and mandatory quality control practices validate adequate measurement quality.

The objective of this project is to demonstrate that the recently revised ASTM D7220 sulfur test method initially used for EPA's 2006 Diesel Ruling which reduced allowed sulfur concentration down to 15 PPM, can also be utilized to meet EPA's Tier 3 Ruling. D7220 takes advantage of monochromatic EDXRF to reduce background radiation interference and produce a single energy of excitation for sulfur.

Experiments were conducted using a monochromatic EDXRF system with a close-coupled, doubly curved HOPG crystal to reflect Ag K α radiation, a vacuum chamber, a Pelletier-cooled Ag anode X-ray tube, and a Silicon Drift Detector. Sample volumes of 5 mL were analyzed. Testing parameters and example data that exhibit pass/fail conditions are described.

Findings conclude that compliance with all EPA PBMS requirements for both ultra-low sulfur diesel and gasoline for sulfur levels at and below 3 mg/kg, well within the Tier 3 Ruling, is demonstrated using the recently revised ASTM D7220 Method.

Abstract Text

Aramar Experimental Center (AEC) is part of military organization of Brazilian Navy that develops the Nuclear Program for the first Brazilian Nuclear Submarine. It's located at Iperó, São Paulo, in Sorocaba river basin, near a permanent conservation unit called Ipanema National Forest. The objective of this study is monitoring points upstream (A) and downstream (B, C) the effluent discharge of AEC (Fig.1a), using an alternative technique for direct analysis of total uranium and other metals, in sediment samples. The application of wavelength dispersion X-ray fluorescence (WDXRF) techniques with univariate calibration method and fundamental parameters, used for inter-elemental (or matrix) effects corrections with reduced sample preparation steps has shown promise for direct analysis of uranium, thorium, cobalt, lanthanum, cerium and lead. The assessment methodology performed by statistical tools using Certified Reference Material from International Atomic Energy Agency "Soil7", showed acceptability of methods of analysis to agree with HORRA values, i.e. ratio of the observed relative standard deviation calculated from the actual performance data, to the corresponding predicted relative standard deviation calculated from the Horwitz equation, since the calculated values are <2 for all elements listed. The accuracy in terms a Z-score value has also been accepted, since for every element the values are <1.4, effectiveness proving of the proposed methodology. The quantification limits are between 0.1 and 2.3 [micro]g.g-1, enough to achieve the aims of this work. The analysis results (Fig.1b) showed there's no significant influence after effluent discharge and nuclear area activities, when compared with a control point (D).

Abstract Title **Chlorine Analysis of Cement Materials by XRF Using Borate Fusion as Sample Preparation**

Primary Author Mathieu Bouchard
Claisse

Date: Tuesday, March 10, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) John A. Anzelmo, Marie-Ève Provencher, Sébastien Rivard

Abstract Text

This paper evaluates the benefits of using borate fusion preparation combined with XRF to analyze chlorine in cement and raw material products. In this industry, it is important to quantify the chlorine content in the cement-related materials because the production process can be slowed down if the level of chlorine is too high. Also, the level of chlorine in most cement finished products must be maintained as low as possible because it reacts with the metal reinforcements in the structures. It reduces the strength and the lifetime of the concrete. Also, some types of cement need a specific amount of chlorine to give the product its distinct properties.

Many cement laboratories use an alternative method to XRF for their chlorine analysis since it is challenging to find CRMs with good certified values for chlorine. Integrating the analysis of chlorine into their borate fusion and XRF routines would allow them to reduce the number of analytical methods, diminish the workload and decrease the operations costs.

MATERIALS

All experiments were done with an electric fusion instrument: TheOx. LOI on all samples and CRMs were made on a Fisher Scientific Isotemp® muffle furnace. Spectrometer analytical conditions were selected and optimized to qualified standard method ASTM C 114 and to validate ISO/DIS 29581-2.

SIGNIFICANCE

This research examines the analysis of chlorine using a well-accepted analytical method for the analysis of all oxidized compounds found in cement related materials. The chlorine data compiled will be presented to explain how the chlorine calibration curve was elaborated and validated. The spectrometry, standards preparation and calibration strategies for chlorine will also be widely discussed in the presentation. Precision testing on the analysis of chlorine were done following the ASTM C 114 regulation for cement material analysis and accuracy evaluations were conducted following the standard methods ASTM C 114 and ISO/DIS 29581-2.

Abstract Title **High Resolution Field Cycling ^{31}P NMR Relaxometry – A Tool to Identify Novel Phospholipid Binding Sites on Amphitropic Proteins**

Primary Author Mary F. Roberts
Boston College

Date: Tuesday, March 10, 2015 - Afternoon

Time: 02:15 PM

Room: 243

Co-Author(s)

Abstract Text

Changes in the rate of recovery (R_1) of the phosphorus nuclear spins as a function of magnetic field (particularly in the region from 0.005 to 0.5 T) in the Redfield high resolution field cycling system provide a new way to explore phospholipid dynamics and interactions with amphitropic proteins. The methodology is particularly useful for identifying and localizing novel phospholipid binding sites on a protein that is spin-labeled on discrete sites. Whether the amphiphile is presented in a vesicle or micelle, or mixed with variety of other lipids, the differences in the proximity of the amphiphile to spin-labels can be easily monitored. Combining these NMR-derived ^{31}P -electron distances with modeling provides testable models for discrete amphiphile binding sites. The method is illustrated with studies of three enzymes, transiently anchored on membranes, that are known to bind phosphatidylinositols but also have interactions with other phosphorylated amphiphiles (whereabouts unknown until this work). (1) A bacterial phosphatidylinositol (PI) specific phospholipase C forms a cation- π complex with phosphatidylcholine $\sim 15 \text{ \AA}$ from the enzyme active site that enhances PI-specific phospholipase C binding to vesicles for processive catalysis. (2) The PH domain of Akt1 has a unique site for a cytotoxic alkylphospholipid near but not overlapping with the natural $\text{PI}(3,4,5)\text{P}_3$ binding site; the bound alkylphospholipid misorients the protein on the membrane thus preventing phosphorylation and kinetic activation. (3) The tumor suppressor PTEN has a binding site for its hydrolysis product $\text{PI}(4,5)\text{P}_2$ distinct from its active site whose occupation can aid in membrane binding and enhance enzyme catalytic efficiency.

Abstract Text

The flexible nature of protein loops and the timescales of their dynamics are critical for many biologically important events at the molecular level, such as protein interaction and recognition processes. In order to obtain a predictive understanding of the dynamic properties of loops, we classify them into three types, namely fast loops with correlation times < 10 ns, slow loops with correlation times between 10 ns and 500 ns, and loops that are static over the course of the whole trajectory based on the detailed comparison of experimental and predicted NMR chemical shifts and order parameters from 500 ns MD trajectories of 38 different proteins. Chemical and biophysical loop descriptors, such as amino-acid sequence, average 3D structure, charge distribution, hydrophobicity, and local contacts were used to develop and parameterize the algorithm for the prediction of the flexibility and motional timescale of every protein loop. The results demonstrate that loop dynamics with their timescales can be increasingly well predicted, which helps better understand the various roles of protein loops for protein-protein interactions during biomolecular recognition events.

Abstract Text

Ras proteins are critical regulators of multiple pathways involved in cellular growth control. Activating mutations in Ras genes are found in 33% of human cancers, with Ras well recognized as the most commonly mutated oncogene in human cancer. The population of activated, GTP-bound Ras in normal cells is controlled by protein regulators. Mutations in Ras associated with cancer promote cellular activation by populating the active state of Ras, most frequently by impairing the action of proteins that downregulate its activity. We are investigating novel mechanisms of Ras regulation by posttranslational modification of lysine and cysteine residues in the conserved guanine nucleotide binding domain. Our previous studies of K- and H- Ras have shown that monoubiquitination and cysteine oxidation can upregulate Ras activity and promote Ras-mediated tumorigenesis. We are further characterizing these and other posttranslational modifications. Multiple approaches are being used generate and characterize lysine and cysteine modifications, including mutagenesis, chemical biology and unnatural amino acid incorporation. To better characterize mechanisms by which these posttranslational modifications modulate Ras function, NMR, modeling, biochemical and biological studies are being conducted. Results from these analyses will be presented, along with our recent work on an oncogenic variant of Ras, K-Ras G12C, prevalent in lung cancer. We find that this activating mutation introduces a redox active cysteine that renders Ras G12C sensitive to thiol oxidation. Thiol oxidation at this site alters Ras activity in a manner distinct from other oncogenic mutations at position 12.

Abstract Text

TRIM5 α retroviral restriction factor is a member of the TRIM family of RING E3 ubiquitin ligases. TRIM5 α of the rhesus monkey binds to the HIV capsid and potently blocks HIV replication, whereas the human variant of the protein is not active against HIV. Affinity of TRIM5 α for the capsid is a major host tropism determinant of HIV and other primate immunodeficiency viruses, but the exact molecular interface involved in this host-pathogen interaction and the details of the restriction mechanism are not fully understood. We use spectroscopic and biophysical methods to characterize the molecular basis of the TRIM5 α -mediated antiretroviral immunity. NMR-based approaches have proven particularly powerful for this system. NMR techniques allow mapping of the TRIM5 α -capsid interactions mediated by the highly-variable and mobile loops of the C-terminal SPRY domain, whereas NMR studies of the mobility at the capsid-binding interface shed light on the remarkable ability of TRIM5 α to restrict divergent retroviruses and to tolerate capsid mutations. In addition, NMR allows characterization of the weak, but critical, protein-protein interactions involved in the catalysis of poly-ubiquitin synthesis. Our data elucidate how SPRY-capsid interactions and the higher-order oligomerization of TRIM5 α contribute to the activation of the E3 ubiquitin ligase function and HIV restriction. Our studies provide mechanistic insight into the emerging role of TRIM proteins in innate immunity.

Abstract Text

Chemical recognition by complexation may occur in homogenous solution phase or in a separate phase that is immiscible with water. The former lays the foundation for molecular probes, complexing agents and indicators, the latter is at the heart of electrochemical detection and sensing. We will here show that nanomaterials allow us to blur the lines between the two previously separate concepts. With suspensions of suitably doped micelles or hydrophobic nanospheres we achieve short diffusion distances that are approaching those in homogeneous phase. Water insoluble recognition elements can now be used to effect sample concentration changes in analogy to homogenous reagents, and the combination of an ensemble of reagents may be used to develop functional toolboxes that are truly innovative. Examples will include the development of nanoscale probes for exhaustive ion sensing, the use of light to induce oscillating sample concentration changes in a selective and reproducible manner, the introduction of a nanoscale mimic of complexometric titration reagents with much improved selectivities, and potentiometric nanoscale sensing based on the incorporation of potential sensitive dyes.

Abstract Text

Nitric oxide (NO) controls many important physiological processes. Although NO's role as a potent vasodilator is well known, NO is also very effective at preventing clotting and is a powerful antimicrobial agent produced by several innate immune cells (e.g., macrophages, neutrophils, etc.). Therefore, it should be possible to prevent infections and/or clotting widely associated with a variety of medical devices (e.g., intravascular catheters/sensors, urinary tract catheters, extracorporeal blood loops, etc.) by developing materials/devices capable of releasing low levels of NO gas over extended time periods. In this presentation, it will be shown that a variety of hydrophobic polymers (PVC, polyurethanes, silicone rubber, etc.) often utilized to fabricate biomedical devices/systems can be formulated/designed with relatively simple chemistries (including electrochemical approaches) to release NO gas for days and weeks with NO fluxes at or above those generated by many cells in our bodies. It will be further shown that such NO release materials/devices can be employed to make simple intravascular or urinary catheters that exhibit potent antithrombotic and antimicrobial activities when tested in vitro and in vivo (in animals). Finally, it will also be demonstrated that these new NO release materials/devices can be combined with more classical electrochemical analytical sensor technologies to create implantable sensors for oxygen, glucose, and lactate that exhibit greatly enhanced thromboresistance and thereby improved analytical accuracy when placed in veins or arteries for continuous monitoring of these important species in blood.

Abstract Text

Detection of toxins is of particular importance because near real-time detection is essential in cases of imminent threat and because toxins can be modified or otherwise disguised while remaining active. The objective of this project is the creation of new, low-cost, appropriately sensitive paper diagnostic devices for the electrochemical detection of biological weapons. To satisfy this objective, we initiated development of a quantitative ricin sensor using a magnetic microbead supported silver nanoparticle (AgNP) metalloimmunoassay to probe the ricin A chain protein. The sensor integrates picomolar affinity antibodies with our easily handled, but sophisticated, electrochemical detection platform: the [i]o[/i]Slip. The [i]o[/i]Slip incorporates two simple, but effective, preconcentration steps. The first involves magnetic preconcentration of AgNP labels at a working electrode, followed by the spontaneous oxidation of these labels in the presence of a chemical oxidant stored on the device. Importantly, this oxidizing agent is delivered into the channel at a specific time and location by simply slipping a moveable piece of paper. The resulting Ag ions are then electrodeposited onto the working electrode (the second preconcentration step). Oxidation of this Ag layer leads to detection of the AgNP-labeled target. We have demonstrated quantitative electrochemical detection of ricin A chain at a LOD of 78 pM by means of fast (3.5 minutes) and non-enzymatic signal amplification. Importantly, the custom antibodies can bind to both glycosylated and recombinant ricin, allowing for the detection of genetically modified toxins. This project is sponsored by the Defense Threat Reduction Agency (Contract Number HDTRA-1-13-1-0031).

Abstract Text

Non-invasive separation-free protocols are attractive for quantitative analysis in complex mixtures. To address the demanding selectivity issue, we propose to perform analysis under kinetic control upon exploiting the reactivity of labelling contrast agents. In particular, our simple analytical protocol has been applied in optical fluorescence microscopy, where autofluorescence, light scattering as well as spectral crowding presently bring limitations. We have introduced OPIOM (Out-of-phase imaging after optical modulation), which exploits the rich kinetic signature of a photoswitching fluorescent probe to achieve its selective and quantitative contrast. Filtering the specific contribution of the probe simply requires matching its photoswitching dynamics to the intensity and frequency of a modulated monochromatic light excitation. We validated OPIOM for selective imaging in mammalian cells and zebrafish, opening attractive perspectives for multiplexed observations under adverse conditions in biological samples.

Abstract Text

Light and electrodes have a long history with spectroelectrochemistry, electrochemiluminescence and photovoltaics. Here we exploit light shined on an electrode to locally activate the electrode surface to allow Faradaic electrochemistry to occur on the illuminated spot only. The light is shined onto a modified silicon electrode where Faradaic electrochemistry is observed at defined locations whereas in the dark no electrochemistry is observed. To achieve this, first an oxide free silicon electrode is modified with a self-assembled monolayer of 1,8-nonadiyne which protects the surface against oxidation. Subsequently a redox species is attached to the surface, either a ferrocene derivative for n-type silicon or an anthraquinone derivative for p-type silicon. Provided at the potential at which oxidation/reduction of the redox species occurs the silicon is in the depletion, then no electrochemistry is observed in the dark. Upon illumination distinct Faradaic electrochemistry is observed. We show this electrochemistry can be confined to 50 μm with backside illumination and 30 μm with frontside illumination. Subsequently, using SECM we show that the surface bound redox species can be used as a mediator to detect redox species in solution. We next show that we can detect DNA hybridization and form DNA electrode arrays (an example of reading electrochemical information from the electrode surface) and show that we can write conducting polymers to the surface. Finally we demonstrate an application for the capture and localized release of cells from the surface.

Abstract Text

Continuous synthesis of fine chemicals and pharmaceuticals using microfluidic platforms enables rapid investigation of reaction chemistry with small amounts of reagents and under conditions difficult to realize in batch. Current continuous flow systems are based on two basic approaches: 1) experimental setups consisting of plastic, glass or steel pipes that are easy to construct, replace and iterate, or 2) intricate setups made of silicon/glass which require the use of photolithography and micromachining, and taking significant resources to iterate. 3D printing of polymers, metals and glass can promise to combine the advantages of both types. Intricate setups can be designed and fabricated quickly and at a fraction of the cost compared to traditional machining methods. We describe the adaptation of an additive 3D printer to create reaction vessels for continuous flow chemistry. We explore the use of different materials to test their utility for additive printing, and their stability for handling the broad range of solvents and reagents used in flow chemistry. We use the thermoplastic, amorphous polymer acrylonitrile butadiene styrene (ABS) first to understand the capabilities of the 3D printer. The relationship between the extrusion temperature, bed temperature and extrusion rates are explored to make repeatable test objects. We then extend additive printing techniques to create polypropylene channels and reactors. We characterize the physical properties of the printed reactors. Finally, we study model chemical reactions of interest to the pharmaceutical community to study the dependence of reaction rates on channel geometry.

Abstract Text

Oftentimes there is a gap between when a microfluidic device needs to be field tested in other labs and before it is ready for commercialization. The burden and high failure rate of fabricating PDMS based devices to disseminate to non microfluidic labs can hinder the adoption of these new devices. This is where 3D printing can help bridge the gap between proof of concept and commercial reality and allow new devices to be more rapidly disseminated and for microfluidics to more easily integrate into non microfluidic labs. Recently 3D printing has emerged as a method for directly printing complete microfluidic chips, although printing materials have been limited to non-oxygen permeable materials. We demonstrate the addition of gas permeable PDMS (Polydimethylsiloxane) membranes to 3D printed microfluidic devices as a means to enable oxygen control cell culture studies. Specifically, we use negative pressure to drive these devices with the integration of an additional 3D printed Venturi microfluidic device which allows us to pull desired oxygen conditions through the network using the oxygen condition as the compressed air source. The negative pressure has two main benefits; it reduces bubble formation in the culture chambers and serves to help hold the gas permeable membrane in place. We use this setup on three separate 3D printed microfluidic devices including a 100 mm petrie dish with integrated hose barbs, a 24 well plate insert, and a microfluidic dilution network able to generate 21 different stable oxygen conditions from two separate inputs.

Abstract Text

3D printing is a potentially attractive fabrication and prototyping method for microfluidic devices. In particular, there has been great interest in using commercially available 3D printers or 3D printing services to fabricate microfluidic devices. To date, however, only passive devices (i.e., no integrated valves or pumps) have been demonstrated. Moreover, material selection tends to be limited to commercially available resin formulations. In this presentation we report the fabrication and characterization of pneumatically-controlled on-chip valves in microfluidic devices with fluid channels having minimum dimensions approaching 100 [micro]m. We use an inexpensive projector-based stereolithographic 3D printer, the B9Creator v1.1 (B9Creations, LLC) with our own poly(ethylene glycol) diacrylate (PEGDA) resin formulation, which we have explicitly developed to exhibit low non-specific protein adsorption when polymerized. Initial testing of our non-elastomeric membrane valves indicates that the fluid pressure needed to open a closed valve is the same as the applied valve closure pressure. We are exploring a variety of valve dimensions and geometries to maximize valve robustness and longevity for potential applications in small volume bioassays.

Abstract Text

Despite being an old technique, additive manufacturing has received significant hype because of the ability to create just about anything. Our research has focused on addressing the issue of how mass-consumer targeted printers can be used to create microfluidic devices. We have evaluated low-cost (<\$5k) printers based on UV polymerisation using a digital micromirror device (DMD) projector and fused deposition modelling (FDM). Each approach has advantages and limitations for making flexible, 3D enhanced microfluidic devices. The use of these printers to create integrated microfluidic devices with advanced 3D analytical capability will be discussed.

Abstract Text

Microfluidic devices have been a very useful and important tool in our group and others for studying cells and cellular processes. In particular, our laboratory has employed various devices for investigating blood components and interactions of these components with other cell types. Here, we will present recent results demonstrating the utility and efficiency of 3D-printed devices and how they are helping our group understand the chemistry and biology of stored red blood cells that are used in transfusion medicine. Specifically, this presentation will describe various fluidic devices that are used to examine modifications to solutions used to store red blood cells prior to transfusion. Current storage solutions are extremely high in glucose and are thought to impair cell performance upon transfusion. Our results, using a 3D-printed circulation mimic, show that solutions modified to have lower glucose levels are beneficial to the stored cells. In addition, we will show other devices that have been printed that enable us to investigate the deformability of the stored cells and how these cells may behave after transfusion back into a patient environment.

Abstract Text

Organs-on-chips (OoCs) bioreactors, which aim to replicate human cellular responses in a microfluidic environment, may lead to advances in systems biology and provide new avenues for drug development and testing. Microfluidic devices are needed to enable automated fluid handling to allow for increased OoC lifetime and online analysis of OoC health and behavior. This presentation will describe the use of commercial and fabricated pumps and valves to develop Perfusion Controller/ Microclinical Analyzers (PC/ μ CAs). One PC/ μ CA is a stand-alone perfusion controller with continuous on-line analysis and calibration assembled from microfluidic syringe pumps and valves from LabSmith, Inc. This instrument consists of numerous pumps and valves integrated with a microfluidic cell trap, a multi-analyte electrochemical array, and Synapt G2 and de-salter for on-line ion mobility mass spectrometry (IM-MS). This combination enables the multiplexing of microscopy, electrochemical monitoring, and on-line IM-MS to monitor cellular morphology and metabolic flux of small molecules and proteins over time into one platform. In a parallel study, fabricated rotary planar peristaltic micropumps (RPPM) and rotary planar valves (RPV) have been developed to perfuse OoCs for days to weeks within an incubator. As with the LabSmith-based PC/ μ CA, additional RPPMs and RPPVs are utilized to sample fluid directly from the OoC and deliver this fluid, as well as calibration solutions, to an electrochemical sensor placed downstream. The RPPMs and RPPVs are customizable, allowing for a range of flow rates in the pumps and input ports for the valves, and can be used in a variety of projects. The use of these pumps and valves in the development of a Neurovascular Unit on a Chip will be discussed. In summary, the automation, measurement capabilities, customizability, and abilities for long-term use make both the commercial and fabricated pumps and valves valuable tools for high-yield systems biology research.

Abstract Text

Dielectrophoresis, the motion of a particle in a non-uniform electric field, is an emerging technology for identifying and isolating targeted mammalian cell populations. Here, we present a new technique, contactless dielectrophoresis (cDEP), which uses fluid electrodes isolated from the sample channel by a thin membrane to induce large electric field gradients. These fluid electrodes enable the creation of complex 3D electrode geometries and the production of high throughput sample channels.

cDEP systems are a complex network of resistive and capacitive elements which behave as a high-pass filter. Producing electric field gradients necessary for DEP within these devices is non-trivial and requires the use of high-voltage, high-frequency electrical signals and optimization of these devices is necessary if we wish to employ both positive and negative dielectrophoretic forces to separate cells. Multi-physics simulations were used to study the electro- and thermo-dynamics of these systems, predict particle trajectories, and trapping efficiencies prior to experimentation. These simulations have enabled us to develop systems which can manipulate mammalian cells between 1 kHz and 1 MHz in a completely sterile environment.

The cDEP platform has been used to study the electrical properties of numerous cell types. Interestingly, we found that the membrane capacitance of syngeneic ovarian cancer cells changed significantly as the cells progressed from benign to aggressively metastatic. Additionally, our team has shown the utility of cDEP to enrich and subsequently re-culture tumor initiating cell populations. The work presented will cover the conceptual optimization of cDEP devices, current experimental results, and future prospective.

Abstract Text

In this talk I will discuss two microfluidic systems that take advantage of the ability to control flow exquisitely. In the first set of applications, we designed a series of microfluidic devices that can systematically load and keep in place single suspension cells, embryos, and cell aggregates. These devices take advantage of the well-behaved hydrodynamics at the micro scale, and can manipulate particles without using moving parts and yet with high reliability. We demonstrate several applications using these systems for image-based cell assays. For the second set of applications, we designed devices for handling highly active biological samples – the genetic model system *C. elegans* – for high-throughput applications. Although these devices require active control, several design features largely reduce the complexity and enhance robustness of the operation of these devices. By computer automation and coupling with advanced image informatics, we demonstrated several applications using this system to perform high-throughput and high-content screens.

Abstract Text

Type 1 diabetes mellitus, an autoimmune disease resulting in destruction of the insulin-producing pancreatic beta cells, is one of the most common and costly chronic pediatric diseases. A significant impediment to understanding disease pathology and the development of cellular replacement therapies for Type 1 diabetes is the inability to sustain mature human beta cells in culture. We seek to engineer physiomimetic 3D niches within higher throughput microfluidics devices for maturation, maintenance and monitoring of human beta cells via the convergence of technologies from stem cell biology, matrix engineering, micro/nano fabrication, and microsensors. The microfluidic devices will connect to universal docks and provide intimate control over the cellular microenvironment by independent and simultaneous modulation of liquid and gas phases, multiparameteric monitoring and assessment of cellular readouts and samplers for off-line biochemical analyses. With this degree of control, the effect of various niche parameters, such as the extra cellular matrix, nutritional gradients, soluble factors, and oxygen microenvironments on human islet maintenance and generation of mature islets from human pancreatic precursors can be clearly delineated. Of particular interest in this application are the contributions of the physiological and extracellular matrix environment on islet health and maturation. Physiological oxygen, a critical parameter in steering pancreatic progenitor differentiation towards endocrine lineage, can be intimately modulated on the microscale via the control afforded by the microfabricated platform. Further, systematic evaluation of the contributions of matrix components on promoting islet health and directing islet differentiation within controlled 3D niches is feasible via tailored presentation of native extracellular matrix components.

Abstract Text

Microfluidics is a dynamic and rapidly growing field with potential applications in numerous areas, from food and water safety, to environmental monitoring and clinical analysis. Working on the microscale offers attractive advantages such as shorter processing times, low sample and reagent consumption and the possibility of portable systems.

Sample preparation is a challenging task, in particular for applications involving biological particles. Miniaturizing sample preparation opens the possibility for fully integrated systems. Important research efforts are being devoted towards the development of microscale techniques suitable for sample preparation. Dielectrophoresis (DEP), an electric field driven technique, offers great potential due to its flexibility and ease of integration. DEP has been successfully employed to significantly enrich, sort and separate samples containing DNA, proteins, cell organelles, virus and cells.

DEP is a transport mechanism driven by polarization effects when a dielectric particle is exposed to a spatially non-uniform electric field. DEP can be used with charged and neutral particles, employing AC or DC electric potentials. DEP offers more versatility than electrophoresis since it has the capability for significant particle enrichment.

This work is focused on insulator based DEP (iDEP), a dielectrophoretic mode that uses insulating structures between two external electrodes to create electric field gradients and generate dielectrophoretic forces on particles. In this presentation we will analyze the application of iDEP systems for sample preparation and demonstrate the potential of this novel technique for successful manipulation of biological particles, such as cells. This study includes experimental work and mathematical modeling with COMSOL Multiphysics. Experimentation was carried out with devices made from polydimethylsiloxane.

Abstract Text

In this presentation, I will introduce an innovative approach to resolve DNA using a narrow bare open capillary. When DNA are transported inside a narrow open capillary under a pressure-driven condition, DNA molecules move as particles. Larger DNA fragments have greater effective diameters and cannot go to the capillary wall (the slow-moving region) as close as smaller fragments can and, therefore, they move faster. On the basis of this principle, DNA fragments of a wide size range can be separated with resolutions comparable to gel electrophoresis. Because this technique uses Bare Narrow Capillaries and its separation mechanism is primarily HydroDynamic Chromatography, we call it BaNC-HDC. I will start by telling briefly how this technique was evolved, I will then show the major accomplishment we have achieved, and I will also share with the audience our thoughts on the future of this technology.

Abstract Text

Chromatographic separation of proteins is a formidable, long-term challenge because even one protein is a complex mixture due to post-translational modification. Consequently, a sample having just one protein that was purified by antibody capture can have hundreds of proteoforms. Multidimensional separations have been used to address this challenge in proteomics and also in quality assurance of protein drugs. In our work, we focus in increasing the resolution in each constituent separation. We have particularly given attention to using submicrometer particles in chromatography to reduce broadening arising from mass transport and packing heterogeneity. We discuss how far this technology can be pushed for real samples and commercially available instruments.

Abstract Text

The present contribution aims at illustrating and demonstrating how micro-machining technology can give a boost to Liquid Chromatography (LC). Currently, LC is routinely used in nearly every chemical analysis lab. Despite its high degree of maturity, the technique however suffers from serious performance limitations when faced to the complex samples that need to be separated to solve the current state-of-the-art problems in the biological and pharmaceutical research (e.g., proteomics and metabolomics), the food and environmental analysis, etc.....

Currently, LC is conducted in packed particle columns. As this packing inevitably is disordered, the flow pattern in these columns is to a large extent disordered as well, in turn leading to an unnecessary loss in separation efficiency. To solve this packing disorder problem, the present contribution focuses on the possibilities of advanced photolithographic etching techniques such as the Bosch-process to produce perfectly ordered porous support columns with optimized hydrodynamic shape and optimized external porosity.

The work presented here in fact aims at putting to work an original idea of Fred Regnier wherein he advocated the use of micromachining to produce perfectly ordered chromatographic supports. Since then, the technological possibilities have clearly evolved and it is now possible to fabricate pillar array columns with a very tight (i.e., sub-micron) control of the pillar to pillar distances and the pillar dimensions.

At the conference, we will demonstrate the possibility of rapid multi-component separations and the possibility to achieve very low plate heights with a microfabricated column in pressure-driven LC.

The possibility to combine the pillar array technology with the recipes used to produce monolithic columns, leading up to a brand new class of column technologies, will be highlighted as well.

Abstract Text

Present day commercial UHPLC columns are typically 5 to 15 cm long, packed with sub-2 micron particles, and operated with upper pressure limits of 1,000 to 1,500 bar (15,000 to 22,000 psi). We have developed a system for capillary UHPLC columns with operating pressures to 3,400 bar (50,000 psi) and with elevated temperatures. This opens up the possibility for developing capillary columns with still smaller particles (down to 1 micron) and/or longer columns packed with sub-2 micron particles. We are routinely packing columns 25 cm long packed with 1 micron particles yielding 125,000 plates, 100 cm long packed with 1.5 micron particles yielding 350,000 plates, and 200 cm long packed with 1.9 micron particles yielding 600,000 plates. The shorter columns with 1 micron particles offer very significant performance advantages over existing HPLC and UHPLC columns but with UHPLC type speeds. The longest columns packed with 1.9 micron particles require analysis times of hours, but provide extremely high separation efficiencies and peak capacities in return. All of these columns are well suited for separations of peptides in combined LC-MS-MS proteomics applications. The range of particle sizes and column lengths provides a wide spectrum of speed vs. separation power permitting us to match the separation column to the difficulty of the particular separation problem at hand.

Abstract Text

Guidelines for high-speed chromatography are by now well understood for the most widely used columns (e.g., 2.1 mm ID). When sample size is limited and concentrations are near the detector's detection limit, then capillary columns must be used to avoid sample dilution and even achieve sample concentration on-column. Under these circumstances, it is necessary to optimize the column diameter as well as particle diameter and column length given a certain pressure and theoretical plate requirement (N). The goal is to squeeze a sample with a volume V_s into a peak with a volume V_p where V_p/V_s is as small as possible without suffering from volume overload which degrades N . With this approach, we have found conditions for making online microdialysis measurements for dopamine or serotonin over many hours with one-minute time resolution. By using superficially porous particles and temperature assisted solvent focusing, we are able to improve the method significantly.

This talk will discuss a multi-dimensional multi-channel micro-gas chromatography ([micro]GC) system and one of its important components, non-destructive flow-through gas detector, which makes the multi-dimensional [micro]GC possible. We will first present the multi-dimensional [micro]GC design and describe its performance. Then we will introduce various GC detectors developed in our lab in the past few years, including graphene nanoelectronic detectors and metallic nanoparticle detectors, as well as optical ring resonator detectors and photo-ionization detectors. Advantages of those detectors in comparison with other existing detectors will be emphasized. Finally, we will show examples of the potential applications of the multi-dimensional [micro]GC, if time permits.

Abstract Text

Metal-Organic Frameworks (MOFs) are a new class of crystalline materials exhibiting tailorable micro-to-mesoporosity. Comprised of metal ions linked to organic electronic donors such as aromatic amines and carboxylates, these materials possess a high degree of synthetic versatility that enables them to be used as recognition materials when integrated with a sensing platform. Sensing concepts using MOFs that adsorb small molecules to generate changes in mass, strain, electrical resistance, and luminosity have been demonstrated, for example. Here, we describe three novel MOF sensing modes that we are developing: First, we will discuss the use of MOFs for detecting molecular oxygen. Although O₂ detection by quenching MOF luminescence is feasible, this approach has low sensitivity relative to mass-based sensors such as surface acoustic wave (SAW) devices. We describe a process for growing oxygen-sensitive MOF thin films and demonstrate O₂ detection using a SAW sensor. Second, a less explored sensing approach using MOFs is colorimetric detection. We describe a colorimetric small-molecule sensor concept based on a composite comprised of a MOF powder embedded in an organic polymer. In this architecture, a MOF containing exchangeable metal coordination sites that bind small molecules is used as the sensing element. Upon binding, the electronic energy levels of the MOF are perturbed, leading to an easily detectable change in color. We demonstrated this concept using a MOF known as HKUST-1, which changes color upon adsorbing molecules that coordinate to the copper dimers in its structure. Finally, present a new sensing concept, in which analyte adsorption induces multiple response modes within a single MOF. The concept is demonstrated using an electrically conducting MOF film grown on MEMS devices, enabling transduction by measuring both mass uptake and the change in electrical conductivity.

Abstract Text

MOFs are a class of inorganic-organic hybrid materials with high porosity and massive internal surface area. The tunability of organic linkers and metal cluster SBUs make MOFs of great candidates for variety of applications. Most of the reported fluorescent MOFs are not suitable for sensing purposes due to their low chemical stability. Zr-MOFs have been acknowledged for their high stability, which possess great potential for chemical sensing purposes.

In the course of targeting stable MOFs, we have constructed a series of porphyrin containing Zr-MOFs, PCN-22X, with exceptional stability and applications. Most of the PCN-22X MOFs were found to retain their frameworks after emerging into aqueous solutions with pH ranging from 1 to 11. As a remarkable example, PCN-222 was proved to remain intact after the treatment of concentrated HCl. The pH dependent fluorescence of PCN-225 was investigated and was concluded that the fluorescent intensity of PCN-225 is largely influenced by the protonation and deprotonation of the nitrogen atoms in porphyrin centers. The results indicated that PCN-225 is a promising material for pH sensing, especially in the pH range of 7-10.

We have recently reported PCN-94, which constructed from Zr₆ clusters and H₄ETTC linkers, with ftw topology. This MOF showed extraordinary fluorescent properties with a 99.9% ± 0.5% quantum yield under argon. By using the same linker, PCN-128, which possesses a csq topology, was also constructed. A novel piezofluorochromic behavior of PCN-128 was discovered, in which PCN-128 undergoes a phase transition under chemical or physical stimulations. This phenomenon was observed from the color change as well as the change in emission spectra. Interestingly, the transformation of the material can be monitored stepwise by fluorospectroscopy. Both PCN-94 and PCN-128 show very high stability and high fluorescent sensitivity against their environments which makes these material of great candidates for chemical sensing uses.

Abstract Text

An emerging approach for diagnosing diseases relies on profiling volatile biomarkers that are emitted from cells in the affected area. These volatile biomarkers can be detected either via the exhaled breath or from the skin, without going invasively into the human body. The current talk will present solid-state and flexible arrays of artificially intelligent nanomaterial-based sensors that are trained in their ensemble to detect such volatile disease biomarkers. The development and the use of these systems to identify high-risk groups for specific diseases and genetic mutations and to monitor the therapy provided to people affected by that disease will be presented and discussed.

Abstract Text

Vapor sensors have their niche in gas-phase bioanalytical diagnostics when an unobtrusive, low-power, and cost-sensitive technical solution is required. Unfortunately, existing vapor sensors often degrade their vapor-quantitation accuracy in the presence of high levels of interferences and cannot quantitate several components in complex gas mixtures. Thus, new sensing approaches with improved sensor selectivity are required. Our presentation will demonstrate that this technological task can be accomplished by the careful design of sensing materials with new performance properties and by coupling these materials with the suitable physical transducers that have multivariate response. We will demonstrate the capabilities of our developed multivariable sensors for selective vapor sensing. We have developed diverse transducers based on electrical, mechanical, and optical readout principles that provide vapor-response selectivity previously unattainable by using other sensing approaches. This ability for selective vapor sensing provides opportunities to significantly impact the major directions in development and application scenarios of vapor sensors.

Abstract Text

A suite of mass-spectrometry-based approaches are described that allow the investigation of individual neurons and small brain regions for their metabolites and peptides. Direct single cell MALDI-MS, SIMS-MSI, and MALDI-MSI provide unmatched information on the contents of the cells in the brain. Single cell MALDI-MS has been used for the discovery of hundreds of novel peptides and in the characterization of the heterogeneity of cellular populations. While this approach typically requires manual sample preparation and therefore is low throughput, it provides unmatched performance. MSI has evolved into a sensitive approach capable of probing tissues at cellular-level resolutions. We have adapted MSI to dissociated cell populations and hyphenate it to other information rich measurement capabilities. MALDI-MSI can acquire thousands of mass spectra from cell-sized samples, and can even be used to directly acquire spectra only from cells and not the spaces between them.

The high sensitivity of MALDI-MS, requiring attomole to zeptomole amounts of analyte, allows a range of analytes to be characterized in individual cells. Several applications of single cell MSI are highlighted including metabolite profiling of selected cells. Using these approaches, literally hundreds of new neuropeptides have been characterized in well-defined neuronal networks, and in several cases, the functional roles of these molecules described. MSI and dynamic sampling of the extracellular environment are used for elucidating novel cell to cell signaling molecules in a range of neuronal model systems. Current efforts involve extending the depth of chemical coverage and adapting these analytical approaches to higher throughput single cell assays. Our overarching goal is to uncover the complex chemical mosaic of the brain and pinpoint key cellular players in physiological and pathological processes.

Abstract Text

In order to image biological tissues by mass spectrometry, samples typically must be sliced into a series of 2D sections to accommodate ion source geometry restrictions. During this process, there is potential for disturbing the natural spatial distributions of molecules of interest. Instead of altering the sample to fit the method, a new technique for imaging irregular, 3D surfaces was developed using a robotic sample introduction/ionization system for mass spectrometry termed Robotic Plasma Probe Ionization Mass Spectrometry (RoPPI-MS). In RoPPI, a Universal Robots UR5 robotic arm with six degrees of freedom maneuvers an acupuncture needle to probe the sample surface, then places the probe into the ionization region of a plasma ion source for subsequent MS detection. The motion of the robot is guided by a PrimeSense Carmine short-range sensor communicating to an RViz software package that generates a point cloud within for x,y,z coordinate selection on the sample surface. By probing multiple points across a sample, a chemical image of the surface may then be rendered. Direct analysis in real time (DART) was selected as a plasma-based ionization source for RoPPI given its ability to ionize both polar and non-polar analytes and its relatively large ionization region. The modularity of the RoPPI system makes it conducive to the imaging of various samples such as irregular mineral surfaces, biopsies, whole organs, or skin lesions, through any number of interchangeable sampling/ionization probes.

Abstract Text

As lipids are the most common biomolecules in the brain after water, we studied brain lipid profiles using mass spectrometric imaging, to follow the molecular progression of Traumatic Brain injury in a mouse model of Blast Induced Traumatic Brain Injury (bTBI) and a rat model of controlled cortical Impact (CCI), in order to find biomarkers for early detection and treatment and the biochemical pathways involved.

We developed a new MALDI matrix that allowed us to detect all gangliosides, which only make up 6% of all lipids in the brain. The ganglioside GM2, which is present in the brain at a concentration of 0.08% increased after blast and REMAINED elevated. A surprising finding, as GM2 is only expressed in embryos, between weeks 17 and 21, in cortical and other neurons, during dendritogenesis. The only pathological condition where it is detected is a gangliosidosis due to mutations that lead to hexosaminidase A deficiency. The absence of this hydrolytic enzyme, whose alpha subunit is able to hydrolyze GM2 to GM3 due to a key residue, Arg424 which is essential for binding the N-acetyl-neuraminic acid residue of GM2. [Woods AS et al. Gangliosides and Ceramides Change in a Mouse Model of Blast Induced Traumatic Brain Injury. ACS Neuroscience 4, 594-600 (2013).]

In the case of CCI we developed a new technique, where we implanted tissue with silver, and found that in this type of trauma, it's the sphingomyelins that increased, indicating that a different pathway is involved. We are in the process of studying the lipid profiles of the CSF of these animals, to establish a correlation between body fluids and brain tissue profiles. In addition nanoparticulate implantation has allowed us to get perfect reproducibility. In addition, we are testing a peptide drug, which has given promising results.

Abstract Text

Direct measurement of metabolites from diseased tissue remains a challenge owing to structural diversity of the large number of primary and secondary metabolites present. These metabolites represent the climax of all physiological responses and reflect ecological relationships between pathogenic microbes and human response. Strategies aiming at direct measurement of metabolites will enhance our understanding of the roles that these molecules play and may result in emergence of new molecules and novel biosynthetic pathways. Untargeted metabolomics employed for such studies generates large volume of datasets that are rich in information hampering comprehensive analysis. Recent advancements in mass spectrometry and bioinformatics tools have reinvigorated the field of untargeted metabolomics of complex samples. Herein, we employ high-scan-speed QTOF coupled with ultra high performance liquid chromatography for data collection combined with molecular networking as organizational tool, cytoscape and spatial mapping as visualization tool, and automated database search for rapid identification of metabolites.

Abstract Text

Three dimensional cell cultures are attractive models for biological research. They combine the flexibility of cell culture with some of the spatial and molecular complexity of tissue. For example, colon cancer cell lines form spheroids, in vitro mimics of poorly vascularized tumors. The spheroids are composed of a central necrotic core, a middle quiescent layer and an outer proliferative layer of cells, similar to a rapidly growing colon tumor. Our laboratory has characterized the distribution of endogenous proteins via MALDI imaging mass spectrometry in colon spheroids and determined that the molecular gradients correlate with the pathophysiological changes in the structure. We have also developed an approach to evaluate the penetration of compounds into 3D cell cultures. Most novel drugs are initially evaluated with 2D cultures before moving directly to costly animal studies. 3D cultures, like spheroids, provide an ideal testbed to minimize these studies. Working with the chemotherapeutics oxaliplatin and irinotecan, our data supports differential penetration of these clinically relevant drugs into spheroids. We can either perform traditional imaging mass spectrometry or add a complementary analysis of enzymatically generated concentric rings of cells via serial trypsinization. In this procedure, radial layers of cells are sequentially removed, analogous to "peeling an onion", and then analyzed via nLC-MS/MS. We are now evaluating the pharmacokinetics and pharmacodynamics of the spheroids with clinical treatments. We dynamically treat spheroids in 3D printed microfluidic devices and then use imaging mass spectrometry to explore the molecular distributions of the prodrug and its metabolites. Our future studies include evaluation of drug libraries to evaluate the functional moieties that contribute to the penetration of compounds, including the development of novel statistical workflows to evaluate imaging data generated from 3D cell cultures.

Abstract Text

Target-specific drug delivery that treats cancers but leaves normal tissue unharmed, is the ultimate goal of cancer therapy. Nano-sized drugs have virtually limitless synthetic possibilities enabling a variety of payloads to be delivered to the tumor resulting in effective therapy. Tumors have relatively higher concentrations of nano-sized drugs than normal tissue due to the leaky nature of tumor vasculature, a phenomenon known as enhanced permeability and retention (EPR). The EPR effect, while permitting an increase in intratumoral nano-drug concentration, nonetheless has a limited ability to achieve concentrations that take full advantage of the capabilities of nano-sized drugs. Thus, a method for better nano-drug delivery might lead to improved cancer therapy. We have recently developed a new type of highly selective, molecularly-targeted cancer therapy, named photoimmunotherapy (PIT), that is based on conjugating a near infrared silica-phthalocyanine dye, IR700, to a monoclonal antibody (MAb) thereby targeting cancer-specific cell-surface molecules. After the administration of the conjugate and the targeted application of light, the intratumoral vascular barrier is significantly disrupted enabling a dramatic (up to 24 fold) increase in nano-drug concentration in PIT treated cancer tissue compared with non-treated control tumors. In this lecture I will discuss general pharmacokinetic characteristics of nano-sized molecules in the body, especially focusing on drug delivery in cancer tissue and routes of excretion that are important for improving the safety profile. In addition, I will discuss the basis and applications of the PIT-induced super-enhanced permeability and retention (SUPR) effect that could dramatically improve nano-drug delivery thereby enhancing the therapeutic effects of nano-sized anti-cancer agents.

Abstract Text

Genomic information flows from DNA to RNA and from RNA to peptides and proteins; therefore, genomic information is stored in both the base sequences of DNA and RNA and in the amino acid sequences of peptides and proteins. Chemically modified bases and amino acids are particularly important in the expression of life functions and disease markers. However, no existing sequencing technologies can directly sequence RNA and peptides, or detect chemically modified molecules. Consequently, innovative methods for sequencing DNA, RNA, and peptides as well as detecting their chemical modification will greatly advance the fields of molecular biology, medical science, and drug development. In this lecture, I will report a single-molecule sequencing method based on single-molecule conductance measurements. Single-molecule conductance can be determined by tunneling currents created when single bases and amino acids pass through nanogaps. This method sequences DNA, RNA, and the partial amino acid sequences of peptides by detecting the differences in single-molecule conductances of the constituent molecules. In addition, this method detects chemically modified bases and amino acids at single-molecule resolutions. Because nanodevices for single-molecule sequencing technologies are fabricated using semiconducting technologies, the sequencing technologies are expected to realize label-free, ultra-low cost, and high-throughput genomic information sequencers for use in personalized medicine. Toward this goal, we have launched a venture company, Quantum Biosystems. Our company is currently working on the development of single-molecule DNA sequencers.

Abstract Text

Identification and quantification of substances in biological samples is a subject of great interest today, particularly in drug metabolism and pharmacokinetics, biomarker discovery and validation, and clinical diagnostics. The fact that mass spectrometry (MS) can analyze hundreds of metabolites, drugs, and proteins in milliseconds suggest it could vastly accelerate decision making. But mass analysis is preceded by a lengthy set of sample preparation steps involving sampling, the removal of cells or cellular debris, taking a sample aliquot, chemical modification in some cases, analyte enrichment, and selection of a portion of the sample for MS analysis or archiving. Collectively this requires hours and involves multiple sample transfers. Clearly, sample preparation limits the potential of MS.

Abstract Text

LC-MS/MS has rightfully earned a prominent position in pharmaceutical, toxicology, and clinical analysis due to its enhanced sensitivity and increased dimensions of analysis. The quantitative analysis of multiple protein biomarkers is an emerging area in biological mass spectrometry research. The translation of discovery-based data into targeted quantitative analysis is critical for the successful advancement of biomarker research projects. Typical workflows require either many methods for optimization or select only a small number of peptides for quantitative analysis. A procedure for rapid method optimization is described, with a goal to achieve specific, reproducible, and efficient multivariate quantitative analysis.

Abstract Text

A Cryo-SEM can be used for observation of specimens containing water by freezing. The Cryo-SEM used in this experiment is composed of a Cryo preparation chamber and a cooling stage. Recently, the spatial resolution at low voltages of an SEM, which can be used with a Cryo-SEM has been improved. You can observe specimens in a low vacuum mode with a Cryo-SEM. We used the Quorum Technologies Cryo unit PP3000T on the JEOL FE SEM JSM-7100F as a Cryo-SEM. Observation results of biological and food specimens containing water are reported.

Abstract Text

Nanoscopy (super-resolution) techniques such as STED and FPALM/PALM/STORM microscopy utilize either targeted or stochastic switching of fluorescent molecules to achieve ~25 nm spatial resolution – about 10-fold below the diffraction limit. However, their primary application has been focused on fixed samples because of a lack of suitable live-cell compatible labels and time resolutions that have been limited especially for FPALM/PALM/STORM to seconds to minutes [1].

In this talk, I will present recent advances in live-cell nanoscopy. Newly developed probes, labeling procedures and instrumentation optimized for live-cell imaging have expanded the application range of live-cell STED microscopy. Using recently introduced sCMOS cameras in combination with a set of novel algorithms, we have shown acquisition speeds of up to 32 super-resolution images per second are possible in FPALM/PALM/STORM [2].

I will present the underlying technologies and demonstrate their performance with cell biological applications demonstrating the versatility of live-cell nanoscopy.

Abstract Text

A conventional fluorescence microscope is limited in the range of spatial frequencies, and therefore detail, that it can transmit. This limit is defined by the numerical aperture of the microscope's objective lens and wavelength of light used for imaging. Structured illumination microscopy (SIM) expands the frequency response of the system by exposing the sample to patterned excitation illumination. The illumination pattern combines with sample structures to create Moiré fringes, optical artifacts representing previously unobservable frequencies. By patterning the illumination laterally and axially, a two-fold improvement in x,y, and z dimensions is achieved. Current implementations of SIM are capable of fast illumination pattern generation and data acquisition rates. Also, SIM requires relatively low illumination intensities compared to most other super resolution technologies and works with commonly used dyes and fluorescent proteins. Therefore, this method is well suited for both fixed and live cell super resolution imaging applications.

Abstract Text

By definition, living specimens are animate. Therefore, a full understanding of dynamic biological systems will only be obtained by observing them with enough 4D spatio-temporal resolution and for a sufficient duration, to capture the phenomena of interest. Unfortunately, conventional widefield or confocal microscopes are either too slow, lack the spatial resolution, or induce too much photodamage to meet these requirements. To address these limitations, we have developed a new approach for sub-cellular light-sheet microscopy capable of imaging fast three-dimensional (3D) dynamic processes in vivo at signal to noise levels typically obtained only in total internal reflection fluorescence (TIRF) illumination. By utilizing 2D optical lattices, we generate a thin (~400 nm full width half maximum) plane of light coincident with the focus of a high NA detection objective. Using this technique, we demonstrate substantial advantages in speed, sensitivity and reduced phototoxicity compared to conventional point scanning and spinning disc confocal microscopes as well as light-sheet microscopes utilizing single Gaussian or Bessel beams. We leverage these advantages to image samples ranging over three orders of magnitude in length scale from single molecules to whole embryos. Specific examples to be presented include: 3D single molecule tracking of fluorescently tagged transcription factors in densely labeled embryonic stem cell spheroids, 3D imaging of microtubule growth phases and organelle dynamics throughout the course of cell division, rapid 3D imaging of Tetrahymena motility at over 3 volumes per second, and 3D protein localization throughout the course of dorsal closure in *Drosophila* embryos. By combining lattice light sheet microscopy with novel fluorescent probes, we will also demonstrate 3D super-resolution localization microscopy with unprecedentedly rich detail over large fields of view and in thick 3D samples such as dividing cells and small embryos.

Abstract Text

Over the past decade several new far-field super-resolution microscopy methods have emerged which overcome the diffraction limit, improving the spatial resolution to the nanometer scale. Stimulated emission depletion microscopy achieves super-resolution purely optical by engineering the point-spread function through a second red-shifted, donut shaped depletion beam. STED microscopy provides easy and intuitive access to multi-colour super-resolution as well as live cell imaging and has successfully been applied and gave novel insight in cell biology and neurobiology.

This presentation explains the basic principle of STED, summarizes the development of STED microscopy and illustrates the different STED modalities - STED CW, pulsed STED and gated STED. Application examples of 2D- and 3D-STED with fluorescent proteins as well as standard organic fluorophores will be shown. Furthermore I present recent developments in labelling strategies and discuss their potential for live-cell STED imaging.

Abstract Text

In the last two decades the evolution of the scientific method has moved traditional disciplines forward and has led to the development of multiple completely new fields. In each case the unifying change has been the continued expansive integration of technologies on all fronts, including molecular, biochemical and computer based. Few fields of endeavor have embraced these changes as much as microscopy. At all levels in the last 20 years there has been a massive and continuous expansion of the capabilities of the microscope on all fronts. The current research microscope represents the integration of modern optics, robotics, computing, probes and cameras. The impact of modern imaging on our understanding of disease and the potential for therapeutics has been extreme, particularly as we continue to expand scientific progress towards discovery rather than reductionist approaches. Equivalently there has been an explosion in the probes suitable for use in the modern microscope such that single molecules can be chased in 3 dimensional space and the local environment assessed in real time. Integrating novel fluorogen based probes into highly sensitive and extremely fast high throughput screens to define protein, delivery and function in 3D space at high speed and with absolute certainty of localization has been the focus of our work. This seminar will discuss these technologies and their development as we attempt to develop methods to specifically develop assays to unravel molecular fates within cystic fibrosis and the specific functional sites of therapeutic correctors within living cells.

Abstract Text

Eurofins CAL performs contaminants and residue testing for the import/export market, providing services to leading global feed, food and beverage retailers and producers. The methods offered include pesticide residues, industrial contaminants, multi-residue mycotoxins, medicated feeds testing and antibiotic residues. In this environment of rapidly changing customer needs, we must fully utilize the technical capabilities of the instrumentation to increase application scopes of our methods without the luxury of time for method development. To meet our clients needs we are continually adding new analytes to existing screens and applying existing methods to a wide-variety of matrices. LC-MS/MS and GC-MS/MS applications are essential to high-volume, fast throughput testing and instrument capacity (run time) also is a key factor. Sample preparation and clean-up are frequently the rate-limiting steps in terms of production. Examples of current challenging matrix / analyte combinations and approaches for resolution will be discussed.

Abstract Text

It has been seven years since the widespread acceptance of the AOAC and EN versions of the “QuEChERS” sample preparation protocol for food analysis and over that time about a dozen companies have entered the market with consumable kits to address these specific methods. These kits seem frightening simplistic with salts in packets and common centrifuge tubes such that one would think it is easy to manufacture and sell these kits. It is just salt in a tube, right?

This presentation discusses some of the unexpected and unknown problems that can arise in setting up to manufacture a QuEChERS product. Issues with product quality related to sourcing and process with discussed along with solutions learned along the way. This somewhat entertaining path also has let to useful insights on the methodology itself and how one can potentially improve their use of sample preparation techniques for LC/MS and GC/MS analysis.

Abstract Text

Strategies used to develop LC-MS/MS based methods for vitamin analysis in food and dietary supplements will be presented by discussing some of the relevant case studies. First case study is a LC-MS/MS based method development and validation of the analysis of different folate vitamers. Schemes and strategies used in the method development and optimization of the relevant parameters including chromatographic conditions, mass spec parameters and extraction and solid-phase extraction conditions will be discussed. The strategies employed in evaluation of the method precision and accuracy will also be presented. The second case study will similarly discuss studies employed to develop and validate a LC-MS/MS method of analysis of vitamins D2, D3, 25(OH)D2 and 25(OH)D3 in various food and pet food matrices employing an extraction method more efficient than the conventional extraction methods.

Abstract Text

With food regulations continuing to expand, labs are required to monitor more compounds in more commodities, and with consumer drivers to survey for other non-targeted potential hazards that could arise, there is an increasing demand for analytical techniques and methods that enable identification and quantitation of targeted, regulated compounds with capabilities for non-targeted surveillance of other unknowns. The advent of MS/MS libraries and high resolution / accurate mass instruments are now capable of performing both targeted and non-targeted screening in a single LC-MS/MS run. In this presentation, we will show the development of a workflow using a very generic extraction procedure and full scan MS/MS and high resolution MS and MS/MS data acquisition to confidently identify and accurately quantify targeted chemicals based on retention time, accurate mass, isotope pattern and MS/MS library searching. In addition, the implementation of sample-control-comparison was used to enable routine labs to successfully survey samples for unexpected contaminants in addition to targeted lists of known regulated compounds. Identification was based on high resolution MS and MS/MS information, including empirical formula finding, ChemSpider searching, and automatic MS/MS fragment ion interpretation. The automation of this challenging data processing workflow allows easy result review and reporting for practical implementation of either QTRAP or high resolution QTOF mass spec workflows for routine food contaminant screening in the modern food laboratory.

Abstract Text

The development of the Reciprocating Cylinder Apparatus arose from a need for an alternative drug release apparatus capable of providing pharmacokinetic and mechanical conditions that more closely represented the various regions throughout the gastro-intestinal tract. While the traditional paddle and basket apparatus offered a convenient means to evaluate most oral drug formulations at single and multiple pH and over long periods it was difficult to change pH during the test and changes in agitation rates during the in-vitro test are seldom noted. The material presented in this session not only shows the compliance of the apparatus to meet more biorelevant requirements above but, illustrate the versatility of the apparatus to test products from immediate release to extended release as well as poorly soluble compounds, chewable formulation and numerous modified release products. Several case studies will be presented.

Keywords: Dissolution, Drugs, Instrumentation, Pharmaceutical

Application Code: Pharmaceutical

Methodology Code: Other

Session Title Current Trends in Pharmaceutical Dissolution Testing

Abstract Title **Biphasic Dissolution**

Primary Author Geoffrey Grove
Sotax

Date: Tuesday, March 10, 2015 - Afternoon

Time: 01:50 PM

Room: 265

Co-Author(s)

Abstract Text

A review of biphasic dissolution instrumentation and results, including a comparison of various instrumentation configurations. The application of biphasic dissolution in general will also be discussed relative to the drugs and formulations where biphasic dissolution may be beneficial.

Keywords: Dissolution, Drugs, Quality Control

Application Code: Pharmaceutical

Session Title Current Trends in Pharmaceutical Dissolution Testing

Abstract Title **In Situ Measurement Techniques: Applications and Validation for Dissolution Testing**

Primary Author Scott Stephenson
Pion Inc.

Date: Tuesday, March 10, 2015 - Afternoon

Time: 02:10 PM

Room: 265

Co-Author(s) Konstantin Tsinman

Abstract Text

The ability to monitor the concentration of a solution in real time with in situ monitoring instrumentation has significant advantages over traditional techniques which require the sample be removed for analysis. This is especially true when measuring a kinetic environment like a dissolution test. Fiber optic UV probes have been used for this analysis for close to 15 years and are a widely accepted technique in the drug development tool box. As drug product make its way through the development process, the need for this technique to be used in a validated environment becomes necessary. Controlling variables and other special considerations need to be taken when validating an in situ technique type of analysis whether UV or any other technique used to measure concentration within the vessel.
