New drug applications (NDAs) and Applied New Drug Application (ANDAs) submitted to Food and Drug Administration (FDA) contains the bioavailability data and in vitro dissolution data, that, together with chemistry, manufacturing and controls (CMC) data, characterizes the quality and performance of the drug product. For NDAs, in vitro dissolution specifications are generally obtained from batches that have been used in pivotal clinical and/or bioavailability, bioequivalence studies and for ANDAs, the in vitro dissolution specifications are based on the performance of acceptable bioequivalent batches of the drug products and CMC data. The FDA recommends dissolution testing of 12 dosage units for a variety of applications. Some of those applications are: ANDA submission to evaluate the difference factor (f1) and similarity factor (f2), Scale up Post Approval Control (SUPAC) conditions, development of an applicant's dissolution method which is different from the FDA recommended method, modified release formulations, evaluation of alcohol-induced dose dumping, and manufacturing of multiple strengths of a dosage form from different blends. A dissolution tester possible of testing 12 dosages at one time may offer advantages with respect to time-saved, reduction in test variability and provide efficient use of resources such as water, electricity, man power and space. While a dissolution tester capable of testing 12 dosage forms may prove especially beneficial to a generic drug manufacturing company and a contract research laboratory, it may also prove to be useful to an 'innovator' pharmaceutical company.

Abstract Text

Fiber-optic analysis for dissolution for a variety of dosage forms provides a range of benefits over traditional dissolution practices. Fiber-optic methods have been used for dual actives, high surfactant concentrations and unique excipients. Benefits include automation, sample manipulation, and use of complex media compositions.

Abstract Text

This talk focuses on dissolution and drug release from suspension dosage forms that are dosed by the oral route of administration and include oral suspensions, suspensions for reconstitution and suspensions in capsules. The suspension typically consists of uniform particles that are readily suspended and easily dispersed. The most common reason to develop a suspension dosage form is limited aqueous solubility of the active pharmaceutical ingredient (API) at the dosage required. Another common reason to use suspensions is that they typically offer improved chemical stability compared to solutions. Suspensions are also used to achieve accurate weight-based dosing, which is limited for unit dosage forms such as tablets, by varying the volume of suspension delivered. Because suspensions are considered to be solid dosage forms, dissolution or drug release testing is required for these dosage forms as specified in USP general chapter <1088>. This talk will outline the factors that influence the dissolution for these formulations and what factors are unique to suspensions.

Abstract Text

Glutamate is an important excitatory neurotransmitter and is known to regulate learning, cognition, and memory. There are two types of glutamate receptors: ionotropic receptors and metabotropic receptors. Adenosine is a neuromodulator and regulates processes in conjunction with glutamate. Recently, we discovered fast acting spontaneous adenosine in the rat brain that is modulated by A1 receptor. Adenosine is released and cleared within a couple of seconds in the extracellular space and is not released through equilibrative nucleoside transporters. Here we examined the effect of ionotropic NMDA and AMPA glutamate receptors on the concentration, duration, and frequency of spontaneous transient adenosine. The NMDA antagonist, CPP (3-((R)-2-Carboxypiperazin-4-yl)-propyl-1-phosphoric acid), and the AMPA antagonist, NBQX (2,3-Dioxo-6-nitro-1,2,3,4-tetrahydrobenzo[f]-quinoxaline-7-sulfonamide), were both administered to examine any effects on fast acting spontaneous adenosine. CPP increased the frequency of adenosine release events, while the agonist NMDA, did not decrease the frequency. The inter-event times between consecutive transients significantly decreased from 70.4 ± 4.5 seconds to 47.1 ± 3.0 seconds ($p < 0.0001$). Conversely, NBQX did not significantly change the inter-event times from 82.3 ± 5.7 seconds to 82.0 ± 6.0 seconds ($p > 0.05$). These results indicate that the frequency of spontaneous transient adenosine is regulated by NMDA glutamate receptors but not AMPA receptors. The feedback loop between transient adenosine and glutamate receptors indicates that these two molecules are tightly regulated and their mechanisms are connected in the brain.

Abstract Text

Microfluidic paper-based analytical devices (mPADs) have been of increasing interest in point-of-care diagnostics and environmental monitoring due to paper's inherent low cost, ease of modification, disposability, and ability to create flow without the need of external pumps or tubing. Although colorimetric detection has been the most common detection technique, electrochemistry offers a fast, sensitive, selective, inexpensive, and portable detection technique that can be readily adapted to paper, as our group first showed using screen-printed carbon electrodes. Here, two alternative mPADs with electrochemical detection (ePADs) will be discussed. Previously our group developed a colorimetric mPAD to detect enzymes produced by bacteria (*Salmonella* and *E. coli*) in both food and water samples. These same enzymes can also be used to produce electrochemically active products. Research to characterize these reactions and provide lower detection limits with shorter reaction times using electrochemical detection at carbon paste electrodes in ePADs will be discussed. While most reported ePADs have used carbon electrodes, microwires have only recently been incorporated. Microwires are available in a variety of compositions, highly conductive, well characterized, and can be easily cleaned and/or modified before being incorporated into the paper-based device. We have utilized microwires for the detection of analytes in a device design that produces quasi-steady flow, is capable of flow injection analysis and provides an increase in electrochemical signal in paper due to enhanced mass transport with flow and decreased electrode resistance.

Abstract Text

Real time in vivo sensing of analytes in blood is the “holy grail” of sensor technology since, to date, intravascular chemical sensors often suffer from inaccurate results due to poor biocompatibility (clot formation, etc.). In addition, use of such devices poses significant risk of infection. Nitric oxide (NO) serves as a potent antithrombotic and antimicrobial agent in our bodies. In this presentation we will describe a new electrochemical NO generation approach to improve the biocompatibility and, thereby, the in vivo performance of an amperometric oxygen (PO₂) sensing catheter. The new oxygen sensing catheter is fabricated using a dual lumen silicone rubber tubing, with one lumen dedicated to NO release from a copper complex mediated electrochemical reduction of nitrite ions at a stainless steel wire electrode, and the other lumen dedicated to PO₂ sensing at a Pt wire electrode. The sensor has linear response to oxygen from 0% to 100% and this response is fully compatible with the electrochemical NO release chemistry. Electrochemical NO releasing PO₂ catheters implanted within veins and arteries of animals (rabbits and pigs) for >8 h provide more accurate analytical results and less surface thrombus area compared to control devices without e-chem NO release. In vitro studies show that the catheters with e-chem NO release also exhibit greatly reduced surface attached bacteria, which would potentially decrease the risk of infection.

Abstract Text

One of the key technical challenges for polymer electrolyte fuel-cell researchers is improving both the activity and stability of the oxygen reduction reaction (ORR) catalysts at the cathode. Pt-based alloys have shown great promise for achieving these targets. Herein, we report a new strategy for producing a highly active and stable class of PtCu catalysts with tunable compositions. Several unique nanoparticle catalysts were prepared by galvanically displacing a monolithic nanoporous Cu support with Pt, leading to a Pt-enriched PtCu shell over a PtCu core. It was observed that temperature during galvanic displacement is a key experimental parameter and a novel means to control catalyst particle size. This paper presents several modifications to the galvanic displacement process and describes the resulting enhancements in ORR activity (up to 2.1 mA/cm²/Pt) and stability relative to pure Pt.

Abstract Text

Rapid, real-time and on-site metal analysis is a useful diagnostic tool to treat trace metal contamination in the environment. We recently described an electrochemical method with high temporal resolution (100 ms) to detect copper and lead at carbon fiber microelectrodes (CFMs) using fast scan cyclic voltammetry (FSCV). Additionally, we characterized metal adsorption onto CFM surfaces as the fundamental mechanism of the rapid metal FSCV signal. In this work, we find that FSCV shows comparatively higher signals to Cu^{2+} than predicted by solution free metal content using geochemical, equilibrium models. Availability of free metal in complex matrices is a function of several intervening complexation reactions with different ligands. Equilibrium constants for these complexation reactions are an index of the strength of binding between metal and ligand. We explore the interactions between Cu^{2+} - CFM and Cu^{2+} - ligand equilibria using electrochemical, geochemical, and mathematical models. We find that different matrices do not affect the monolayer adsorption of copper on CFMs but that the Cu^{2+} - CFM equilibrium competes with solution equilibria to increase FSCV's sensitivity. We model the correlation between the FSCV signal, equilibrium constants for Cu^{2+} - ligand complexation, and free copper concentrations. This work is critical for further development of metal FSCV, particularly to increase sensitivity and selectivity.

Abstract Title **Dopamine Transporter (DAT) Compensates for Impaired Serotonin Transporter (SERT) Function in the Small Intestine of Mice on a High Fat (HF) Diet**

Primary Author Marion France
Michigan State University

Date: Tuesday, March 10, 2015 - Afternoon

Time: 03:25 PM

Room: 264

Co-Author(s) Greg M. Swain, James Galligan

Abstract Text

Background: Decreased transit time in diet-induced obesity (DIO) may result from increased gut mucosal 5-HT (serotonin) availability. 5-HT availability is dependent upon 5-HT uptake by the serotonin transporter (SERT) following its release from enterochromaffin (EC) cells. We determined if 5-HT availability was increased in the jejunum of control and high fat fed (HF) DIO mice.

Methods: 5-HT uptake was measured using amperometry in real time near the mucosal surface (i.e. near sites of release and uptake). Measurements from current approach curves were plotted as the $\ln(\text{current})$ vs. electrode distance. A decrease in the slope of this plot described reduced 5-HT uptake. The SERT inhibitor fluoxetine ($1 \mu\text{mol L}^{-1}$) or the dopamine transporter (DAT) inhibitor GBR 12909 ($0.1 \mu\text{mol L}^{-1}$) was used to study changes in 5-HT uptake. Whole tissue 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) levels were measured using HPLC. SERT protein levels were measured using Western blotting.

Results: In HF jejunum, 5-HT uptake was insensitive to fluoxetine compared to controls suggesting SERT function was impaired. This was independent of SERT protein levels. GBR 12909 reduced 5-HT uptake in HF jejunum compared to controls suggesting DAT compensates for loss of SERT function. In agreement, whole tissue mucosal levels of 5-HIAA were similar in HF and control jejunum. Whole tissue mucosal 5-HT levels were not different in HF compared to control jejunum.

Conclusions: DAT compensates for loss of SERT function in DIO jejunum. Impaired SERT function increases 5-HT availability thereby potentiating 5-HT signaling to decrease transit time.

Abstract Text

Our group has been developing a new electrochemical imaging tool termed fluorescence-enabled electrochemical microscopy (FEEM). The technique utilizes bipolar electrochemistry and fluorescence microscopy to simultaneously monitor electrochemical signal from very large (e.g. $>10^6$) arrays of parallel ultramicroelectrodes (UMEs), enabling the imaging of transient electrochemical processes with excellent spatial and temporal resolution. The central concept of FEEM is the use of a closed bipolar electrode to couple a conventional redox reaction of interest, such as the oxidation of dopamine, to a complimentary fluorogenic indicator reaction, such as the reduction of resazurin. The fluorescent product can be optically monitored via fluorescence microscopy to report the progress of the reaction of interest. This technique has several unique aspects, including the ability to drive the array with only one small voltage source (<1 V) and without any direct electrical connections to the array. Importantly, FEEM enables the study of non-fluorogenic redox reactions. Fluorogenic reduction and oxidation reactions have been incorporated into FEEM, meaning that both oxidizable and reducible species can be studied with the technique. Our initial studies on FEEM include imaging the diffusion of redox molecules from a micropipette and the electrocatalytic activity of platinum for H_2O_2 oxidation, as well as the development of a suitable fluorogenic oxidation indicator reaction. Present imaging studies involve using FEEM to image the transient formation of diffusion layers of UMEs in both two and three dimensions. Work is also underway to understand and improve the spatial resolution of FEEM, develop and incorporate new fluorogenic indicator reactions, and improve the detection sensitivity. We hope to develop this technique into a tool that is useful and accessible to the broader analytical chemistry community and beyond.

Abstract Text

The protein [alpha]-hemolysin forms a pore with nano-meter dimensions in a lipid membrane through which single-stranded DNA (ssDNA) can translocate. As the DNA translocates through the pore, there is a momentary reduction of the current due to blockage of the ion flow. This system has been extensively studied as a potential method for rapid and cost effective sequencing of ssDNA.

However, the interactions of double-stranded DNA (dsDNA) with [alpha]-hemolysin are less well-studied. While dsDNA can enter from the wider (vestibule) side of the pore it does not translocate because its diameter is larger than the tightest (0.14 nm) constriction located at the center of the protein. With sufficient energy dsDNA can unzip (denature) inside the vestibule, and the blocking current observed during dsDNA residence is due to its presence within the vestibule.

In this report, we describe a previously unrecognized sensing zone for dsDNA, in the vestibule of [alpha]-hemolysin that is sensitive to the presence of an abasic site (a missing base) within the DNA sequence. The presence and position of an abasic site can be detected over a 4-5 base (1.36 nm) range centered near to the entrance of the vestibule, with a sensitivity that is dependent on the precise position of the abasic site within the sequence. Temperature-dependent ion channel recordings that the detection of an abasic site in this newly-discovered sensing zone is possible because of a decrease in the activation energy required for transport of the electrolyte through the pore when an abasic site is in proximity to the constriction site. While previous efforts at nanopore DNA sequencing have focused on characterizing and sequencing ssDNA, The discovery of this new sensing zone offers exciting possibilities for characterizing and sequencing more biologically-relevant dsDNA instead.

Abstract Text

We present a method to identify and quantify methane using a hydrophobic ionic liquid (IL)–electrified metal electrode interface by electrochemical impedance spectroscopy. We investigated the mechanisms of the responses of the IL-electrified electrode interface to the exposure of methane and other interfering gases (H₂, C₆H₁₂, SO₂, NO, NO₂, CO₂, O₂, H₂O). Our results show that at low frequency the IL-electrified electrode interface shows a predominantly capacitive response. The IL-electrode double layer (EDL) was found to be the primary response layer while the transition zone and bulk region of the IL-electrode interface contribute little to the overall signal change. For recognition and quantification of methane using the Langmuir adsorption model and measurement of differential capacitance change, an optimum EDL interface structure was found to form at a specific DC bias potential. The cumulative results shown in this work suggest that an ideal IL-electrode interface can be formed by varying IL structure and applied DC bias electrode potential for a specific analyte and that the semi-ordered structure of IL-electrified interface can act as a recognition element for the sensitive and selective adsorption and detection of gaseous molecules.

Abstract Text

Extractive multi-pass cells have been used in the quantification of gas species present in flare vent gas systems using Fourier Transform Infrared Spectroscopy (FTIR). In a recent field test, FTIR has demonstrated an ability to match the performance capabilities of current gas chromatography based systems. FTIR's ability to accurately quantify gas species present in flare vent gas systems is paramount to determining the Net Heating Value of the vent gas (NHV_g) in units of BTU/scf in order to meet regulatory requirements. However, in addition to FTIR, separate monitors and/or calculations are required to obtain concentration values for oxygen, hydrogen and nitrogen as these species cannot be directly measured using FTIR. The coupling of FTIR and Raman spectroscopy in a single extractive gas cell offers an intriguing combination of capabilities at a much lower total cost than current gas chromatography based systems. In addition to oxygen, hydrogen and nitrogen, Raman possesses the potential to detect and quantify many of the same gas species as FTIR albeit at higher mol % concentration levels. Results from the first operational prototype are presented here that demonstrate the capabilities of the Dual Function Gas Analyzer's potential to simultaneously measure gas species of interest at both ppm levels for FTIR and mol % for Raman without additional monitors, calculations or specialized shelters.

Abstract Text

Raman spectroscopy can be beneficially applied to characterize oil shale for both its carbonaceous material content as well as the sedimentary rock consisting of clays, calcites, silicates, and titanium dioxides among other inorganic minerals. We have studied a variety of shale samples from different formations in the USA. We show that Raman spectroscopy is useful for characterizing the varieties of kerogen structure (chemical bonding and solid state) and the maturity of the carbonaceous matter, for identifying shales with different amounts of kerogen relative to inorganic mineral, and for differentiating polymorphs of naturally occurring inorganic oxides. Specifically, the Raman D and G band positions, widths and separations are a means by which the maturities of carbonaceous materials can be determined. Furthermore, we have found that Raman scattering excitation wavelength is a significant component to the proper interpretation of Raman data when comparing results obtained from different geological formations. Through Raman imaging, we find that inorganic minerals, including crystalline forms, can be imaged, identified and differentiated. Raman imaging complements optical microscopy by revealing the chemical and structural heterogeneity of carbonaceous and inorganic shale components that are not always revealed by optical microscopy.

Abstract Text

We report herein the photoelectrochemical studies on anatase TiO_2 photoanodes for solar water oxidation in the presence of a homogenous pentanickel silicotungstate molecular water oxidation catalyst $\text{K}_{10}\text{H}_2[\text{Ni}_5(\text{OH})_6(\text{OH})_2]_3(\text{Si}_2\text{W}_{18}\text{O}_{66}) \cdot x\text{H}_2\text{O}$ (Ni_5 -POM). Anatase TiO_2 thin films were prepared in-situ on fluorine-doped tin oxide (FTO) glass slides by a spin coating/thermal annealing technique, and XRD and SEM studies were employed for crystallographic and surface morphological characterization. Photoelectrochemical studies were performed in a quartz cell with a conventional three-electrode setup. A 150 W Xe lamp solar simulator equipped with an AM 1.5G filter was used as the light source for photocurrent and electrochemical impedance spectroscopic (EIS) measurements on FTO/ TiO_2 in the presence of the Ni_5 -POM catalyst. In addition to a significant cathodic shift in the water oxidation potential, a maximum photocurrent of 0.2 mA/cm^2 was obtained from the FTO/ TiO_2 - Ni_5 -POM system at 0.7 V vs Ag/AgCl (3 M KCl). These results could be attributed to the effect of catalyst on decreasing electron-hole recombination and facilitation of faster hole utilization kinetics on the semiconductor electrolyte interface upon light illumination, as indicated by EIS data. This is the first report on the use of water oxidation catalyst Ni_5 -POM as a functional co-catalyst for photoelectrochemical water oxidation with semiconductor photoanodes. Moreover, the higher photocurrent characteristics of this system relative to a variety of previously reported POM based hybrid photoanodes has provoked further studies and possible employment in tandem photoelectrochemical water splitting strategies.

Abstract Text

Significant shale deposits exist in 22 states including the Northeast states of Ohio, Pennsylvania, and New York Utah and Wyoming in the West; and gas-producing states such as Texas, Louisiana, Arkansas and Mississippi. The use of horizontal drilling and hydraulic fracking of shale has catapulted the US into the leading producer of natural gas in 2013. Natural gas is bought or sold based on the quantity of energy delivered. The product of the concentration (determined by gas chromatography) and the heating value (BTU) determines the BTU content of the fuel. Although the natural gas from Marcellus shale is primarily methane, the composition can vary considerably from region to region. Shale gas streams can vary in composition from primarily CH₄ to one that can contain heavier HC (to C₆+) species. One does need flexibility in a GC and the GC301C with temperature programming does have it. The 301C has dual detectors (FID & TCD), packed and capillary column capability and temperature programming. It has an embedded PC and Windows 7.0 operating system with PeakWorks chromatography control software. It is a compact industrial gas chromatograph in a 19" rack mount or wall mount enclosure. Outputs include RS485, and 4-20 mA. It can be connected to the internet and can be controlled remotely. For natural gas, the methane content can vary from about 85 to 98 mole %, ethane varies from 1-7%, propane from 0.1 to 6%, nitrogen 0.2 to 6%, carbon dioxide from 0.1 to 1% with the balance of C₄ and C₅ hydrocarbons at trace levels. The exact composition can significantly change the BTU content. Methods can be stored for different compositions and changed remotely for additional flexibility in fracking operations.

Abstract Text

The determination of bactericide efficacy in process drilling water has become a key process control problem faced by fracking drillers in areas where there is a limited supply of useable process water, limited disposal options for spent drilling water or concerns on bactericide concentration and the subsequent costs in the reuse water. The drilling project manager requires a rapid analytical test that measures the remaining active biocide in the drilling water. A bioanalytical process test utilizing aerobic and facultative anaerobic bacteria and measuring their active respiration has shown itself to be a sensitive quantifying process analytical test and producing accurate rapid results. This bioanalytical tests is based on the "Standard Methods for the Examination of Water and Wastewater, 22nd Edition, Method 2710" utilizing an optical dissolved oxygen meter, constant temperature incubation optimized for biological growth at 40 C, 15 mL sample vials with in-situ oxygen sensors, a nonspecific bacteria growth media and a bacteria source containing the biomass representative of that found in the environment. Samples prepared from a fracking water challenge matrix based on reference data from the petroleum industry and containing active biocide have shown a linear response between active biocide and bacteria mortality. This testing procedure will allow the drilling operations staff to make decisions on whether additional biocide should be added before drilling water reuse or if the spent water can be discharged to a biological treatment process for disposal. Funding provide by Baseline Industries.

Abstract Text

In recent decades many researchers have focused on the development of novel alternative energy solutions, with notable success in the arena of solar energy conversion. Progress has been somewhat limited based on expensive processing materials, processing costs, and generally low efficiencies. Nature, however, has already developed a comprehensive process of creating chemical energy from solar radiation. Photosystem I (PSI) is one of the enzymatic components in Photosynthesis that through a single photon absorption creates an electron-hole pair with nearly perfect quantum efficiency. This remarkable protein, once extracted from green plants, can be deposited onto electrode materials and used as a very inexpensive active layer in a simple photovoltaic cell. When found in nature, PSI functions with high efficiency by shuttling electrons unidirectionally across the thylakoid membrane bilayer from lumen to stroma. Thus, *ex vivo*, it becomes very important to orient the PSI complexes with high uniformity to minimize competing electrochemical reactions introduced by oppositely oriented proteins on a surface. In order to properly orient PSI we have developed a set of functionalization strategies, in which we selectively modify the exposed stromal side of this integral membrane protein prior to extraction, utilizing the thylakoid membrane bilayer as a natural barrier, leaving the luminal side of the protein completely unmodified after membrane lysis and purification. During a typical stromal-side functionalization procedure, a thiol-terminated ligand is conjugated to specific amino acids, which can activate our protein for preferential binding to a gold electrode. Through various spectroscopic and electrochemical analyses, we have demonstrated our control over the orientation of PSI. This work has enhanced the performance of PSI-based photovoltaics not only by aligning the proteins, but also through the direct “wiring” of the protein to the electrode.

Abstract Text

It is imperative to understand biological variation in expression of metabolites due to genotype, environment, or both to assess the potential of metabolomics to supplement compositional analysis for substantial equivalence assessment of genetically modified crops. In the present study, we evaluated the biological variation of metabolites in various maize hybrids due to environment (growing location), genetic modification, trait, and interaction of the three. A total of 480 forage and 480 grain samples from 21 genetically diverse non-GMO DuPont Pioneer maize hybrids grown at eight North America locations were analyzed. GC/MS and LC/MS were used as complementary analytical platforms to detect a wide range of compound classes. A total of 166 and 137 metabolites were detected in forage and grain samples by GC/MS, while 1341 and 635 metabolites were detected in forage and grain samples by using LC/MS positive mode and negative mode combined. Univariate and multivariate statistical analyses were utilized to investigate the main effects and interaction of environment, genotype and traits on the maize metabolome. The results revealed that the environment had far more impact compared to genotypes or traits. In forage samples, the environment affected 50% to 80% of the metabolites, while less than 7% were affected by genotypes. In grain samples, the environment affected 50% to 90% of the metabolites, whereas less than 20% were affected by genetic backgrounds. Additionally, the effects of drought and disease resistant traits were studied within each location, and less than 10% of the metabolites were affected by these traits. Overall, the results of this comprehensive study support and extend previous findings about the environmental and genetic perturbations on the maize metabolome.

Abstract Title **Standard Test Method for Water in White Lint Cotton by Karl Fischer Titration Extended to Colored Cotton, Flax and Rayon**

Primary Author Joe G. Montalvo
USDA-ARS-SRRC

Date: Tuesday, March 10, 2015 - Afternoon

Time: 01:50 PM

Room: 241

Co-Author(s) Crista Madison, Doug Hinchliffe, Terri M. Von Hoven

Abstract Text

In the oven drying procedure to measure moisture content in cotton by drying in ambient air at 105 – 110°C, the weight of the lost volatiles is the measure of moisture content, all of which is incorrectly attributed to water. The origin of these biases is incomplete drying and weight change due to side reactions in opposing directions. The standard test method (ASTM D7785-12) for water in white lint cotton by oven evaporation combined with volumetric Karl Fischer Titration (KFT) is specific for total water (free and bound). A test specimen is sealed in a glass vial, placed into a micro oven and dry nitrogen transports the water vapor from the fibers into a titration cell. The amount of water is determined by volumetric titration with Karl Fischer reagent; the end point indicated by electrodes that measure a sharp change in potential when the iodine in the reagent is reduced by sulfur dioxide in the presence of water. The objective of the present study was to extend the ASTM method to measure total water in three other cellulosic fibers: brown cotton, flax and rayon. Method validation involved checking for residual water in a specimen by NIR spectra taken through the bottom of the vial and Karl Fischer selectivity to water over interfering substances. Relative water concentration in the cottons (white and colored) and non-cottons (flax and rayon) will be discussed. Sample conditioning in a glove box placed in the isothermal textile testing room ($21 \pm 1^\circ\text{C}$) to control humidity within $65 \pm 0.5\%$, by the use of a saturated aqueous salt solution, provided the best precision. ASTM D7785 was successfully applied to measuring the level of water in all cellulosic materials. Comparative information on the water content of different types of fibers conditioned side-by-side is highly desirable since their physical properties are significantly affected by moisture. Variations in the amount of water present, or its regain, affect the mass of dry fiber in a lot of material.

Abstract Text

Explants treatment with growth regulators is a widely adopted procedure in vegetative plant propagation, being more crucial in difficult-to-root species or cultivars where otherwise the adventitious rooting process may never occur at all. Several studies have suggested that differences in rooting ability of cuttings could be attributed to the differences in uptake or metabolism of the absorbed auxins. Hence, it is important to monitor the evolution of endogenous levels of these compounds in auxin-treated cuttings, preferentially as a routine practice. Gas chromatography/mass spectrometry (GC/MS) has been widely used for the analysis of plant growth regulators and, despite the significant progress achieved in analytical methods for auxins quantification, sample preparation is still the bottleneck of the process. Microextraction techniques such as dispersive liquid-liquid microextraction (DLLME) offer several advantages like low solvent consumption and fast sample extraction. However, since auxins are not naturally volatile, their analysis by GC/MS is dependent on previous derivatization, which so far has been done using time-consuming conventional silylation methods. Microwave derivatization (MAD) takes advantage of the dielectric heating effect to greatly reduce derivatization time and improve reaction efficiency. Here we report the development of a new method for the quantification of free auxins in *Olea europaea* L. samples, using DLLME and MAD followed by GC/MS analysis. Optimization of DLLME conditions, as well as MAD conditions, is described. The proposed method proved to be substantially faster than other alternatives, and has already been applied to real samples of semi-hardwood cuttings and microcuttings of olive, which results are presented.

Abstract Title **Jamaican Sorrel (*Hibiscus Sabdariffa*) and Citrus (*Citrus Sinensis*) Waste Extracts: Potential Applications and Utilization**

Primary Author Andrea M. Goldson
University of the West Indies

Date: Tuesday, March 10, 2015 - Afternoon

Time: 02:30 PM

Room: 241

Co-Author(s) Vanessa Ranger

Abstract Text

Waste extracts of Jamaican sorrel (*Hibiscus sabdariffa*, S) and citrus (*Citrus sinensis*, C) were evaluated for their potential commercial applicability. Pectin (0.84 % C; 0.48 % S), crude fiber (3.94 % C, 4.16 % S), ash (3.21 % C; 4.37 % S) and crude fat (2.65 % C; 3.15 % S) of the extracts were assessed. Fatty acid analyses utilizing gas chromatography/mass spectrometry revealed that the extracts are a source of omega 6 (19.90 % C; 25.37 % S) and omega 9 fatty acids (18.24 % C; 20.82 % S). Palmitic acid (32.94 % C; 42.45 % S) and stearic acid (7.21 % C; 7.64 % S) were also identified. Nuclear magnetic resonance spectroscopy showed characteristic triglyceride signals, a doublet of doublet (δ 4.15; δ 4.30) and a multiplet (δ 3.35) which are due to the protons on the glyceride backbone. Elemental analysis by atomic absorption spectroscopy revealed higher levels of iron (69.76 ppm S; 8.36 ppm C) and zinc (367.13 ppm S; 5.00 ppm C) in sorrel extracts. The antioxidant activity of extracts was determined by the 2,2-diphenyl-1-picrylhydrazyl (DPPH) assay and the total phenolics by the Folin-Ciocalteu assay. Total phenolics was higher in citrus extracts. Conversion of cellulosic biomass to usable value added products presents an opportunity for agro processing industries to reduce the quantity of waste effluent which arises from the agriculture industry. Sorrel and citrus extracts may be considered for use in nutraceuticals.

Abstract Text

Fast, low level detection of chemical warfare agents (CWAs) in the field is needed to keep both military personnel and civilians safe during and after chemical threats and incidents. Ideal detectors need to be fast, rugged, and person portable, with the ability to detect, identify, and quantify complex mixtures containing chemical warfare agents and related chemicals. The HAPSITE ER, the only person portable GC/MS, was designed for the analysis of volatile and semi-volatile organic chemicals in air. The higher boiling points and increased chemical activity of organophosphate CWAs required modifications to the GC/MS system to increase detection. Modifications include increased sample pathway deactivation, higher temperature sample pathway components, and longer sample desorption times. Maintaining battery-operated portability requires lower than ideal component temperature settings, but by prioritizing critical portions of the sample pathway, detection limits of the CWAs tested were significantly reduced with improved reproducibility. Effects of system modifications were monitored using tributyl phosphate, a CWA simulant chemical. Testing with actual CWAs was carried out by a third party surety lab in the United States. Detection limits were found to meet or exceed IDLH (Immediately Dangerous to Life and Health) limits for airborne exposure.

Abstract Text

The utility of hyperspectral imaging (HSI) passive chemical detection that utilizes wide field, standoff screening continues to advance for detection applications. With a drive for reduced size, weight, and power (SWaP), near real-time detection capabilities, and improved sensitivity, developing a portable sensing platform that is robust and user-friendly increases the detection capabilities of the sensor.

ChemImage Sensor Systems has developed a portable HSI sensor, called VeroVision[®], for real-time, wide area surveillance and standoff detection of explosives, chemical threats, and narcotics. Utilizing liquid crystal tunable filter technology, VeroVision[®] provides wide-field SWIR imagery combined with an intuitive user interface that produces automated detections and a real-time display of threats with a built in library of threat signatures that is easily updated, allowing for the input of additional materials of interest. Unlike existing detection technologies that often require close proximity for sensing, VeroVision[®] allows the individual operator to detect threats from a safe distance.

This presentation will provide an overview of shortwave infrared spectroscopy, focus on the design and operation of the sensor, and discuss specific use scenarios that VeroVision[®] can be applied to, such as explosive detection or narcotic identification.

Abstract Title **Trace Chemical Signatures of Calcium Hypochlorite; Implications for the Attribution of Hypergolic Mixtures**

Primary Author Stephanie A. Yocca
Virginia Commonwealth University

Date: Tuesday, March 10, 2015 - Afternoon

Time: 03:05 PM

Room: 255

Co-Author(s) Alicia M. Zimmerman, Christopher J. Ehrhardt, Eric J. Hazelrigg, Joseph Turner, Monique Jones, Sarah C. Rutan, Stephanie R. Harrold

Abstract Text

The goal of this research was to investigate trace metal composition across different sources of inorganic pool chlorine (calcium hypochlorite) both as a precursor compound and as residues from a hypergolic mixture. This is a new forensic signature system for the attribution of unknown chemical residues recovered from arson-related crime scenes.

Three different sources of calcium hypochlorite were combined with automotive brake fluid to create a self-igniting mixture. The residues were extracted with nitric acid and analyzed with Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES) for 24 different elements. Multivariate chemical profiles were then analyzed using Discriminant Function Analysis (DFA).

ICP profiles showed that each hypochlorite source exhibited distinct variation in the presence and relative abundance of certain elements that was consistent in both pre- and post-reaction residues. For example Aluminum was enriched in the UC sample group (~40ppm vs. <7ppm) while Boron was more concentrated in the SS group (~2ppm compared to the other sources (<0.09ppm). Error rates for all measured elements were less than 0.05ppm. DFA of ICP profiles revealed robust separation among all three hypochlorite sample groups along the first two functions. Function coefficients indicated that Al, Cr, Cu, K, Ni, and Sr contributed most to the variation among groups. Overall, this work suggests that trace metal variation can be used to differentiate each source of calcium hypochlorite and that multivariate metal profiles may be a useful signature for comparing hypergolic residues to precursor compounds or different residue samples to each other during an investigation.

Date: Tuesday, March 10, 2015 - Afternoon

Time: 03:25 PM

Room: 255

Co-Author(s) Christopher J. Katilie, Frank L. Steinkamp, Susan L. Rose-Pehrsson

Abstract Text

Binary explosive mixtures are commonly found in improvised explosive devices (IEDs) which have become increasingly commonplace in the Middle East. The components of such mixtures often have common, innocuous uses independent from each other and thus are only of concern when they are combined. Binary explosives require an oxidizer and a fuel component. Examples of oxidizers include ammonium nitrate (AN) and potassium chlorate (PC), while examples of fuels include, but are not limited to, sugar, aluminum powder, and fuel oil. Detection protocols often focus on the detection or sensing of the oxidizer alone. Canines, for example, are often trained on solely AN, though recent canine evaluations have shown that the canines perform better when trained to the mixed components.

Hazards associated with binary explosives mixtures often limit or preclude analytical research and other testing using the mixtures themselves. Through this research a novel device was designed that safely segregates the binary explosive components, but provides a mixed volatile signature. For this reason, it is important to establish differences, if any, between explosive components and component mixtures. Qualitative and quantitative differences in the headspace of the individual fuel and oxidizer components and the mixtures were compared, with the age of the mixture being explored as well. Vapor analysis was carried out by GC/MS with whole air sampling with online cold trapping, as well as solid phase micro-extraction (SPME). Ammonia, derived from the dissociation of ammonium nitrate in ambient humidity, was collected by passive sampling onto sorbent disks with analysis by ion chromatography. Results showed minimal differences between individual explosive components and fresh mixtures.

Abstract Text

We examined the 229 nm deep ultraviolet resonance Raman spectra (DUVRR) of solution and solid state trinitrotoluene (TNT) and hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) and their solution and solid state photochemistry. TNT photodegrades with a quantum yield of ≈ 0.015 . The initial photoproducts of TNT photolysis have similar enhancement of the $-\text{NO}_2$ stretching vibrations as TNT, resulting in DUVRR spectra that are very similar to that of pure TNT. The photoproduct bands result in TNT-like DUVRR spectra even after TNT is completely photolyzed. These ultraviolet resonance Raman (UVRR) bands enable DUVRR of trace and standoff detection of TNT. RDX rapidly photodegrades with a high performance liquid chromatography (HPLC) measured solution quantum yield of ≈ 0.35 . During the photolysis of RDX, new spectral features evolve indicating photoproduct formation. A stable DUVRR spectrum is seen after long irradiation times that enable standoff detection of RDX. Nitrate is a photoproduct that forms in the solution state photolysis of RDX and is a signature for detection of RDX even after photolysis.

The structures of the initial TNT photoproducts were determined through liquid chromatography mass spectrometry (LCMS) and tandem mass spectrometry (MS/MS). The solution and solid state photochemistry of TNT shows similar DUVRR spectra and initial photoproducts. The major solution state initial RDX photoproducts were determined with high performance liquid chromatography-high resolution mass spectrometry (HPLC-HRMS) and gas chromatography mass spectrometry (GCMS). We used X-ray photoelectron spectroscopy (XPS) to determine photoproducts formed during solid state RDX photolysis. This work was funded by the Office of Naval Research (ONR) N00014-12-1-0021 contract.

Abstract Text

Ion mobility spectrometers are already in routine use e.g. as handheld systems for military use (chemical warfare agents) or fire fighters (hazardous substances) and at airports for the detection of drugs of abuse and explosives using wipe tests and thermal desorption units. However, all those instruments have in common that they are optimised for particular compound groups and are not selective enough to cover a broad range of applications. We demonstrated that using rapid gas-chromatographic pre-separation combined with an internal gas-supply, a GC ion mobility spectrometer can be applied as a mobile system with the full analytical performance. Particular applications are searching for trapped victims during urban search and rescue operations but the detection of hidden persons as well, the detection of the consumption of drugs of abuse e.g. for traffic control and the detection of explosives or other hazardous substances e.g. in room air. The use of pattern data bases and suitable algorithms enable rapid on-site data evaluation.

Abstract Text

Multiple Sclerosis (MS) is a disease of the central nervous system where the myelin sheath covering the axons of nerve cells becomes damaged. There is currently no cure for MS and the mechanisms of action for current therapies are unknown. In some cases, the diagnosis of the disease may require multiple MRIs over a period of months to years to diagnose. In an attempt to better-understand the mechanisms involved in demyelination, our group has discovered that, when exposed to mechanical deformation, red blood cells (RBCs) from MS patients release nearly 2-3 fold more ATP (~385 nM) than control RBCs (~190 nM). Importantly, ATP is a stimulus of NO, a molecule known to break down the blood brain barrier, a classic feature of MS. Recently, we have also shown that physiological steroids, such as estrogens, can decrease the NO stimulated by RBCs. In this work we use a 3D-printed microfluidic device to mimic in vivo conditions to better understand the mechanisms of action of common MS steroid therapeutics. These measurements are performed using both chemiluminescence (for ATP) and fluorescence (for NO) detection in different wells on the 3D-printed device. Other data to be presented, from 40 MS blood samples, may provide insight for these high ATP release values. Our device allows for multiple steroids or multiple concentrations of the same steroid to be measured in parallel for high-throughput results, while still maintaining flow-based measurements and communication between a circulating blood stream and the baso-lateral side of an endothelium.

Abstract Text

The ability to select ligands that specifically bind a target of interest can aid in the development of drugs, clinical assays, and more. Some binding events, however, result in only minor perturbations to the inherent physicochemical properties of ligand or target, making separation and detection of bound and free species a challenge, especially for restricted sample sizes and trace sample constituents. The goal of this work is to overcome these challenges by developing versatile and highly efficient capillary transient isotachophoresis [i]ct[/i]ITP methods suitable for the selection of candidate ligands ranging from small macrocycles to large aptamers, acting on various classes of targets, ranging from proteins to microbes. By employing background electrolyte modifiers such as dilute, soluble polymer to facilitate sample zone focusing (by the method of Polymer Enhanced Capillary Transient Isotachophoresis, PectI), and/or SYBR Gold nucleic acid stain for on-column fluorescent labeling of samples, we have been able to resolve, detect, and collect ligand-bound target fractions for subsequent characterization. In preliminary studies, the average enrichment of thrombin-binding aptamer from a random DNA library was almost 40-fold after a single [i]ct[/i]ITP run, opening the door to advanced method development for the discovery of new ligands from a 13,824 member library of DNA-encoded small molecules against clinically relevant Src tyrosine kinase, and from an 88-base random DNA library against model microbial targets [i]Escherichia coli[/i] and [i]Bacillus subtilis[/i]. These selection experiments are fast and highly efficient, and show promise for future application to microbial pathogens, disease biomarkers, and other targets of relevance to human and environmental health and safety.

Abstract Text

Synthetic unmethylated cytosine-guanine (CpG) oligodeoxynucleotides (ODNs) are immunostimulatory motifs that have shown tremendous promise as vaccines or adjuvants for treatment of cancers and infectious diseases. For effective immunotherapy, it is necessary to efficiently deliver these nucleic acid therapeutics intracellularly into target immune cells while protecting them from nuclease degradation. We have developed novel immuno-nanoflowers (NFs), which are self-assembled from long DNA encoded with tandem CpG through rolling circle replication (RCR), for efficient CpG delivery and protection from nuclease degradation. In a model of macrophage-like cells, the CpG-NFs proved to be potent immunostimulators by triggering the proliferation of these immune cells, which, in turn, secreted immunostimulatory cytokines, including tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6) and interleukin-10 (IL-10). These results demonstrate the ability of CpG-NFs to induce cancer cell apoptosis and necrosis through their immunostimulatory properties.

Abstract Text

Cystic Fibrosis (CF) is an autosomal recessive genetic disorder that disrupts the cystic fibrosis transmembrane conductance regulator protein (CFTR). An important chloride ion channel, CFTR is present in numerous cell types, including pancreatic beta-cells, red blood cells (RBCs), and neutrophils. Perhaps not surprisingly, patients with CF have complications associated with diabetes, blood flow, and immune response. In this presentation, we will present data showing a possible link between these three body systems (endocrine, circulatory, and immune). Specifically, we will present results quantifying the amount of C-peptide (0.76 +/- 0.16 pmol/million cells) and zinc (2.5 +/- 0.3 pmol/million cells), two secretogues from beta-cells, bound by control human neutrophils. C-peptide, when secreted from the endocrine system, has known effects on the circulation, including binding to RBCs and stimulating increases in blood flow. However, its downstream effects on the immune system are not understood. We will describe the design and use of a rugged, reusable 3D-printed microfluidic device to determine the role of C-peptide and Zn²⁺ on neutrophil adhesion and chemotaxis. This novel fluidic device enables exquisite control of included cells and tissues and allows for high-throughput analysis of different conditions, such as chemoattractant concentration and neutrophil stimuli, in parallel.

Abstract Text

LC-MSn screening of “sexual performance enhancing” dietary supplements resulted in the discovery of several analogs of approved erectile dysfunction drugs not previously detected by the Food and Drug Administration’s Forensic Chemistry Center. Additionally, many recently analyzed products have contained multiple active pharmaceutical ingredients and/or analogs, which have been identified by liquid chromatography with mass spectral detection (LC-MS) and assayed by high performance liquid chromatography with ultraviolet detection (HPLC-UV). Here we report the recent trends observed in the detection of PDE-5 inhibitors and their analogs contained in dietary supplements, including the first identification of a compound that structurally resembled tadalafil. One new analog was isolated from the supplement matrix using HPLC with fraction collection, and was further characterized using nuclear magnetic resonance (NMR) and LC-MS with accurate mass determination. The analog had an accurate mass of m/z 420.15614 (error is 1.77235 ppm) for the protonated species $[M+H]^+$, corresponding to a molecular formula of $C_{23}H_{22}N_3O_5$. Mass spectral fragmentation data suggested that the modification occurred in place of the $-CH_3$ located on the pyrazinopyridoindole-1,4-dione of tadalafil. NMR was utilized to further elucidate the configuration of the substitution. The analysis indicated that the moiety is a $-CH_2CH_2OH$, hydroxyethyl group. The new analog has been named 2-hydroxyethylnortadalafil.

Abstract Text

The rise in antibiotic resistance has resulted in a need for high throughput platforms that enable generation of dosing profiles and measurement of bacteria response. Here, a 3D-printed device was used as a platform to control dosing profiles to bacteria (*Escherichia coli*). The 3D-printed device has 6 channels, each with dimensions of 1 mm x 1 mm x 0.5 mm. Each channel holds a transwell membrane insert (polyester membrane, 0.4 μ m pore size) that is used to house the bacteria. *E. coli* was chosen as the model bacteria, while Levofloxacin was chosen as the antibiotic. *E. coli* was grown in lysogeny broth with shaking overnight. After approximately 14 hours, the cells were centrifuged and rinsed with albumin free physiological salt solution (BSA-free-PSS) 3 times and adjusted to a concentration of 108 cells/mL. Samples were loaded into the transwell inserts and antibiotic was pumped through each channel at 10 μ L/min using syringe pumps. Exposure profiles were monitored using LC/MS and were controlled by variation in the concentration of antibiotic flowing in the channel and pumping time. Preliminary fluorescence data using 2-color staining (SYTO9 and propidium iodide) indicates that after dosing with levofloxacin over a period of 3 days, 87% \pm 13% (day 1), 17% \pm 19% (day 2), and -1% \pm 2% (day 3) bacteria remained live after dosing. Bacteria viability, determined using the 2-color system and flow cytometric methods, in response to various dose curves will be discussed.

Abstract Title **Bench Top NMR of Street Drugs – The New Presumptive Drug Test**

Primary Author Alexander Valente
The Pennsylvania State University

Date: Tuesday, March 10, 2015 - Afternoon

Time: 03:45 PM

Room: 256

Co-Author(s) Frank Dorman, John Frost, Roscoe Bennett

Abstract Text

Bench top NMR has proven itself to be an interesting new tool for obtaining quick, easy, and inexpensive NMR spectra for research and instructional purposes. It can also be used to attain spectral profiles on pure samples of drugs that produce “legal highs”. This work attempts to create an NMR database of synthetic compounds known to be in use recreationally, or analogs thereof. Such a library would be useful to those working in crime laboratories to identify unknown chemical compounds found at crime scenes. This test is more accurate than a color indicator and is easier to administer than a traditional mass spectrometric (MS) analysis. A single test requires only twenty minutes and is very cost effective.

Major classes of compounds tested include psychedelics, cathinones, and cannabinoids. Standard samples were provided by Cayman Chemical (Ann Arbor, MI) and street samples were provided by the Pennsylvania State Police (Harrisburg, PA). These street samples were mostly mixtures of compounds most notably XLR-11, PB-22, and AB-Fubinaca. Compounds were dissolved in the appropriate deuterated solvent and centrifuged to insure the compounds completely dissolved.

The standards’ spectra are comparable to those of the samples. An interactive library will be compiled so a drug profile can be quickly compared against a library and a presumptive identity can be established. This method will not be meant to definitively identify an unknown compound but it can aid in rapid presumptive analysis so that follow-up analyses are more targeted.

NMR will consistently give a general profile of a given compound. If there is no discrepancy in shimming and solvent choice, NMR can be used to compare spectral similarities among unknown compounds. A quick and easy presumptive test for drugs, provided by the bench top NMR, can be useful to save time on a more in depth instrument and accurately identify at least the class of compound of an known substance.

Abstract Text

Chirality is an important characteristic of many pharmaceutical drugs. Often, one of the enantiomers exhibits specific pharmacological and biological function, or even toxicity. Thus, the information about chiral purity is needed for better evaluation of the drug. To facilitate this analysis, we developed a new class of chiral selectors that could be used as additive in capillary electrophoresis (CE) for the separation of enantiomers: sulfopropyl ether- α -cyclodextrin polymer (SPE- α -CDP), which was a novel, highly-hydrophilic, negative charged chiral additive.

SPE- α -CDP could synthesize through a simple and efficient procedure and it proven to have statistic uniformity through indirect UV detection. Elemental analysis and blue tetrazolium detection had been used to characterize the degree of sulfonation and the content of α -CD, respectively. By using this chiral selector, model chiral drugs of weak acid, weak base and neutral drugs had been separated with different separation conditions including the concentration of SPE- α -CDP and buffer, pH of buffer, and the applied voltage. Comparing to the non-polymerized sulfopropyl ether- α -cyclodextrin (SPE- α -CD), SPE- α -CDP gave a much lower operation current under similar conditions. The polymerization made SPE- α -CDP readily recyclable. The recycled products were proved to have similar resolution with original ones through separating the same analytes.

Abstract Text

Direct alcohol fuel cells (DAFCs), particularly those utilizing ethanol as a fuel, have attracted more attention as alternative energy source[1]. Direct ethanol fuel cells can work at low temperature, possess high theoretical mass energy density, and are environmentally friendly. Ethanol Oxidation Reaction (EOR) can be operated both in acidic or alkaline solutions. Fundamental studies of ethanol electro-oxidation in acidic media have been mostly performed on platinum. Palladium, on the other hand has been less studied in acidic media due its relatively low performance[2-4]. An efficient electrode for a fuel cell must be conductive, hydrophobic, requires high surface areas and high porosity to enable mass transport of H⁺ as well as be corrosion-resistant. Numerous materials are widely studied including carbon nanotubes, carbon black, and graphene. We hereby present the use of π -conjugated poly(amic) acid (PAA) [5-8] as novel materials for EOR.

Abstract Text

Biological analysis, environmental monitoring, food safety and disease diagnosis require sensitive, low-cost and multiplex assay. Microelectrode array (MEA) could meet these requirements and has been receiving significant attention because of its advantages such as higher sensitivity (versus macroelectrode) benefited from the enhanced mass transportation, improved signal-to-noise ratio and larger current response (versus microelectrode). So far, the fabrication of regular MEA has been accomplished mainly by depositing an insulating layer on a macroelectrode surface and then making patterned holes in this layer with photolithography, which were often prohibitively expensive and time-consuming. Soft lithography has been proved to be a rapid and cost-effective method to form and transfer patterns and structures. Our group commit to develop various soft lithography for fabricating MEA. We reproducibly fabricated regular Au band MEA with hydrogel etching and prospected a new technique to fabricate reduced graphene oxide (rGO)-based MEA with microtransfer molding. The developed MEA showed a lower detection limit and a larger current density for the detection of biological compounds, such as H₂O₂, dopamine, as compared with the macroscopic electrode.

Abstract Text

Carbon-fiber microelectrodes have proven to be an ideal sensor for studies in vivo. When combined with background-subtracted fast-scan cyclic voltammetry (FSCV), they provide a highly sensitive platform for working in biological tissue. The performance of carbon-fiber electrodes is significantly improved by electrochemically oxidizing the surface of the electrode. Thus, it is common to electrochemically condition a carbon-fiber microelectrode before an experiment by repeatedly cycling to 1.0 V or greater; however, the fundamental mechanism underlying the resulting signal enhancement has not been fully resolved. We have used a combination of Raman spectroscopy and electrochemical methods to characterize electrochemically oxidized carbon surfaces. Spectroscopic measurements were taken while polished carbon-fiber electrodes were conditioned using a variety of dynamic waveforms and static potentials. The disorder associated with the carbon surface was correlated to electrochemical sensitivity for the detection of dopamine and ascorbic acid using FSCV. The work herein provides unique insight into the chemistry of a dynamic surface that will prove invaluable for future studies seeking to improve detection performance for specific analytes.

Abstract Text

Tetrahedral amorphous carbon (ta-C) is a type of diamond-like carbon that exhibits properties closely resembling those of diamond including high hardness, wear resistance, optical transparency, corrosion resistance, as well as, electrical conductivity. Additionally, doping ta-C with different concentrations of nitrogen (ta-C:N) during film growth is a common way to control these properties. Knowledge of the physical, chemical and electrical properties of ta-C:N films is necessary to understand the mechanisms and kinetics of various redox systems. This presentation will focus on describing the background voltammetric response and voltammetric response of ta-C:N films, doped with various amounts of nitrogen, to behaviorally-different redox systems in aqueous media. The results will show that these carbon materials are particularly good for electroanalysis.

Additionally, ta-C has been used to inhibit protect various metals from both corrosion and wear. Detailed studies of the corrosion inhibition mechanism of these coating on various steels have not been fully conducted. Our research is addressing this knowledge gap and the presentation will highlight some of our recent findings on the degree of corrosion inhibition the coatings provide on steel. Specifically, the ability of ta-C and ta-C:N coatings to protect steel from corrosion in accelerated corrosive testing environments.

Abstract Text

In spite of their significance in determining battery performance, a comprehensive understanding of how local surface (de)activation and site-specific differential reactivity impacts the dynamic ion-transfer capabilities of ion-battery anode interfaces has yet to be fully elucidated. New in situ analytical tools are required to address present and future battery challenges by incorporating versatile platforms capable of analyzing alkaline ions at interfacial nano-structures in aqueous and organic solvents.

Here, we introduce two approaches for the imaging of ionic reactivity based on scanning electrochemical microscopy using liquid probes. In the first approach, Hg hemispheres supported on micro- and nano- probes were used for the detection of ionic fluxes of Na^{+} , Li^{+} and K^{+} in propylene carbonate over operating Au and C electrodes. In the second approach, the ion transfer across immiscible electrolyte solutions (ITIES) was used at the aqueous/1,2-dichloroethane interface using suitable ionophores to detect Li^{+} and Na^{+} fluxes in aqueous media over operating TiO_2 electrodes. In both cases, the probe potential provided chemical specificity while the limiting current for ion ingress into the liquid probes allowed the measurement ionic fluxes with excellent stability and linearity for concentrations in the mM and sub-mM range. SECM electrochemical maps with sub- μm spatial resolution probed quantitatively the alkaline ionic reactivity of controlled-defects generated by focused ion beam on C and Au, as well as surface-segregated redox domains on TiO_2 . This technique represents an unprecedented step in the analysis of anode ion insertion mechanisms, accessing aspects of surface reactivity that are lost during averaging in conventional electrochemical methods.

Abstract Text

Ionic liquids (ILs) were widely used as nonvolatile solvents and electrolytes.^{1, 2} However, their properties resembling the crystalline solids have not been fully recognized. In this report, we show that an IL-electrified electrode interface has a potential-driven crystalline ordering with cavities enabling selective adsorption of a specific size of gas molecule. With this unique interface, a kinetic size spectroscopy related to the molecule dipole moment and kinetic diameter (KD) of adsorbate molecules was established for gas identification with 0.1 Å of KD resolution.

Abstract Text

Electrochemical aptamer-based (E-AB) sensors are specific, selective, sensitive, and applicable to the detection of a variety of targets. The specificity is afforded by an electrode bound RNA or DNA recognition element, or aptamer. A redox tag on the distal end of the aptamer enables the signaling of these sensors. Signaling results from target-induced conformational changes or flexibility of the aptamer probe. These changes, which alter the efficiency of electron transfer, are measured as a change in current. Because of this signaling mechanism, there are a variety of methods to optimize the analytical properties of these sensors, including sensitivity, dynamic range, and binding affinity. Here, I present a general method to tune the analytical figures-of-merit of representative RNA and DNA-based E-AB sensors. First, varying the voltammetric interrogation frequency and rationally engineering the aptamer sequences with different signaling abilities allows for control over the sensor sensitivity, limit of detection (0.01-12 [micro]M), and observed binding affinity (0.22-42 [micro]M). Second, combining the newly engineered aptamer sequences at varying ratios on the biosensor surface allows for control over the sensitivity and linear range of the resulting sensor. These sensor guidelines represent a universal method for the development of electrochemical, aptamer-based biosensors with desired performance attributes.

Abstract Text

Accurate measurements of environmental exposure are central to determining the risk of hazardous substances. National Institute of Environmental Health Sciences (NIEHS) Superfund Research Program (SRP) invests in development of fast, accurate, robust, and advanced technologies that allow for portable real-time, on-site characterization, monitoring, and assessment of contaminant concentration and/or toxicity. This presentation highlights SRP innovations in devices and tools for exposure assessment of organic, inorganic and mixtures of contaminants with a particular focus on passive sampling devices used in contaminated sediments. Featured research will include: recent advances in a universal passive sampling device (PSD) for measuring the time-weighted-average chronic exposure to hundreds of organic chemicals in water; wearable PSDs to measure the bioavailable fraction of PCBs, PAHs, and their metabolites in water, sediment, and soil; extraction techniques utilizing a convenient repository sample collection device for practical shipment, storage, and analysis of aliquots (both environmental and biological samples); in situ sampling devices for measurement of emerging sediment contaminants (fipronil, triclosan, and triclocarban); newly developed polymeric materials for passive sampling during remediation efforts using activated carbon sorbents in the field for PCB impacted sediments; and employing stable isotope labeled hydrophobic organic compounds can improved the efficiency and accuracy of bioavailability measurements from PSDs. Looking forward, SRP research is advancing detection science to enable rapid assessment of bioavailable fractions of hazardous substances in the environment; and development of innovative detection technologies for combined exposures. Lessons learned from field application of these new tools will be discussed, including the technical, policy, and other practical issues that must be addressed for new technologies.

Abstract Text

Oil and Grease analysis is a simple measurement that can give an indication of water quality indicating a variety of possible pollutants. The determinative step is often gravimetric, also simple to use and balances are easily obtainable. This method is used in various forms around the world and is written into a variety of regulatory and consensus standards. For example, oil and grease is a method defined parameter and used quantitatively to assess compliance of a waste stream. But for evaluation of a waste site or landfill it may be used as a screening method and further analyses initiated to more specifically determine the amount and type of contamination.

In the US, oil and grease measurement is typically used as a permit parameter in the National Pollutant Discharge Elimination System (NPDES). As an example, more than 15,000 establishments in the state of Alabama are required to control oil and grease discharge to a permit value. Laboratories performing this analysis are generally accredited and subject to audits from state assessors. In addition, they have requirements from clients that constrain the number and quality of samples.

The intent of this paper is to address some of the more common audit findings or individual concerns using statements taken directly from the method itself or from official releases made by EPA. In addition, a special focus will be made with regards to addressing both user and auditor concerns regarding the use of automated Solid Phase Extraction (SPE) for this analysis. Implementation of method requirements, also consistent with client needs will be discussed.

Abstract Text

Air quality monitoring and investigation applications can be challenging due to the chemical complexity of the air. Since traditional gas chromatography-mass spectrometry (GC-MS) requires daily calibration checks, the number of compounds that can be quantitatively determined is typically limited to approximately 100 compounds. However, most air samples contain hundreds of chemical compounds making it impractical to calibrate for all of them.

Coupling of gas chromatography (GC) with a novel spectroscopic analyzer (MAX™) combines the compound separation of the GC with the qualitative and quantitative capabilities of optical spectroscopy. Unlike mass spectrometry detection, the MAX™ technology calibration is constant so a one-time characterization of the compound is the only requirement. This allows for the quantitative determination of all compounds in every sample without individual compound calibration beyond the initial characterization.

An initial demonstration was performed for several hundred compounds typical of most indoor air environments. Subsequently, representative air samples were collected and analyzed via this method to determine the feasibility. Comparison of these results with traditional GC-MS demonstrates that this technology can provide similar compound identification with better analytical accuracy.

This new combination of GC compound separation with MAX™ detection represents a significant improvement in the ability to separate and quantify complex mixtures such as indoor air with reduced calibration requirements while maintaining low detection limits.

Abstract Text

As helium continues to become more expensive and its availability remains not always consistent, many laboratories are searching for adopting more cost effective carrier gas options.

This study demonstrates the effectiveness of a purge-and-trap preparation system's automatic nitrogen purge feature in conjunction with an innovative gas chromatography split splitless injector capable of using two different gases for its operations.

While helium is used as carrier gas, maintaining the same existing performance normally obtained another less expensive and more common gas as nitrogen is used for the injector split and the purge-and-trap purge phase.

High quality data will be presented for the most common USEPA VOC Methodologies obtained with such instrumentation without time-consuming method revalidation and while also reducing helium consumption. Data on calibration and method detection limit (MDL) samples prepared, analyzed and quantitated according to US EPA methods will be presented and the total potential helium savings of such a system for continues operations will be discussed as well.

Abstract Text

US EPA method 625 is a general semivolatile method for wastewater analysis applied to a large suite of target analytes. Although method 625 was developed a number of years ago, through the EPA Office of Water, Office of Science and Technology, the method has been updated several times. As new technology is developed either for the determinative measurement or, earlier in the analysis process, for the sample preparation, data must be collected to demonstrate that the new technology is compliant and reproducible. Two small round-robin studies using multiple vendor products and solid phase extraction (SPE) materials in a variety of laboratories have been run to demonstrate the compliance of SPE with method requirements. The first study relied on the quality control in the existing method to catch when the equipment or sorbent did not work properly. In the second study, the choice of surrogates was enlarged to ensure that errors not caught with the criteria in the older version of 625 would be identified in this version.

This paper will discuss the performance of SPE in general for method 625 and the specific performance of a disk used with a single pass of acidified water through it rather than a pass with basified water and a second pass with the same water, now acidified, which is typical for liquid-liquid extraction. Recoveries of a large suite of compounds from a variety of matrices and laboratories will be examined and the effect of surrogates will be considered. The results from the first round robin demonstrated recoveries from 70-130% of most all the acid/base/neutral/pesticides chosen for the study using a multi-mode disk adsorbent. These results will be compared to results from the second study and comparisons of large and small volumes of sample, different surrogate mixes and interlaboratory performance will be discussed.

Abstract Text

Liquid chromatography - mass spectrometry (LC-MS) is a powerful technique for analysis of the metabolome due to its sensitivity, selectivity, and versatility. However, metabolomic studies are still challenging due to the vast size and diversity of the metabolome. Polar metabolites are not well retained on a reversed phase column, often requiring separate analysis from less polar metabolites. This can be avoided by derivatizing metabolites with a hydrophobic tag, increasing retention as well as electrospray ionization efficiency. [¹³C]-labeled internal standards are frequently added to improve quantification, which is a daunting task for a large sample size of metabolites. Derivatization simplifies this task, as [¹³C]-labeled derivatizing agents can be used to label [¹²C] standards and generate a stable isotope-labeled internal standard for every analyte.

We have used benzoyl chloride and aniline as two such derivatizing agents. [¹³C]-labeled versions of both are commercially available, further simplifying the production of internal standards. Benzoyl chloride reacts with primary and secondary amines, phenols, and thiols, while aniline reacts with carbonyls, carboxyls, and phosphoryls. Benzoyl chloride increases sensitivity 10- to 1000-fold, and has been demonstrated in a directed assay for 66 metabolites, including key components of tryptophan and phenylalanine metabolism. Aniline has been used to target 18 metabolites to date. These complementary techniques are capable of targeting a significant portion of the metabolome. Here the advantages of benzoyl chloride and aniline derivatization are demonstrated in metabolomic studies in a variety of biologically relevant samples, including cerebrospinal fluid and [*Drosophila*] tissue homogenate.

Abstract Title **Development of a LC-MS/MS Method for the Determination of Sugar and Humectant Profiles in Tobacco**

Primary Author Liqun Wang
Centers for Disease Control and Prevention

Date: Tuesday, March 10, 2015 - Afternoon

Time: 01:50 PM

Room: 267

Co-Author(s) Clifford H. Watson, Roberto Bravo

Abstract Text

[Abstract] Sugars and humectants are additives in tobacco products that can impart positive sensory attributes, and could serve as precursors for potential addictive and harmful chemicals in smoke. We developed and validated an isotope dilution liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) method with high sensitivity, throughput, selectivity and accuracy for the simultaneous determination of sugars (fructose, glucose, mannose, sucrose, and maltose), alditols (xylitol, sorbitol, and myo-inositol), and humectants (glycerol, propylene glycol, and triethylene glycol) in tobacco products. Determination of these tobacco components is important to aid in the ability to characterize tobacco ingredients and their potential effects on acceptability, smoke chemistry and toxicology, and to distinguish tobacco product categories. The developed method provides recovery levels for the targeted analytes ranging from 90% to 113%, limits of detection ranging from 0.0002 to 0.0045 $\mu\text{g/mL}$ and high precision with coefficients of variation ranging from 1.4 to 14%. Calibration curves for all analytes were linear with linearity R^2 values greater than 0.999. Each LC-MS/MS run takes 15 min. Different tobacco products were characterized using the developed method. Differences in total sugar and total alcohol were observed: Cigarette total sugar range 3.37 -9.09% and total alcohol range 1.05 - 4.59%; little cigar total sugar range 0.06 – 1.11% and total alcohol range 1.10 - 3.34%; cigarillo total sugar range 0.07 – 15.12% and total alcohol range 0.76 -10.69%. The calculated total sugar levels could unambiguously distinguish little cigars from cigarettes examined. The results obtained from this method could be further used to study the correlations between sugar or humectant levels and tobacco smoke products, and to investigate how different tobacco compounds would affect the levels of sugar or humectant related tobacco smoke products.

Abstract Text

The ability to detect and identify metabolites and lipids makes metabolomics a valuable tool for biomarker research. Examination of endogenous metabolites and lipids can reveal the fine detailed information regarding active metabolic pathways and biological process occurring in living cells.

Samples undergoing mass spectrometric analysis should be prepared in an unbiased and reproducible manner that maintains the integrity of intracellular compounds. Cellular metabolomic studies are challenging because universal workflows for cell quenching, cell separation from medium or ideal cell washing solutions, and metabolite/lipid extraction methods do not exist. This work includes optimization of a sample preparation workflow for LC-MS cellular metabolomics studies of primary and established suspension T cells to identify untargeted metabolites and lipids involved in Type 1 Diabetes.

Type 1 Diabetes (T1D) results from the auto-immune destruction of insulin-producing pancreatic beta cells by white blood cells or T-lymphocytes. T cells, which normally direct the immune system to counteract infections, are defective and play a large pathogenic role in the mediation of diabetogenesis. This work monitors the metabolic profile of T cells in a normal and high glucose environment to identify biomarkers of immune dysregulation using commercially available Jurkat T-lymphocyte cells as a model system. The metabolic profile of CD4+ t cells from Type 1 Diabetic patients and 1st-degree relatives (controls) are compared to the in-vitro model system to determine putative biomarkers.

This work is funded by SECIM (NIH Grant #U24 DK097209) and the JDRF Research Grant (#17-2012595).

Abstract Text

Electron ionization can significantly benefit LC-MS through the provision of automated library identification and extensive fragment information. Thus, bringing back EI to LC-MS is highly valuable, if a reliable and robust EI interface can be developed.

We developed a novel EI-LC-MS approach, based on interfacing LC and MS with supersonic molecular beams (SMB) and sample ionization with electrons as vibrationally cold compounds in the SMB.

The output of the LC is sprayed via a pneumatic spray at about 1.5 Bar, followed by fast, thermal vaporization of the sample compounds. The vaporized sample passes a 20 cm 0.25 mm ID fused silica flow restrictor capillary into a supersonic nozzle and expands into the vacuum system from a 300 μm supersonic nozzle at about 0.2 Bar pressure to suppress cluster formation while obtaining efficient vibrational cooling for the electron ionization of cold molecules in the SMB.

EI-LC-MS with SMB provides several important benefits including:

- A. Library based identification with names and structures.
- B. Enhanced molecular ions and MS information with EI of cold molecules in SMB.
- C. No ion suppression or enhancement effects are exhibited.
- D. Uniform semi-quantitative ionization yields is provided for the provision of chemical reaction yields and improved impurities analysis.
- E. Broad range of compounds including non-polars are amenable for analysis.
- F. Fast LC-MS is enabled via no ion suppression and deconvolution software (AMDIS) and fast flow injection MS-MS can replace lengthy LC-MS.
- G. GC-MS and EI-LC-MS can be integrated into a one system with method based switching.

Abstract Text

LCMS instruments get more sensitive with each new product introduction. Every year, new instruments that have Femtogram and Attogram sensitivity are becoming readily available. Parts per trillion and even quadrillion are becoming routine. Even though LCMS instruments are now capable of such performance, actually achieving detection of such low level amounts reliably is getting more difficult. Contaminants that you never knew about are getting in the way of good quantitation. And getting reproducible results at such low levels leaves a lot to be desired.

This presentation will illustrate some of the ways low level samples are lost, explore what goes bad in the mobile phase, and how to get back all the sensitivity you want. A major emphasis for this presentation is how samples get contaminated, by what chemicals, and how to prevent this from happening. Also to be discussed are some of the artifacts and impurities that are becoming more common as instruments become more sensitive, and we will explore some practical techniques for sensitivity enhancement.

Abstract Text

Silver nanoparticles (AgNPs) have been incorporated into a broad variety of consumer products because of their bactericidal properties. Because of the unique nature of nanoparticles, silver nanoparticles have the ability to deliver silver ions to targeted toxins more effectively than silver in its salt form (Ag⁺). The release of Ag⁺ from AgNPs can be directly attributed to the nanoparticle size and surface modifications. Methods are in demand to discriminate AgNPs with a variety of surface modifications from Ag⁺ and also separate AgNPs by size. Although a variety of peer reviewed silver/nanoparticle methods have been established, there are still gaps with regard to the ability to separate small silver nanoparticles (>20nm) from Ag⁺.

Recently, chromatography with inductively coupled plasma mass spectrometric (ICP-MS) detection has been explored as a means for nanoparticle size separations and differential detection of AgNPs from Ag⁺. Traditional techniques such as field flow fractionation and capillary electrophoresis have demonstrated the capability to separate AgNPs by size with Ag⁺ eluting during the exclusion time. However, these techniques require relatively clean matrices and the very smallest nanoparticles may coelute with silver complexes, neutral species or Ag⁺. High performance liquid chromatography (HPLC) methods are becoming more common as a tool to do AgNP size separations and differential detection of Ag⁺ from AgNPs as shown by Bettmer, et al. and Hanley, et al. HPLC in tandem with ICP-MS offers element specific detection and the flexibility of being able to separate the smallest of nanoparticles from Ag⁺.

The proposed study demonstrates how chromatography can be used in tandem with diode array/ICP-MS detection to separate silver nanoparticles functionalized with a variety of agents by size while isolating Ag⁺. The goal is to provide a separation where the AgNP surface modification is conserved and does not control the ability of the AgNP to elute.

Co-Author(s)

Abstract Text

Analysis of mercury species in drinking water is being reduced to parts-per-trillion level (pg/g of water) by regulatory bodies in the US and this trend is also observed worldwide. Naturally occurring mercury has been widely distributed by natural processes such as volcanic activity. The use of mercury in industrial processes significantly increased following the industrial revolution of the 19th century. Today coal fired power plants and crude oil are the largest sources of environmental mercury species and continue. The solubility of mercury compounds in water varies according to their molecular form. The elemental mercury is insoluble, mercury (II) chloride is readily soluble, mercury (I) chloride is much less soluble and mercury sulfide has a very low solubility. Methylation of inorganic mercury is an important process in water and occurs in both fresh water and seawater. The environmental levels of methylmercury depend on the balance between bacterial methylation and demethylation. New methods are required for the preconcentration, separation and quantitation of the mercury species such as inorganic mercury ions (Hg^+ and Hg^{2+}), methylmercury (CH_3Hg^+), ethylmercury ($C_2H_5Hg^+$) and others. In the present study, a new method of ion chromatography ICP-MS using Direct Speciated Isotope Dilution method has been developed and is described that has achieved quantification of mercury species in one batch using IC-ICP-MS with quantification levels at the pg/g level in drinking water.

Abstract Text

It is well known that the elution strength of the solvent of your sample diluent can cause significant effects on peak shape in gradient elution chromatography. Depending upon the volume of the injection, these strong solvents can even cause early eluting analytes to break through the column, resulting in no retention. There are several reasons why it might be desirable, or even necessary to inject samples in strong eluting solvents. One of these cases would be for samples that are not soluble, or are sparingly soluble in the initial mobile phase, and need larger concentrations of organic solvent. Another example would be in a case where a solid phase sample cleanup step requires strong organic solvent for analyte recovery. Usually in this latter case, the sample is blown down to concentrate the sample, and then reconstituted in weaker eluting solvent. However, this step is time consuming and it would be desirable to be able to directly inject the sample without need for the blowdown step. In this presentation we will show a sample injection strategy that allows for the injection of relatively large volumes of strong elution solvent, while significantly reducing sample break through and peak shape distortions of early eluting peaks. The ultimate goal of this work is to be able to directly inject protein precipitated and other pretreated samples directly, in high enough volumes for adequate sensitivity, while still maintaining good chromatographic performance.

Abstract Text

Tricresyl phosphate (TCP) is an organophosphate used as an additive in a variety of applications including industrial lubricants, hydraulic fluids and gasoline. Commercial TCP consists of a mixture of ten positional cresyl isomers. The ortho isomers are considered to be the most harmful, exhibiting neurotoxic properties. Human exposure to tri-ortho-cresyl phosphate (ToCP) can cause peripheral nerve damage and degeneration of the spinal cord. The largest reported ToCP exposure occurred in the United States during the 1930s from the consumption of ToCP-adulterated Jamaica Ginger. Approximately 50,000 people experienced paralysis often referred to as the "Jake leg". The neurotoxic effects of ToCP arise from the liver-activated metabolite cresyl saligenin phosphate (CBDP). Similar to other organophosphates, CBDP inhibits esterase enzymes including butyrylcholinesterase (BChE). CBDP forms a covalent bond with BChE at the serine 198 position. Following BChE adduction, CBDP undergoes hydrolysis to form two aged adducts. Ortho-cresyl phosphoserine BChE (oCP-BChE) is formed immediately and a second aging step produces phosphoserine-BChE (P-BChE). Currently, no laboratory assay is available to quantitate human exposure to ToCP. In this work, an immunomagnetic-UHPLC-MS/MS method was developed to quantitatively measure the long-term biomarkers oCP-BChE and P-BChE in human serum. The reportable range of adduct concentration was from the lowest reportable limit 2.00 ng/mL to 150. ng/mL, which is consistent with the sensitivity of methods used to detect organophosphate nerve agent adducts.

Abstract Text

Mycotoxins are ubiquitous food contaminants produced by filamentous fungi. Human exposure to mycotoxins occurs via contaminated food intake, inhalation and/or dermal contact. Studying mycotoxin contamination is of utmost importance today because of their diverse effects on human health. The objective of this work was to develop a sensitive and reliable multi-mycotoxin assay allowing simultaneous detection and quantification of common toxicologically important mycotoxins and their metabolites: ochratoxin A, aflatoxins B1, B2, G1 and G2, zearalenone, 7[alpha]-hydroxy-zearalenol, 7[beta]-hydroxy-zearalenol, zearalanone, 7[alpha]-hydroxy-zearalanol, 7[beta]-hydroxy-zearalanol, fumonisins B1 and B2, T-2 toxin, HT-2 toxin, deoxynivalenol, nivalenol, 15-acetyldeoxynivalenol, 3-acetyldeoxynivalenol, fusarenon X, and beauvericin in human blood samples. The proposed exposure-monitoring method uses liquid chromatography - mass spectrometry (LC-MS) in combination with a universal sample preparation technique that requires low sample volume and has high sensitivity, speed, and accuracy. Optimization of LC-MS method included detailed comparison of sample preparation techniques (solvent precipitation, solid-phase extraction, solid-phase microextraction and liquid-liquid extraction), sample pH, chromatography, and LC-MS instrumentation (Orbitrap and triple quadrupole). Solvent precipitation was not found suitable for plasma samples for this application. Liquid-liquid extraction and solid phase microextraction did not provide high recovery for polar mycotoxins and fumonisins. The best result was provided by hydrophilic-lipophilic-balanced solid-phase extraction which provided balanced coverage of both hydrophobic and polar mycotoxins. The optimized LC method relied on pentafluorophenyl column with water/methanol/acetic acid mobile phase for best sensitivity. The optimized method was validated according to regulatory guidelines and is suitable for mycotoxin exposure studies.

Abstract Text

This presentation provides attendees with a complete overview of the medical cannabis industry, from “seed to store”. Medical marijuana (MMJ) refers to the use of cannabis and its corresponding cannabinoids, as a therapy to treat diseases and/or alleviate symptoms. This industry is projected to be an \$8B industry by 2018. With this growth has come an explosion in medical marijuana testing labs, which perform testing that spans across many market segments, including medical, food safety, environmental, microbiological and QA/QC to ensure that patients receive safe medicines free from pesticides, contaminants, residual solvents and microorganisms.

This presentation will begin with a visual tour of grow operations and cannabinoid extractions. Current forms of medical cannabis products will be presented along with considerations for patient safety. The focus of the presentation will be an in-depth look at lab testing, highlighting the analytical instrumentations (including LC, LC-MS and GC-MS) used for profiling and potency testing as well as other typical lab services, such as pesticides/fungicides, residual solvents and microorganisms. This review will include an overview of sample prep and cannabinoid extraction techniques.

While THC is the most abundant cannabinoid (known as a mild analgesic with antioxidant activity), there are over 70 different cannabinoids in marijuana, with 8 commonly tested. Knowledge of both the cannabinoid profile and potency is essential in allowing the patient to choose the correct medicine for their needs, as well as determine dosing. The known therapeutic effects of these phytocannabinoids will be explored, with a look into future opportunities for personalized medicine therapies. Lastly, this presentation will conclude with opportunities for future cannabis laboratory testing, including marijuana strain typing, standards development and certification.

Abstract Title **LC-MS/MS Analysis of Urinary Nicotine Metabolites, Anabasine, and Anatabine to Determine Nicotine Exposure and Metabolic Profiling**

Primary Author Sharyn E. Miller
Centers for Disease Control and Prevention

Date: Tuesday, March 10, 2015 - Afternoon

Time: 03:05 PM

Room: 268

Co-Author(s) Ben Blount, Binnian Wei, Imran Rehmani, June Feng, Lanqing Wang

Abstract Text

This presentation will provide attendees with knowledge on tobacco exposure assessment via quantification of urinary nicotine, six of its metabolites (trans-3'-hydroxycotinine, cotinine, cotinine-N-oxide, nicotine-N-oxide, nornicotine, and norcotinine), and two minor tobacco alkaloids, anabasine and anatabine. Nicotine metabolic profiles are paramount in determining population risk assessments, exposure, and user trends- from traditional cigarettes to newly emerging tobacco products.

Sample preparation utilizes a customized robotic automation system that includes sample aliquoting, enzymatic hydrolysis, incubation, acetone precipitation, centrifugation, and evaporation. The accuracy and precision of the system allows for reliable plate preparation overnight; current method configuration prepares four 96-well plates each day, compared to the manual method, which takes two days for a single plate.

Samples are quantified using isotope-dilution LC-MS/MS with an analytical run time less than 8.5 minutes. Analyte MS de-tuning allowed for the quantification of all compounds, despite significant concentration variations across their reference ranges in urine. Automated integration software was used to reduce data processing time by hours per run based on customized QA rule settings and optimized peak picking parameters.

The validated method was applied to ~100 smoker samples to assess nicotine exposure and individual metabolism characteristics. The correlation of individual analytes to the total nicotine exposure indicated that cotinine was the preferred biomarker to measure compared to trans-3'-hydroxycotinine, despite trans-3'-hydroxycotinine concentrations in smoker urine being quite high compared to that of cotinine. Trans-3'-hydroxycotinine-to-cotinine ratio variation persisted (Range= 0.2-7.1), indicating a high degree of variability in CYP-450 2A activity among individuals, yielding both fast metabolizers and slow metabolizers.

Current and future analyses will focus on measurement in samples from national cohort studies in collaboration with Roswell Park Cancer Institute, NIH; FDA, Center for Tobacco Products; and UCSF, Center for Tobacco Control, Research, and Education. Following data release to these studies, a reference level in US smokers will be established.

Disclaimer: This study was funded through an interagency agreement by the U.S. Food and Drug Administration Center for Tobacco Products.

Abstract Text

Late Stage Functionalization (LSF) refers to the use of C-H bond activation chemistries for the incorporation of chemical diversity into a final product or advanced intermediate late in a synthetic sequence. LSF technologies offer the exciting possibility of accessing many diverse modifications in a single step from the desired compound of interest, giving discovery chemists an ability to quickly spawn new 'versions' of compounds. This has enabled access to structural diversity and new chemical space without the time consuming necessity of developing entirely new synthetic routes.

The Merck High Throughput Purification (HTP) group has adapted existing purification platforms and work flows to provide the critical chromatographic purification support for chemists utilizing LSF. Due to the possible non-directed nature of the C-H functionalization chemistries, obtaining purified compounds for positive structural identification of the resultant products is a critical step in the work flow. In many instances, a single reaction can produce several positional isomers as well as multiple additions of the desired functional group; in addition, the conversion rates can be low, requiring isolation of low mg quantities of material. These challenging purifications often require application of multiple orthogonal chromatography steps to allow isolation of all relevant products in sufficient quantities and purity for structural identification and subsequent biological assays.

This presentation will highlight the implementation of current HTP work flows toward solving these complex purification problems. This will include application examples utilizing semi-preparative, MS-Directed reversed phase chromatography, as well as both chiral and achiral Supercritical Fluid Chromatography (SFC). Current best practices and lessons learned from this work will also be discussed.

Abstract Text

New drug applications require the applicant to provide acceptable analytical methods to assay the drug product for the active pharmaceutical ingredient (API) and related manufacturing impurities and degradants. Analytical methods need to be precise, accurate and suitable for use as quality control methods for use by the applicant and as regulatory methods for use by the Agency. Method robustness can be improved by the use of quality by design principles during development of the method. Commonly encountered reviewer observations regarding validated methods submitted to the U.S. Food and Drug Administration will be discussed.

Abstract Text

2D-LC is a powerful separation platform that uses orthogonal separation mechanisms in each dimension to maximize the peak capacity and achieve separation efficiency that cannot be obtained by one-dimensional HPLC. Two case studies were presented to demonstrate the advantage of 2D-LC for the analysis complex biotherapeutics samples.

Antibody drug conjugates (ADCs) are a new class of biotherapeutic agents combining the specific targeting property of antibody and the cytotoxicity of a small molecule drug to achieve targeted delivery of cytotoxic drugs. One important quality attribute of ADCs is the content of the unconjugated toxin which poses toxicity concern. In case study 1, a SEC column coupled with RP HPLC method was utilized to analyze the unconjugated small molecule drug and related impurities in ADC directly without sample preparation. The SEC column in the 1st dimension separates the unconjugated small molecules from the ADC, and the small molecule components were further analyzed by RP HPLC in the 2nd dimension for identification and quantification. This 2DLC method can be used for both lot release and stability testing of ADCs.

In the case study 2, a mixed mode-RP method coupled with CAD and MS was developed to characterize polysorbate 20 in protein therapeutics. Polysorbate 20 is a surfactant commonly used in protein formulations to prevent protein denaturation and aggregation. It is critical to understand the molecular heterogeneity and stability of polysorbate as it degrades in aqueous solution and loses its surfactant activity. A mixed-mode column that has both anion exchange and reversed-phase properties was used in the 1st dimension to separate the polysorbate esters from the protein, and the esters were then analyzed by a RP-UHPLC column in the 2nd dimension to further characterize the ester subspecies. This 2D-LC method was used to monitor the heterogeneous stability of polysorbate 20 in the stability samples of a protein drug product.

Abstract Text

Traditional spectroscopic systems are generally constructed by optical components aligned individually in a space. In addition, optical traps and outside shields are obliged to suppress background noise. To keep positioning accuracy, robust holding mechanisms must be fixed on a concrete foundation, and it makes optical systems larger, heavier, and more expensive.

We focus on optical performance of composite and hybrid material based on the PDMS (polydimethylsiloxane) that has good UV transparency and low reflection on optical contact with glasses. This compact and flexible PDMS optical module can be combined on a tablet terminal as an optical foundation that equips power source, light sources (LCD) and sensor camera. Attached PDMS optical system is monolithic and contains solid optical path, optical components, and light coupling interfaces with the LCD and the camera. Simple PCR tube absorbance-meter (Fig.1) was developed as first model of this Labo-On-Tablet (LOT). Polymeric optical fibers were embedded. PDMS doped with Carbon particle (Shinetsu, KE-COLOR-BL, ABS=72/cm) covered a transparent PDMS optical components to reduce outside background radiation and internal scattering. Furthermore, only reflectance of 0.95% per reflection/scattering was obtained.

Pick-up part of LCD light was newly proposed and developed based on reversed taper coupling scheme. The plastic optical fiber was terminated with slanted angle of 45 degree with no-coated surface. The light from LCD lighting spot was picked up, and guided to the PCR chamber. The transmitted light was collected by the POF on opposite side was bundled and guided to the optical detector (face camera) via prism and lens made of PDMS.

The measurement accuracy was evaluated with Sudan-I water ethanol solution with green LCD lighting. The face-camera captured images of terminated POF surface for 10 times at each concentration of 1 μ M to 1mM. The lighting spot of fiber was cropped and the pixel intensity was integrated over the spot as a signal. Experimentally obtained signal scattering of $\pm 0.07\%$ std in the 10 times continuous measurement. Since the scattering of $\pm 0.13\%$ std was obtained when the PCR tube was ejected and reenter, their reproducibility about 0.05% can be estimated. The absorption sensitivity of 0.001 was also approximated from the calibration curve with single capturing. Thus, sensitivity of 0.0001 will be expected by using multiply capturing and averaging.

Abstract Text

Paper-based microfluidic devices are receiving a great attention due to the characteristics of low cost, simple fabrication, and spontaneous capillary action. However, slow flow in paper channel limits a device size and a practical use in various analytical applications due to long analysis time. Here, we present a new paper-based flow channel (hollow-paper channel) having empty space and paper within a channel closed by hydrophilic PET films and wax-printed barriers (see the cross-sectional structure in Fig. 1). The center paper layer was fabricated by wax printing and laser cutting. Fig. 1A shows a flow-test device, and travel distance variations of a dye solution as a function of detection time for three different pressures. Even at the pressure of 0 mbar, it exhibited very fast flow (less than 20 s for 10 cm moving), corresponding to a flow rate 6 times higher than that of a paper channel, probably due to the hydrophilicity and a flexible small gap between paper and PET. In addition, flow became faster as increasing a head pressure. With using the hollow-paper channel, we had fabricated colorimetric pH sensors using a bromothymol blue pH indicator. A measured mean gray value was 114, being much higher than the value of 72 in a comparable paper chip (see Fig. 1B). It clearly demonstrates that our new colorimetric sensor with the hollow-paper channel can detect pH very sensitively via uniform color formation and higher sample transfer ratio into the detection zone together with the short assay time.

Abstract Text

Transfusion of erythrocytes (ERYs) can cause complications in patients, especially if the ERYs have been in storage for longer than 14 days. Recent studies have shown that mortality rates are higher following transfusion in comparison to no transfusion. While many reasons exist for these complications, one of particular interest to our group is the decrease in nitric oxide (NO) bioavailability following transfusion. Recently, we reported that ERYs stored in normoglycemic conditions (5-6 mM glucose) released significantly higher levels of ATP (an NO stimulus) when subjected to flow, than those stored in the standard hyperglycemic storage solutions. Here, we report the ERYs ability to revert back to normal function if transferred to normoglycemic conditions, as would be the case in an actual patient transfusion. A 3D-printed device was used to show the flow-induced ATP release from ERYs stored for 1 day in hyperglycemic conditions before (126.8 ± 10.5 nM, n=7) and after (226.1 ± 2.4 nM, n=7) transfer to a normoglycemic buffer. After 12 days of storage, the ATP release was not reversible (113.4 ± 3.7 nM, 135.9 ± 7.4 nM, n=7). Secondly, ERY membrane deformability during storage was examined by a 3D-printed blood filterometer. Reductions in deformability were observed in hyperglycemic conditions, but were reversible up to day 8; after this point in storage, the ERYs remained permanently rigid. The tools fabricated with 3D-printing technology lasted for the entire timeframe of the study, did not clog due to cell movement, were custom-designed and can be shared with all labs through an electronic dropbox.

Abstract Text

A pillar array column (PAC) is a micro column which is fabricated by reactive ion etching of a silicon substrate and has non-porous pillars with a high degree of order in narrow flow channels. Compared to conventional spherical particles randomly packed in an empty column, the order of pillars is systematically designed to provide a higher efficiency due to a smaller van Deemter A term and higher permeability (Kv) attributed to higher external porosity. Therefore, PACs are expected to have a higher resolution and are promising candidates for the next generation chromatography columns. However, retention capacity (contributing to resolution) with PACs is low because pillars have a non-porous structure resulting in a low surface area.

In order to achieve the same level of retention factor with PACs as with superficially porous particles which are currently drawing much attention in the market because of the high efficiency, electrochemical anodization was applied to grow porous shell layers of 300 nm (30 nm pores) on the surface of pillars with the diameter of 5 μm and spacing (between pillars) of 2.5 μm . A specific injection method (on-chip injection) was established, which enables a small amount of injection (a few nL) to minimize an influence of injection volume on a tiny PAC.

□

Uniformity of the porous PACs were assessed by determining local height equivalent to a theoretical plate (HETP) along the channels, which appeared to be constant. On measuring the retention time as an indicator of the surface area, an increase in the surface area by a factor of about 30 compared to that of non-porous pillars was found as expected. On measuring the efficiency of a PAC with a commercial HPLC instrument, theoretical plate of about 100,000 with a retention factor of 2.2 under an isocratic condition and peak capacity of about 500 under a gradient condition were obtained at an extremely low pressure with a 1 m long PAC, which are ascribed to the increase in surface area.

Abstract Text

Microfluidic electrophoretic affinity assays are a popular method for the analysis of complex biological systems. The success of an affinity assay relies on preservation of the non-covalent affinity complex, which can be achieved by decreasing the dissociation rate constant (k_{off}) of the affinity complex during the separation. However, Joule heating produces temperatures as high as ~ 60 °C which increases k_{off} and therefore complex dissociation. Moreover, the microchip architecture may exacerbate this effect by insulating the channels with the bulk material making it difficult to dissipate localized heating.

To evaluate the heating effects on the sensitivity and performance of affinity assays, a microfluidic device was integrated with temperature controllers and an insulin immunoassay was used as a model assay. Cooling was implemented over the separation domain to preserve the affinity complex and ambient temperature was actively maintained over the sample delivery channel. Separation temperatures of 26, 25, 23, and 21 °C were assessed as well as separation voltages of 3, 4.5 and 6 kV. Optimum conditions were identified by the minimum k_{off} value as determined by kinetic CE. The cooling permitted stable temperatures at higher separation voltages and the assays performed at 6 kV and 21 °C were found to be optimal with 3.4% complex dissociation during the separation. This optimization produced a 10-fold improvement in the LOD to 1 nM. In turn, these contributions will allow for the development of robust affinity assays for the analysis of biological systems.

Abstract Text

Sampling probes, i.e. microdialysis and low-flow push-pull sampling, are essential tools for in vivo monitoring of neurochemicals. However, conventional sampling probes are typically handmade and have several limitations: 1) large in size (probe diameters are over 200 [micro]m), resulting in inevitable tissue damage and poor spatial resolution; 2) limited flexibility in their designs; and 3) tedious to make by hand. To overcome these disadvantages, we have used a microfabrication approach to develop miniaturized sampling probes.

Briefly, microfabrication of sampling probes was performed within a class 1000 cleanroom (Lurie Nanofabrication Facility at UMich). The probes were fabricated from 525 [micro]m thick N-type 100 mm silicon wafers coated with SiO₂ mask. A series of microchannels were patterned on a wafer by photolithography before the wafer was etched by plasma etching tools, i.e. deep reactive ion etching (DRIE) and XeF₂ etching tools. The wafer was then sealed with poly Si using low pressure chemical vapor deposition. Lithography and DRIE were again used to assign and etch probe shapes and sampling areas with desired dimensions. Additionally, for microdialysis probes, nanoporous anodic aluminum oxide was adapted for use as a nanotemplate for making sampling membranes.

Microfabrication allows us to incorporate smaller sampling areas and three 20 [micro]m wide microchannels within a probe, which has overall dimension of less than 100 [micro]m. Furthermore, over a hundred probes can be fabricated within a wafer. Preliminary studies have shown suitability for sampling from small brain regions in live rodent brain.

Abstract Text

Fluorescence polarization immunoassays (FPIA) have been used as alternative methods to electrophoretic immunoassays, ELISAs, and other quantitative affinity assays. FPIAs are attractive because they require no separation or washing steps. However, multicolor FPIAs have not yet been reported, restricting FPIAs to single analyte applications. This limitation is primarily due to the increase in complexity of the optics required simultaneously for multi-analyte polarization measurements. Here we address this issue by utilizing frequency encoded laser induced fluorescence thus simplifying the optics required for a multi-analyte FPIA.

Frequency encoding the fluorescence signals allows the use of a single PMT to detect multiple emission lines without additional filters. The sample is excited with a 635 nm diode laser pulsed at 73 Hz and a 488 nm laser pulsed at 101 Hz, additional lasers can be added for more fluorophores. The resulting fluorophore emission pulses at the same frequency as the exciting laser and we can isolate the individual signals using Fourier analysis. This allows the use of a two PMT set-up to measure vertically polarized and horizontally polarized light split by a polarizing beam splitter and the separate analytes to be encoded in the signals using frequency. We demonstrated the method with an insulin and glucagon immunoassay, which are important peptides for blood glucose regulation. The LOD for is ~ 10 nM for insulin and ~ 50 nM for glucagon, which suffices for monitoring for collections of ~ 10 islets of Langerhans, the endocrine units of the pancreas.

Abstract Text

Enzyme linked Immunosorbent assay (ELISA), usually performed on multi-well plates, is one of the most widely used laboratory diagnosis methods. However, the applications of ELISA in low-resource settings are often limited by long incubation time, consumption of large volumes of precious reagents, and expensive and sophisticated equipment. Herein, we developed a simple, miniaturized PMMA (Poly (methyl methacrylate)) /paper hybrid microfluidic ELISA microplate for low cost and high throughput infectious diseases diagnosis (Figure 1). The novel use of paper inserted in microwells in this hybrid microplate facilitates rapid antigen immobilization, avoiding complicated surface modifications. The top reagent delivery channels and vertical flow-through wells in the middle PMMA layer can simply transfer reagents to multiple wells (7x8 wells), thus avoiding repeated manual pipetting and washing steps in conventional ELISA or the use of costly robots. Unlike traditional microplates, ELISA can be completed within an hour in this microplate. Additionally, results of colorimetric ELISA could be observed by the naked eye. Quantitative analysis was achieved by calculating the brightness of images scanned by a desktop scanner. Using this hybrid microplate, IgG and hepatitis B surface antigen (HBsAg) were analysed. Although no specialized ELISA equipment was used, the limits of detection of 1.56 ng/mL for IgG and 1.60 ng/mL for HBsAg have been achieved, which are comparable to commercial ELISA kits. We envisage that this hybrid microplate can be used to perform enormous bioassays that are currently performed in traditional microplates, in resource-limited settings.

Financial support from NIH and UTEP MRAP is gratefully acknowledged.

Abstract Text

Sodium deoxycholate (NaDC)/ tris(hydroxymethyl)aminomethane (TRIS)-based hydrogels have been developed as multipurpose drug delivery vehicles. Specifically, we have recently formulated NaDC/TRIS hydrogels for the traditionally difficult application of enantioselective drug release. Such a delivery system could eliminate the need for chiral separation prior to drug loading in many cases. Total release and release rate from this system have been found to be unsusceptible to several modifications and additions to the hydrogel. This is a great benefit in that additives to drug delivery systems may be desirable in many applications. For example, a modifier may be added for increased mechanical strength or complementary health benefits. In addition to robust enantioselectivity, benefits of our hydrogel system include low cost, facile synthesis, tunability, high drug loading capability, drug loading concurrent with gelation, and a complete lack of organic solvents. Drug release also seems to be unaffected by gelator concentration, further reducing cost and minimizing required precision and skill for synthesis. Through use of UV-vis absorbance spectroscopy, enantioselective drug release was found to be tunable with hydrogel formulation, drug composition, and drug concentration. Conclusively, our NaDC/TRIS hydrogels can serve as distinctly beneficial, enantioselective drug delivery systems.

We would like to acknowledge funding for this work from NSF CHE – 1307611 and the Louisiana Board of Regents.

Abstract Text

We have evaluated the variation of accuracy for the determination of active pharmaceutical ingredient (API) concentration when the particle size of samples changes. When Raman spectroscopic compositional analysis of powder mixture sample is attempted, the variations in the physical properties of samples such as particle size and packing density have confounding effects on resulting spectral features. Especially, the characteristics of Raman scattering events could sensitively vary depending on particle size although the composition of sample remains unchanged. For the evaluation, binary mixture samples of ambroxol and lactose were prepared with 4 different particle sizes of lactose (under-50, 50-100, 100-150 and over 150[μm]), while the particle size of ambroxol maintained constant (15-30[μm]). The ambroxol concentrations in the samples varied from 9.0 to 15 wt% with increments of 0.5 wt%. Both back-scattering and transmission Raman spectra of the samples were acquired, and the resulting spectra features were examined in relation with the particle size. The shapes of Raman bands were slightly different when the particle size changed. Then, using 4 different datasets prepared using the 4 different particle sizes, partial least squares (PLS) regression was individually performed to determine ambroxol concentrations and the resulting accuracies were compared. The accuracy varied according to the particle size and improved when the particle size was smallest. To probe the origin of the varied accuracy, the propagation of laser and Raman photons in the samples were simulated and variation of spectral feature according to the particle size was investigated using Monte-Carlo method.

Abstract Text

In the production of drug tablets, it is important for pharmaceutical companies to have control of the solid state form of the active pharmaceutical ingredient (API). Process induced transformations can occur to the API during the various production stages. Potential transformations include polymorphic changes, transformation to a hydrate crystalline form, or the formation of amorphous regions. Such changes in the crystalline form of the API can affect the solubility, bioavailability, and stability and thus change the efficacy of the drug tablet. Wet granulation is one processing stage that can cause this type of transformation. During wet granulation an aqueous solution is added to the dry components to form granules. Certain anhydrous crystalline APIs will transform to the hydrate crystalline form when this occurs. One way to slow down or stop this transformation is with the use of polymeric excipients. In this study three model APIs, caffeine, theophylline, and carbamazepine were investigated. The anhydrous API was added to aqueous solutions containing different polymeric excipients and the transformation to the hydrate was monitored using in-line Raman spectroscopy. The collected spectra were correlated to a partial least squares (PLS) regression model to quantify the extent of transformation of the API. The results showed that for each of the APIs different polymeric excipients showed different inhibiting effects. For example, polyacrylic acid inhibited the transformation of caffeine and theophylline but showed little inhibition for the carbamazepine transformation. In addition, there was a pH effect for the polyacrylic acid inhibition indicating the importance of the hydrogen bond donor interaction of the polymer sidechain with the API crystal.

Abstract Text

NIR has become a routine tool in the analysis of solid samples due to its ability to rapidly provide valuable chemical and physical information non-invasively. NIR is a well established spectroscopic tool for process monitoring, process control and real-time release methods in a variety of industries. Even with these advantages application of NIR in the pharmaceutical industry has been limited, in part due to the complexity of robustly extracting a specific response from a complex solid mixture. In this presentation, we will discuss some of these challenges and potential solutions to minimize or eliminate them.

In order to develop an NIR method to address a particular problem, one first has to understand what NIR is interrogating during the analysis. Knowledge of the sampling volume is essential to understand the statistical response of the system and will be considered in this presentation. In addition, the influence of matrix properties, e.g. other components, agglomeration of analytes, sample density, or powder adhesion/cohesion, will also be discussed. As NIR spectra contain both chemical and physical information an understanding of how scattering and absorption is essential when measuring samples. A specific example will be presented that demonstrates the role of powder surface area and particle size distribution on NIR method performance for powder blending. Finally, the effect of environmental factors such as relative humidity will be exemplified.

Abstract Text

Quality by design (QbD) is a central part of biotherapeutic development, laying the framework for building quality into products through detailed process design and control. Building on the principles of QbD, Process Analytical Technology (PAT) is a critical tool for process understanding and control during manufacture. Implementation of PAT tools provides a means to improve the process and ensure final product quality through real-time monitoring of critical quality attributes (CQAs) allowing for rapid process decisions. In 2004 the FDA published an industry guidance for PAT summarizing the principles for innovative pharmaceutical development. Evolving from the FDA Guidance numerous PAT applications have been studied for the manufacture of both small and large molecule pharmaceuticals. The majority of initial PAT applications monitored process steps through spectroscopic sensors such as NIR, Raman, FTIR or UV-Vis. These techniques function very well for the monitoring of small molecule functional groups or chemical reactions however they lack the specificity and resolution for complex samples such as biotherapeutic proteins.

This work demonstrates the application of the online ultra-performance liquid chromatography system for biotherapeutic development. Successful demonstration of both at-line and on-line sampling followed the separation method of choice. Applications of reversed phase UPLC for titer (RP-UPLC) and purity analysis by ultra performance size exclusion (UP-SEC) or ion exchange chromatography (IEX) will be presented. Cases studies for application of these chromatography techniques for online monitoring of upstream, downstream, forced degradation, and clinical compatibility studies will be reviewed.

Abstract Text

A novel electrochemical method has been developed to detect and quantify the elemental impurities, cadmium (II) and lead (II), in pharmaceutical matrices. The approach, involving the use of anodic stripping voltammetry (ASV) on an off-the-shelf, unmodified glassy carbon electrode (GCE), was performed in both aqueous and in dimethyl sulfoxide solutions, without acid digestion or dry ashing to remove organic matrices. Limits of detection in the parts per billion range were obtained for both heavy metals - in the presence and absence of pharmaceutical matrices. The strong reproducibility and stability of the sensing platform, as well as obviation of sample pretreatment show the promise of utilizing ASV as a sensitive, robust, and inexpensive alternative to inductively-coupled-plasma (ICP)-based approaches for the analysis of elemental impurities in pharmaceutical matrices.

Abstract Text

Astronauts have available pharmaceutical drugs to overcome the deleterious effects of weightlessness, sickness and injuries. Unfortunately, recent studies have shown that some of the drugs currently used may degrade more rapidly in space, losing their potency well before their expiration dates. To complicate matters, the degradation products of some drugs can be toxic, such as p-aminophenol formed from acetaminophen (Tylenol®), which can cause liver damage. Consequently there is a need for a space-worthy analyzer that can determine if a drug is safe at the time of use, as well as to monitor and understand space-induced degradation, so that drug types, formulations, and packaging can be improved. To address this need we have been investigating the ability of Raman spectroscopy to monitor and quantify drug degradation and determine if a drug is suitable for use based on the presence of 90% or more of the original API concentration. Raman spectroscopy measures the vibrational modes of molecules, which allows identification of virtually any substance, including drugs. Furthermore, it is a “point-and-shoot” technology, in that the sample is simply placed at the laser focal point to make a measurement, typically in 1 minute or less. Here we present preliminary data by measuring a number of drugs, such as acetaminophen, during forced degradation reactions using a compact, low mass, Raman spectrometer.

Abstract Text

The correct identification of raw materials delivered to any manufacturing facility is an important process, none more so than in the pharmaceutical industry where it is a regulatory requirement. For many of the high value pharmaceutical markets 100% verification of incoming goods is mandatory, which puts a significant burden on analytical resources. The need to maintain sterility during the verification process is a further concern for those with aseptic manufacturing or where product cannot be terminally-sterilized as the incumbent methods all require material to be sampled from the containers.

Spectroscopic techniques are increasingly popular for identifying materials due to their speed, convenience and accuracy. It has emerged that the most versatile technique is Raman spectroscopy due to its high chemical specificity and simple operation. A significant limitation of spectroscopic techniques for verification is that the packaging is often not transparent, which precludes the use of NIR, FT-IR and conventional Raman. This means that the samples need to be measured in a sampling booth where the containers can be opened in safety then sampled, resealed and the booth cleaned. This can be extremely expensive, time-consuming and exposes the material to possible bacterial contamination. This report focuses on the application of Spatially Offset Raman Spectroscopy (SORS) to accurate, robust ID through the packaging supplied to the end user. SORS allows high quality Raman spectra to be measured through opaque containers such as sacks, bottles, tubs and bulk containers made out of paper, plastic, glass or multiple layers. We present data on the spectral quality and reproducibility of SORS measurements on common pharmaceutical incoming goods.

Abstract Text

The efficacy of a many active pharmaceutical ingredients (API) is dependent on either the crystallographic form or even the degree of crystallinity. Indeed, the bioavailability of many APIs is very poor in the crystalline state and must be administered to the patient in amorphous form.

Raman spectroscopy is well-known to be sensitive to polymorphic form, the structural re-organisation of the crystal structure in to another stable or meta-stable form. Conventional Raman surface imaging methods for pharmaceutical tablets can be effective at 'mapping' the distribution of different polymorphic forms, however, they are limited to one plane within the tablet and the preparation of that flat surface could lead to transformation of the form.

Traditional methods for quantifying amorphicity are powder XRD and solid state NMR (ssNMR). XRD suffers from inherently poor sensitivity for materials with poor or no crystalline structure and may involve sample preparation that could lead to phase transformation. ssNMR is not a routine technique and doesn't lend itself to supporting production-scale manufacturing and requires high capital expenditure.

Transmission Raman spectroscopy (TRS) offers the potential to rapidly quantify both the proportions of polymorphic form or ratio of crystalline to amorphous API in tablets and capsules with no sample preparation. Crucially, TRS is a true volumetric method and does not suffer from the limitation of conventional Raman imaging. We present data on the technique's ability to quantify polymorphs and also residual crystalline API in a formulation of amorphous API with sensitivity >10x that of XRD.

Abstract Text

Quality control of formulated protein drugs presents unique analytical challenges compared to small molecule pharmaceuticals. Proteins are complex macromolecules with secondary and tertiary structures that may easily be perturbed or unfolded, potentially resulting in loss of therapeutic properties. Deep ultraviolet Resonance Raman (DUVRR) spectroscopy is distinctively advantageous for quality assessment of formulated proteins because it is sensitive to changes in protein secondary structure, and is capable of analyzing proteins at concentrations of approximately 1 mg/mL, lower than the typical concentrations of formulated products. The deep ultraviolet resonance Raman enhancement from proteins (approximately 10^4) allowed for analysis in the presence of excipients in aqueous media, which exhibit relatively weaker Raman signals. These attributes have allowed us to analyze the secondary structure of formulated monoclonal antibodies (mAbs) with minimal sample preparation. DUVRR spectroscopy was applied for the quality assessment of formulated Rituxan and Avastin. The formulated products were degraded with chemical, heat and mechanical stress and the degradation products were subjected to DUVRR spectroscopic analysis. Chemical stresses included acidification and addition of surfactant to the formulated product. Changes were observed in the DUVRR spectra with each level of stress, and multivariate statistical models were applied to identify trends within the data. The results indicate that the fully developed method may be applicable as a rapid, sensitive and specific tool to detect degradation of formulated mAb pharmaceuticals.

This research is funded by the CDER Critical Path Initiative.

Abstract Text

Liquid chromatography under limiting conditions of adsorption, LC LCD is a technique, which allows separation of macromolecules of distinct chemical composition or physical architecture independently of their molar mass. LC LCD combines exclusion and adsorption retention mechanisms of macromolecules in the column, which is packed by porous particles. Pores are fully accessible to low-molecular substances but macromolecules are pore-excluded. As a consequence, the low-molecular substances elute slowly while the macromolecules elute rapidly. A zone of low-molecular substance, which promotes adsorption of macromolecules, is injected into the column in front of sample. It acts as an impermeable, slowly eluting barrier that decelerates elution of the adsorbing polymer species, while the non-adsorbed macromolecules elute without any delay. In this way, macromolecules that exhibit different adsorptivity can be rapidly, selectively, and efficiently discriminated. The LC LCD method is experimentally well feasible because the results little depend on eluent composition and temperature. It produces narrow peaks of polymers eluted behind barrier and its sample recovery is rather high. LC LCD enables discrimination and identification of minor admixtures present in a polymer matrix, even below 1%. Above merits of LC LCD allow its utilization in two-dimensional polymer liquid chromatography. Important condition for a successful application of LC LCD is adequate solubility of macromolecules in solvents of different polarities. To demonstrate how the latter limitation can be overcome, the low solubility polymers poly(ethylene terephthalate) and poly(butylene terephthalate) with quite similar chemical structure were mutually separated. Above polymers were also easily separated from the aliphatic biodegradable polyesters, polylactides and poly(butylene adipate). The constituents of a model four-component polymer blend were base-line discriminated, as well.

Abstract Text

Polypropylene (PP) is a thermoplastic polyolefin widely used in diverse applications for its versatile properties. PP pellets requires several mechanical property tests during production before the product is approved and released to the market. There is a great deal of interest in developing and implementing new analytical methodologies capable of providing the necessary information in less time, and hence, reducing cycle time during manufacturing. Raman spectroscopy is an attractive analytical technique for polymer materials because it is reproducible, requires no sample preparation, and provides typical spectra with sharp and well-resolved bands with structural chemical information. Polypropylene (PP) pellets obtained from an industrial plant process were used to develop a nondestructive and faster methodology to quantify mechanical properties using Raman spectroscopy. Raman spectra were recorded from 219 samples of the homopolymer PP, random ethylene-propylene copolymer, and impact ethylene-propylene copolymer. Multivariate calibration models were developed by relating the changes in the Raman spectra to mechanical properties determined by ASTM tests. The spectra were randomly divided into calibration (n=167) and validation (n=52) subsets. Calibration models were developed to predict Young's traction modulus, tensile strength at yield, elongation at yield on traction, and flexural modulus (1% secant). The best multivariate calibration models were obtained when a combination of genetic algorithms (GA) and partial least squares (PLS) was used on Raman spectral data with relative errors of less than 9%.

Abstract Text

Identification and quantification of key chemical species exocytosed by single cells is important for correlating cellular stimuli-responses to normal and diseased phenotypes. Measuring these chemicals is analytical challenging because some species, e.g. ATP, lack innate optical or electrochemical activity. To address this challenge, we are developing a biosensor platform in which ligand-gated ion channels (LGICs) are reconstituted into black lipid membranes (BLMs) that are suspended across apertures in glass micropipettes. We have previously demonstrated that a conductance-based measurement for quantifying ion channel activity can achieve 30 millisecond temporal resolution. We now present work towards realizing submillisecond resolution, using an ATP-sensitive, K⁺-channel, Kir6.2 as our model LGIC. Using quartz pipettes with 3-10 μm apertures and capacitance cancellation, BLM capacitance charging decayed in $<100 \mu\text{s}$ for potential steps $<10 \text{ mV}$, and steady-state current could be sampled 100-200 μs afterward. With three different potential steps, membrane conductance could be sampled every 0.9 ms, making this approach reasonable for monitoring chemical release from single cells at biologically relevant timescales. To demonstrate sensor applicability, we modulate Kir6.2 activity with the antagonist, ATP, and agonist, oleyl CoA, in a system which rapidly exchanges solution across the BLM.

Abstract Text

Meaningful characterization of molecular processes occurring within living systems requires monitoring and/or quantitation of biomarkers with high accuracy and precision. Levels of many markers present in qualitatively different states may vary so little that their reliable quantification becomes a nontrivial challenge. The task requires availability of sensing tools capable to operate with precisely defined sensing parameters (i.e. response range and sensitivity). We report on the design of allosterically-regulated DNA-based sensing systems that combine both sensing and regulatory domains within one molecule. This yields structurally simple molecular sensors with uncompromised specificity towards target and capability to tailor response range and sensitivity to a defined interval via rational manipulations of the regulatory domain. In particular, we demonstrated that incorporation of quadruplex structures into molecular beacons allows tuning both range of detectable analyte concentrations and response sensitivity with respect to the target analyte (i.e. ssDNA). We characterized the corresponding binding transitions via multiple techniques (PAGE, fluorescence, CD, UV) and showed that the design does not alter specificity of target binding and can be used to fine-tune aforementioned binding parameters. The general design principles presented in this report can also be applied towards variety of other potential targets (e.g. proteins, ions, RNAs, etc.).

Abstract Text

The methods used to study microRNAs (miRNAs) involved in cancer have failed to keep pace with our understanding of cancer pathology and are imperfect fits for the clinic. qRT-PCR, the current gold standard, is incredibly sensitive, relatively rapid, and cost effective, but only able to quantitate one target per assay. Conversely, microarrays are multiplexable, but slow and expensive. As a result, there are no clinically-adopted technologies for the multiplexed analysis of disease-relevant miRNAs. Here we show that a technology combining silicon photonic microring resonators and asymmetric polymerase chain reaction (aPCR) can fill these voids by simultaneously quantitating 25 miRNAs relevant to glioblastoma multiforme (GBM) and show that these results correlate well with qRT-PCR.

While multiplexed diagnostic panels have emerged in multiple tumor types, biomarkers for brain tumors have lagged behind. We use GBM, an extremely invasive glioma subtype that carries a mean survival time of 12-14 months, as a model system. While mRNA and protein profiling have helped identify underlying GBM biology, survival outcomes and therapeutic strategies have not changed greatly in the past few decades. As a result, researchers have turned to miRNA as a potential solution. In doing so, multiplexed miRNA biopanel panels have emerged that are predictive of GBM grade, recurrence, and survival. This abstract displays a validated microring resonator technology that is easily translatable to the clinic and facilitates the detection of GBM-specific meso-plex miRNA biomarker panels.

Abstract Text

Bacterial protein toxins secreted by pathogenic bacteria such as Cholera toxin can be lethal, pose threats to public health, and may potentially be used as biological weapons. Thus, sensors are needed for specific and sensitive detection of bacterial toxins. Existing methods mostly rely on analyte labeling (e.g. fluorescent labels) or suffer from non-specific interferences (e.g. SPR methods). In this work, we present a novel pull-down assay for the detection of Cholera toxin binding unit (CTB), based on the specific binding interaction between CTB and its cell membrane receptor, ganglioside GM1, combined with label-free mass spectrometry identification. GM1 was incorporated into 200 nm phospholipid vesicles composed of an NH₂-functionalized lipid and a polymerizable lipid (Bis-Den PC or Bis-sorb PC). Polymerization of the lipid formed crosslinking structures within the lamellar region of the vesicles, greatly enhancing vesicle stability. The polymerized, GM1- and NH₂-functionalized vesicles were covalently immobilized on sulfonate-modified, micrometer-sized silica particles, making novel vesicle-shell, silica-core particles. The core-shell particles were incubated with CTB, allowing for specific binding between CTB and GM1. The particles were pulled down by centrifugation for the pre-concentration of CTB. Finally, label-free CTB can be detected by either directly exposing the particles to MALDI-MS or releasing with protein denaturing solution, followed by ESI-MS analysis. Polymerization provides the vesicles with enough stability to survive centrifugation and MS detection conditions. The pull-down pre-concentration step and the large surface area of the vesicles contribute to the sensitivity of the assay.

Abstract Text

Environmental contamination by heavy metal ions is a worldwide problem however current detection of hazardous metal ions requires expensive, laboratory-based instruments that may not be available to all analytical groups. New, low-cost techniques for the remote sensing of these ions is therefore desirable. Surface Enhanced Raman Scattering (SERS) is a highly sensitive, inexpensive technique that can be used for the multiplexed detection of metal ions. One of the main advantages of this technique is the potential for remote sensing due to the widespread availability of portable Raman spectrometers.

However, since metal ions lack a vibrational signature, reporter molecules are required in order to provide a spectral profile. In this work, 2,2-bipyridyl (bipy) is used as a universal ligand to coordinate to the metal ions Zn(II), Ni(II), Fe(II), Cd(II), Cu(II) and Cr(III). Each target ion was added to a solution of bipy and left overnight to allow complexation to occur. The complexes were then added to silver nanoparticles and the SERS response was measured. It was found that, when bipy was complexed to metal ions, changes in the resultant SERS spectrum occurred. Characteristic peak shifts and intensity changes were observed which allowed for unambiguous discrimination between each metal ion. Thus it was demonstrated that reporter ligands that strongly interact with multiple metal ions can be used to discriminate between these species, based on the specific spectral "fingerprints" that are produced.

This has the potential to be used in environmental monitoring, where the rapid, on-site detection of metal ions is necessary.

Abstract Text

Determining the composition of mixtures of solids is a challenge in commerce. Typically, a product resulting from the refinement of plant material requires purity determination. Conversely, a natural commodity may be enriched by blending another ingredient to meet a nutritional or other performance chemically defined specifications. In quantitative near infrared chemical imaging, the qualitative identity of individual pixels in the field of view reveals what is present at each x, y location. How much is present depends upon the Absorbance of the chemical species of interest at its indicator wavelength. Binary pixel counting is refined by PLS data treatment to yield useful, reliable numerical quantitation.

Abstract Text

An external cavity quantum cascade laser (EC-QCL) was applied in the photoacoustic detection of solid samples. Tunable lasers offer some advantages in spectral density and resolution when compared to the traditional Fourier transform infrared (FTIR) spectrometers. Typically, EC-QCLs have been used in trace gas analysis, but the tuning ranges have been dramatically increased enabling also the analysis of the solid samples that generally have much broader infrared peaks.

The high spectral power density of the EC-QCL was combined with an extremely sensitive optical cantilever microphone of the photoacoustic detector to achieve an ultimate sensitivity [1]. The EC-QCL used has a broad tuning range of 676 cm^{-1} (970–1646 cm^{-1}) in the mid-infrared region, which enables accurate broadband spectroscopy of large molecules. The latest designs offer a tuning range for over 1000 cm^{-1} in the pulsed mode in the mid-IR region. Also, some laser manufacturers nowadays offer fast sweeping of the laser, where the full tuning range can be scanned in seconds.

The carbon black, polyethylene, and hair fiber samples were measured with the EC-QCL photoacoustic detection using electrical amplitude modulation to demonstrate the possibilities of the setup. The same measurements were repeated with an FTIR spectrometer combined with a photoacoustic detector for a comparison. The EC-QCL photoacoustic setup yielded roughly an order of magnitude better signal-to-noise ratios than the FTIR setup with the same measurement time. The compact EC-QCL source and photoacoustic cell can be combined as a powerful and robust analyzer for solid samples in the future.

Abstract Text

Evolved Gas Analysis (EGA) is the perfect tool for characterizing the thermal behavior of organic and inorganic solids or liquids in more detail and elucidating the chemistry behind the processes under investigation. Thermogravimetric Analysis (TGA) is often coupled to FTIR as a means of generating more complete thermal characterization of the material under investigation. The TGA gives information on the temperatures at which various gases are evolved, the quantities of those components in terms of mass change, and also the rate at which the gases are evolved. Combining an FTIR into the output gas stream enables identification of the compounds generated in the gas phase. When properly configured, the data between the two instruments can be directly correlated in terms of time and temperature giving a more complete picture of the material's thermal breakdown processes. There exist two ways to connect an FTIR to the evolved gas stream of the TGA; the oldest and most established is connection between the two instruments by a heated capillary tube and the newest method involves integrating the FTIR directly on top of the TGA furnace, eliminating need for a heated transfer line. This lecture will compare and contrast the differences between these two TGA-FTIR coupling techniques, identifying the advantages and disadvantages to both.

Abstract Text

Infrared spectroscopy is widely adopted as a technique for the identification of materials. Infrared microscopy allows spectra to be measured on small samples down to a limit of a few microns, with this limit dictated by the diffraction limit of the infrared radiation. Spectra can be measured on an IR microscope using transmission, reflectance or ATR techniques.

An infrared microscopy experiment can consist of multiple measurements on a sample at multiple points on the sample and the regions of interest (ROI) will almost certainly be of different sizes and shapes. Optimisation of the infrared measurement at each point requires an aperture to be set to fit within the ROI to avoid stray light or spectral interferences from adjacent materials or sample matrix. The experiment can also generate significant amounts of data that needs to be interpreted to get the required information from the sample. Manual evaluation of the data can add significant time to the sample analysis.

An infrared microscope system is described here that offers significant speed advantages over conventional infrared microscopes by utilising both hardware and software automation to streamline the infrared microscopy experiment workflow. New and innovative software algorithms for ROI detection can be applied to a wide range of different types of infrared microscopy experiments. Automation of data collection and data analysis provides answers in a fraction of the time required for manual data interpretation. Examples of applications of infrared microscopy for a range of industries will be presented.

Abstract Text

Interfacial properties are largely determined by molecular structures at buried interfaces. Structure-property relationships at buried polymer interfaces, however, are not well understood due to a lack of non-destructive interface sensitive analytical techniques. This research focuses on the development of the nonlinear optical spectroscopic technique infrared-visible sum frequency generation (SFG) vibrational spectroscopy into a metrology tool for non-destructive characterization of molecular structures at buried metal/polymer and semiconductor/polymer interfaces in situ. Sample geometries for selectively detecting SFG signal generated at buried metal/polymer interfaces were studied which enabled characterization of molecular structure at the buried interfaces. Data analysis methodology for SFG signal generated from silicon-supported polymer thin films was also studied and the molecular structure at the surface and buried interface of the films was deduced. Functional groups such as methyl and phenyl groups were found to be ordered at both metal/polymer and semiconductor/polymer interfaces and interfacial molecular ordering was correlated with interfacial properties such as interfacial adhesion strength, moisture uptake, and dielectric breakdown.

Abstract Text

This presentation will focus on what can be accomplished when you take a portable FTIR to remote locations for oil sampling for condition monitoring. This discussion will include the quality of the FTIR data, what parameters can be tested at the site to pick up early failures and how this data can be quickly uploaded to a lab for quick evaluation and interpretation. The data can be interpreted on the site by technical personnel, utilize a known response to conditions or send the data to a qualified lab for proper interpreted. This opens-up a new realm of condition monitoring.

Abstract Text

Although protein dynamics are increasingly evoked as contributors to proteins function, rigorous experimental assessment of their role has been challenged by both the spatial heterogeneity of proteins and the rapid interconversion of potentially important conformational states. One approach to overcome these challenges is to combine the inherent high temporal resolution of infrared (IR) spectroscopy with the spatial resolution afforded by site-selective incorporation of vibrational reporter groups via protein engineering to generate a spatially and temporally complete picture of the conformational dynamics of proteins. This approach was applied to study the molecular recognition of the Src homology 3 (SH3) domain of the yeast protein Sho1 and a peptide containing the polyproline sequence of its physiological binding partner Pbs2. Carbon-deuterium bonds were used as strictly non-perturbative probes of the conformational changes involved in SH3-Pbs2 peptide molecular recognition. The spectral data reveal that formation of the bound complex leads to the population of multiple conformational states and suggest an induced-fit mechanism of molecular recognition. The site-selective introduction of the vibrational probes permitted a spatially resolved view of rapidly interconverting states involved in the mechanism of molecular recognition between the SH3 domain and polyproline ligand.

Abstract Text

The long-term stability of amorphous pharmaceutical formulations can be negatively impacted by undesired crystallization of the active pharmaceutical ingredient. In previous efforts, we have demonstrated detection limits in the ppb range for crystalline APIs within amorphous formulations by second harmonic generation (SHG) imaging, which is exquisitely sensitive and selective for crystallinity of chiral compounds. However, SHG alone provides little direct chemical information. In this study, SHG microscopy was integrated into a synchrotron X-ray diffraction experimental hutch, allowing rapid identification of regions of interest by SHG for subsequent targeted XRD analysis. By pairing the dimensions of the X-ray beam with the dimensions of the regions of interest, the background X-ray scattering was greatly reduced, allowing high S/N detection by XRD. Using this approach, PXRD has been performed in models for pharmaceutical formulations with average crystalline content in the low PPM to PPB range. Results will also be presented for analysis of a commercial amorphous final dosage form, in which a substantial fraction of the API was found to be in a crystalline state with large batch-to-batch variability.

Abstract Text

Plutonium determination is an essential aspect of safeguards operations of spent nuclear fuel reprocessing facilities. High resolution X-ray (hiRX) is a new technique based on monochromatic wavelength dispersive X-ray fluorescence (MWDXRF) which was developed for quantification of plutonium in spent fuel. hiRX is a highly sensitive and selective technique due to the use of doubly curved crystal optics (DCCs), which provide monochromatic excitation and detection, resulting in high signal-to-noise ratio for the analyte. A benchtop prototype hiRX instrument has been tested with actual spent fuel samples from a reprocessing environment. A custom-designed ultralow volume sample cell, which contains 5 microliters of liquid sample when filled with a pipette, was used in the field testing. Calibration was performed using aqueous standards containing plutonium and uranium, since uranium is the primary matrix element of spent fuel and may be present in amounts greater than 100:1 (U:Pu, g/L). Analytical results including accuracy, precision, and limit of detection (LOD) will be presented and compared with laboratory validation results. Linear response (>0.99) over nearly 4 orders of magnitude and LOD of 0.7 mg/L were demonstrated in the laboratory using strontium as a model element for plutonium. hiRX offers an alternative, nondestructive assay which can provide rapid, direct plutonium quantification in a simple to operate platform. These specific results demonstrate the potential of hiRX for more general analytical applications for sensitive and selective elemental analyses.

Abstract Text

X-Ray Fluorescence (XRF) spectroscopy is useful tool for identification substances and confirming their identity with little or no sample preparation. New capabilities of the energy dispersive XRF analytical microscope (micro-XRF) enable the recording not only spectra of small sand particles (as small as 50-100 microns) but also hyper-spectral image and collect average spectrum over certain area. Multivariate analysis (MVA) can produce chemical distributions of elements and/or material classification based on Principal Component Analysis (PCA), Partial Least Square Discriminative Analysis (PLS-DA), in particular, with association between elements that can aid in identification of bonded phases. The analysis of micro-XRF data of sands taken in different area can be used to identify geographic locations.

The XGT-7200V XRF analytical microscope was used in this study. X-ray fluorescence spectrum of the materials strongly depends on X-ray optical system, sensitivity of the detector and accelerating voltage. In addition of that, background from the substrate will contribute to the spectrum of the small pieces because excitation X-ray penetrates through the material and interacts with substrate.

We collected and analyzed spectra of sand from different location (USA, Europe, Middle East) in the range of 1.00-40.96 keV (<400 spectra). Because the only few spectra have an additional features in the energy range above 15 keV, spectra were truncated and analysis was done in spectral range of 1.00—15 keV. Standard FPM algorithm was used to calculate concentration of oxides in all samples. This set of concentration was used to build a data set for PCA and PLS-DA. Correlation between classification based on spectral analysis and concentration analysis will be shown. The data shows that MVA allows differentiate samples which have very similar spectra features (concentration profiles) and this approach may be useful for forensic investigation.

Abstract Text

Environmental regulations for pollution control and goals for green fuels with higher hydrogen, lower aromatics and low hetero-atoms were the key factors for development of new technologies for petroleum refineries. In India, Auto Fuel Vision & Policy 2025 gives a road map for cleaner fuels such as Euro-V equivalent petrol and diesel. Sulphur content in MS & HSD is being reduced continuously and there are various technologies available to refiners to reduce sulphur in transport fuels.

Removal of sulphur by adsorption process is an efficient and feasible technology that reduces cost for sulphur reduction in gasoline and diesel. Sulphur is removed through adsorption which takes place at lower temperature and pressure compared to hydrotreating technologies thereby significantly reduces operating cost. Further, solid adsorbent can be regenerated easily with retaining activity. Indian Oil has developed an adsorbent based on Zn/Ni/Al system for removal of sulphur compounds from diesel streams. For optimization of Ni/Zn/Al content in adsorbents and to remove sulphur to highest possible level from diesel, various analytical techniques XRD, XRF, XPS, TEM & TGA were used. Characterization of adsorbents for sulphur removal using these techniques at different stages provided valuable guidelines for optimization of adsorbent for sulphur removal.

Fresh, regenerated and spent adsorbents were characterized by analytical techniques and mechanism was proposed. Fresh adsorbent contains oxides of Ni/Zn/Al while spent adsorbent shows significant amounts metal sulphides as revealed by XPS & XRD. Regenerated adsorbent shows reduction in sulphur indicating removal of sulphur upon regeneration as confirmed by XRD which shows absence of metal sulphides. TEM with EDX provided critical information about various phases. Based on analytical inputs, the composition of adsorbent was optimized for effective removal of sulphur from diesel.

Abstract Text

Despite the efficacy of tamoxifen (TAM) in treating breast cancer patients, many women still relapse after long-term therapy. Therefore, it seems imperative to search for alternative remedies. This study investigated the antitumor effect of TAM, caffeic acid phenethyl ester (CAPE) and their combination in MCF-7 cells and tumor bearing mice. Upon combining TAM with CAPE, they exerted a strong cytotoxic effect against MCF-7 cells with IC50 of 4 μ M compared to 20 μ M for TAM and 10 μ M for CAPE. Induction of apoptotic machinery and DNA fragmentation were accompanied by a down-regulation of Bcl-2 and Beclin 1 expression levels. However, microtubule-associated protein light chain 3- II levels were not altered. A time dependent decrease in vascular endothelial growth factor levels was also evidenced. The in vitro effect of this combination was recapitulated in the in vivo model by enhancing the percent increase in life span of mice, and inducing marked regression in size and weight of solid tumor. Conclusively, the anticancer effect of TAM and CAPE is mediated via attenuation of autophagy and elevation of apoptotic and angiostatic potentials. The ability of CAPE to reduce the effective dose of TAM provides the rationale for investigating this combination in preclinical models.

Abstract Text

Both digitoxin and digoxin are widely prescribed for treatment of congestive heart failure. They are hardly distinguished by an immunoassay, in spite of the fact that digoxin is a metabolite of digitoxin. The present work reports a rapid LC-MS/MS method for accurate determination of digitoxin and digoxin in biological fluids. In the method, the two analytes as well as their interferences are rapidly (<5 min) resolved on a monodisperse sub-2 μm particle column and then detected with their specific MRM transitions. Significant ion suppression along with poor accuracy was initially observed due to the presence of high abundance of phospholipids in plasma and serum. These issues have been overcome by using a one-step procedure for simultaneous protein precipitation and phospholipid removal. The final method utilizes a high throughput sample preparation technique to minimize matrix effects using 96-well plate packed with proprietary zirconia sorbents. The result is a rapid and accurate LC-MS/MS determination of digoxin and digitoxin that provides an improved alternative to existing immunoassay methodologies.

Abstract Text

Single Particle-ICP-MS is a new operating mode in ICP-MS that is dedicated to the analysis of engineered nanoparticles (ENPs) commonly used in Nanomedicine and drug delivery systems. Single Particle (SP-ICP-MS) allows the differentiation between ionic and particulate signals, quantitation of both ionic and particulate fractions, measurement of particle composition, concentration (part/mL), particle size, and size distribution, and assists in monitoring agglomeration.

The present work explores the use of SP-ICP-MS as a metrology tool for the analysis of engineered nanoparticles in biological matrices (blood, urine). Preliminary results show that Au ENPs (30 and 60 nm) are stable in diluted blood and urine. No change in the size of Au ENPs and/or concentration was noticed during the 24h study period.

SP-ICP-MS is rapidly becoming a key analytical instrument in assessing the fate, behavior and distribution of (ENPs) in several types of matrices^{1,2} including biological fluids such blood and urine.

Abstract Title **Method for Assessing Residual Trace Metal Contamination in Acid-Washed Vials**

Primary Author Michelle L. Wermers
Mayo Clinic

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Steven J. Eckdahl

Abstract Text

Metal-Free Vial Analysis is an in-house developed method used to measure the residual contamination levels of trace metals in vials that have been acid washed by a third party contractor. Ten randomly selected vials are sent to our lab from each lot of 1,000 washed vials. Each of the vials is analyzed for aluminum (Al), chromium (Cr), manganese (Mn), copper (Cu), zinc (Zn), and nickel (Ni) contamination. Two milliliters of 1% nitric acid is added to each 6 mL vial and allowed to leach the insides of the vial for a minimum of one hour. Analysis of the leachate determines the cleanliness of each vial. Leachate from each vial must contain less than 0.1 ng/mL of Cr and Mn, <1 ng/mL of Ni, <5 ng/mL of Al and Cu, and < 50 ng/mL of Zn for the lot to be deemed acceptable for use in our clinical laboratory.

The validation of this method was performed using blinded analysis of vials that had been doped with NIST 1640 and 1643e water to attain levels near the rejection limit for each analyte. The NIST material was dried in previously washed vials. 1% nitric acid was then added to leach the insides of the vial, per procedure. Recoveries of the doped analytes were within 20% of the target values. Accuracy and recovery experiments demonstrated that the calibration is linear 20 to 100x the highest calibrator. The limit of detection was shown to be well below the rejection threshold for each of the elements. The validation demonstrated that this method is capable of detecting levels of contamination in a vial that would adversely affect patient results. This process ensures that serum and urine samples transported in the vials we provide to our clients are free of contamination from the vials.

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s)

Abstract Text

An electrochemical sensor based on arginine (Arg) functionalized graphene (Arg-G) nanocomposite was fabricated for sensitive detection of acetaminophen. The nanocomposite was characterized by transmission electron microscopy (TEM), Raman spectra etc. The electrochemical behaviors of acetaminophen on Arg-G composite film modified glassy carbon electrode (GCE) were investigated by cyclic voltammetry (CV) and differential pulse voltammetry (DPV). The experimental results indicated that the incorporation of arginine and graphene greatly enhanced the electrochemical response of acetaminophen. This fabricated sensor displayed excellent analytical performance for acetaminophen detection over a range from 0.1 to 100 $\mu\text{mol L}^{-1}$ with a detection limit of 0.05 $\mu\text{mol L}^{-1}$ (S/N=3). Moreover, the proposed electrochemical sensor also exhibited good reproducibility and stability, and has been used to detect acetaminophen in tablets with satisfactory results.

Abstract Text

Adiponectin is a primary endocrine hormone secreted from adipocytes, and its level in blood is an important indicator of diabetes, obesity, and other metabolic diseases. Recent observations have shown acute adiponectin secretion in response to nutrient and hormone signals, implying the existence of a readily-releasable pool of vesicles. Unfortunately, tools to investigate dynamics of adiponectin secretion are lacking. We have previously developed microfluidic perfusion systems for primary adipocyte culture and sampling, yet adiponectin secretion could only be observed over the 1-hour time scale due to insufficient assay platforms. For this reason, we have developed a proximity ligation assay (PLA) to quantify adiponectin in smaller volume samples. This way, microfluidic secretion sampling can offer improved temporal resolution, and the adiponectin PLA can be used as the readout. Consistent with adiponectin's homomultimer structures, we observed the greatest assay response when employing the same antibody with two different oligonucleotide signaling arms, with a current limit of detection of 30 fmol and a dynamic range from 30 – 6 600 fmol (see figure). The assay also showed higher sensitivity toward multimers of higher molecular weight (mixture of 12-36 monomers) compared to trimers (figure inset). At this stage, assay sensitivity needs improvement to be useful for serum samples or small volume secretory samples. Future work will focus on the length and connectivity of the oligonucleotide arm sequences to enhance performance.

Abstract Text

NIST's Chemical Sciences Division (CSD) in the Material Measurement Laboratory and the Centers for Disease Control and Prevention (CDC) Division of Laboratory Sciences began a collaborative effort in 2004 to develop Standard Reference Materials (SRMs) for arsenic species in frozen human urine. Arsenic is a toxic element and a known carcinogen. The element is present in food and water in chemical forms that have varying degrees of toxicity. Toxicological evaluation of arsenic exposure must be based on the mass fractions of arsenic species rather than total arsenic. SRM 3669 Arsenic Species in Frozen human Urine (Elevated Levels) is jointly developed by NIST and CDC. The SRM is intended for use in evaluating the measurement accuracy of arsenite (AsIII), arsenate (AsV), monomethylarsonic acid (MMA), dimethylarsinic acid (DMA), and arsenobetaine (AB) in patients experienced acute arsenic exposure. SRM 3669 is related to SRM 2669 Arsenic Species in Frozen Human Urine that was introduced in 2009 for method validation in biomonitoring measurements of the general population. Whereas the target levels of arsenic species in SRM 2669 are approximately 50 to 95 percentile of the distribution of the population, the target levels of arsenic species in SRM 3669 are > 95 percentile. Value assignment of arsenic species in SRM 3669 was based on liquid chromatography inductively coupled plasma mass spectrometry (LC-ICP-MS) and ion chromatography ICP-MS measurements made at NIST, and LC-ICP-MS measurements made at CDC. Value assignment of total arsenic was based on ICP-MS measurements and radiochemical neutron activation analysis (RNAA) made at NIST.

Abstract Text

Diversity of engineered nanoparticles (NPs) and their contribution to the development of technology and industry are remarkable. While NPs have enabled important technological advances, they might also have adverse impacts on human and environment. Therefore, novel detection techniques are needed in order to provide better understanding on how NPs interact with living organism. This presentation will describe the use of electrochemical microsensors for assessing localized in vivo nanotoxicity, oxidative stress, inflammation and organ dysfunction induced by NPs in intact zebrafish embryos. Electrochemical microsensors display real-time in vivo measurement capability of various biomarkers with high sensitivity and selectivity while providing high spatial and temporal resolution. Fabrication, characterization and in vivo application of an implantable electrochemical biosensor for the detection of physiological concentrations of and nitric oxide (NO) in zebrafish embryos at organ level will be presented. The use of these sensors as quantitative tools for mechanistic investigation of nanotoxicity will be illustrated. Results of these assays and the potential of this method to determine biomarkers of organ abnormality and inflammation during NP exposure will be discussed.

Abstract Text

An authentic science learning model through collaborative learning suitable for large urban public colleges with limited resources was proposed and implemented in the course of Instrumental Analysis (science major), Environmental Science (non-science major), and Undergraduate Research at John Jay College, the City University of New York. The goal of this project is to enhance student learning of science concepts and skills by introducing them to real world problems and solutions. Using sustainability-chemistry as an example, this project allowed students at different academic levels to work collaboratively on field-based environmental projects to investigate pollutants in Hudson River and other EPA Superfund sites in New York City, establish close communication among participants and mentors, and develop positive attitudes towards science learning, and cultivate social awareness.

Abstract Text

Hands on learning in STEM courses is essential. This style of learning is seen quite frequently in the field of chemistry where nearly every undergraduate lecture has a corresponding laboratory course, and a variety of instruments are routinely used to make measurements. With growing undergraduate enrollments larger numbers of students are filling instructional chemistry labs, and the demand for a sufficient number of instruments can be a financial obstacle for many chemistry laboratory coordinators. To alleviate the cost of purchasing large numbers of commercial systems a push has begun to develop low-cost alternatives. In this presentation, a low-cost Raman spectrometer which utilizes a Canon Rebel T2i digital SLR camera as the detector is presented. Similar Raman teaching instruments employ miniature USB type spectrometers as detectors which typically cost \$2,000 - \$3,000. In comparison, the digital camera spectrometer presented here can be built at a cost of \$750 - \$1,000. This type of instrument is ideal for teaching. The open configuration allows for visual inspection of all optical components (reducing the black box effect) and requires manual adjustment of instrument parameters. The system has collected quality Raman spectra of various solids in 100 seconds or less. In addition, spectroscopy topics such as slit width, spectral resolution, signal to noise, signal averaging, and signal smoothing have been demonstrated using the instrument. Furthermore, the instrument can be quickly converted to a visible spectrometer with the addition of a light source and changing to a less dispersive grating for Beer's law type experiments.

Abstract Text

The development of laboratory experiences based on pharmaceutical processes has become increasingly important in the undergraduate curriculum. Adaption of current research techniques for the undergraduate laboratory is vital in order to introduce students to concepts of interest to the scientific community. This allows undergraduate students to become acquainted with a variety of topics with hopes they will find their niche in the chemistry world more readily. A study of the diffusion of drugs through a hydrogel membrane can be used to provide students with experiences in chemical kinetics and polymer application in pharmaceutical sciences. Hydrogels are hydrophilic material created by polymerization of monomers to form a cross-linked material and are able to absorb large amounts of water, making them the perfect drug delivery system. Since water has the ability to enter this system, they are capable of absorbing water soluble molecules. PNIPA hydrogels were formed using N-isopropylacrylamide as a monomer, N,N'-methylenebisdiacrylamide as a cross-linker and sodium disulphite as a polymer initiator. Hydrogels were synthesized, dehydrated, and then reconstituted using a solution of triamterene and aminophylline dissolved in water. PNIPA drug loaded hydrogels were placed in a warm water bath in order to facilitate the release of the solution. Water samples were analyzed at specific time points using Ultra-Violet Visible (UV-Vis) spectroscopy to monitor the release of triamterene and aminophylline.

Abstract Text

A well known and interesting experiment named as Iodine Clock Reaction (ICR) has already been used at graduate and under graduate level since last several years, to demonstrate the function of temperature on the rate of reaction. We present here a double clock kinetics experiment based on the repeated oxidation of iodide by BrO_3^- followed by H_2O_2 . The primary aim of this work is to enhance the scope of ICR experiment by some modification and extension in the existing experimental conditions. The proposed Iodine Double clock Reaction (IDR) has been successfully employed on the determination of the activation energies of two successive reactions in a single experimental setup. The obtained values of activation energies are $24.07 \text{ kJ mol}^{-1}$ and $33.63 \text{ kJ mol}^{-1}$ and Arrhenius factors are 2.65×10^5 and 117.57×10^5 for BrO_3^- and H_2O_2 respectively. The obtained data will be helpful to put forward the comparative reaction mechanisms of both the reactions.

Abstract Text

Research focusing on assessment of abandoned mine drainage (AMD) from the old Marchand coal mine, and remediated at the Lowber AMD treatment facility in southwest Pennsylvania, will be presented and discussed. This study is sponsored by the Rho Theta Chapter of the Gamma Sigma Epsilon National Chemistry Honor Society and in collaboration with the Sewickley Creek Watershed Association (SCWA). AMD is perhaps the most prevalent form of water pollution in southwest Pennsylvania, due to the abundance of abandoned coal mines that accumulate ground and surface water over time. This water eventually reaches the surface and produces insoluble hydrated iron(III) oxides that may contaminate streams and render well water unfit for human consumption. The goals of this research are: (1) to assess selected analytes in AMD from the Lowber facility in the field and laboratory, (2) to assist the SCWA in more frequent evaluation of AMD, and (3) to develop remediation strategies for use at Lowber and other potential sites in the Sewickley Creek Watershed.

□

Determination of such analytes as alkalinity, acidity, pH, sulfate, chloride, total suspended and total dissolved solids, and metals such as iron, aluminum, manganese, and calcium will be performed by appropriate methods. Sample collection and analytical methodologies will be presented and discussed, as will results of determinations performed to date and

Abstract Text

The effectiveness of using videos that undergraduate students could view prior to conducting their experiments in an Analytical Chemistry laboratory course was examined. To this end, we developed instructional videos to show students how to conduct the experiment. Developing a video (lasting 5-10 minutes) for each weekly experiment typically required several days to complete. Filming an experiment required a few hours, but then more time was required to condense and annotate the material. Undergraduate students were required to download the video and view it before the laboratory class commenced. As a result, the instruction time on how to perform the experiment was significantly shortened, thereby allowing more laboratory time. Furthermore, the response to these videos was very positive, with students enjoying the visual impact. Here, we describe our experience in this endeavor.

Abstract Text

In 2014 OSHA implemented new standards (29CFR1910.1200) regarding Classification and Labeling (C&L). This new C&L standard brings the United States in line with the United Nations Globally Harmonized System (GHS). This standard system of labeling applies to hazardous goods shipped and sold in the United States and globally. The new requirements apply to Safety Data Sheets (SDS) and product labels for all chemicals classified as "hazardous" under the OSHA guidelines. They are required to be implemented by all manufacturers, importers and distributors of hazardous goods. By 2015 all suppliers of hazardous goods must be in compliance with the regulation.

The poster will examine the main requirements for GHS compliant hazardous chemicals. The largest of these changes will affect the SDS and product labels. The GHS implementation applies to all levels of the company, and across various departments such as QC/QA, Research and Development, Method Development and Health Safety and Environmental. The GHS labeling requirements apply to all chemicals used in the lab from vials and bottles to cans and drums. The information presented will educate the user on the changes to the law so they will be prepared for the changes.

Abstract Title **Calibration Strategies for Absorption and Emission Instruments**

Primary Author Lauren E. Grabowski
University of South Carolina

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Scott R. Goode

Abstract Text

In order to make accurate analytical measurements, the calibration design must be optimized. Calibration designs are used to aid in determination of an unknown. The optimal calibration design had not been previously determined in which error is minimized. Both absorption and emission have noise sources that affect the optimum region for measurements and the optimal design will be dependent upon the type of limiting noise.

The major source of error is detector noise, which obscures and degrades the ability to interpret the response. Random instrumental noise in spectrophotometric measurements can be divided into three classes: (1) sources that are completely independent of response; (2) sources with variance that is directly proportional to the response; and (3) sources of noise with variances that are related to the square of the response. The magnitudes of these noise sources affect the signal-to-noise ratio of measurements.

This study examined the design of calibration strategies which optimize precision of UV-visible absorption spectroscopy and inductively coupled plasma-optical emission spectrometry measurements. Different calibration strategies, composed of different concentrations and number of replicates, have been evaluated to try to determine the calibration design that will minimize imprecision as measured by the average relative concentration error integrated over the entire calibration graph.

Our research indicates that the range of calibration imprecision varies over a range of 10:1 for ultraviolet-visible absorption and 197:1 for inductively coupled plasma-optical emission spectrometry depending on the location of the standards. This information allows us to conclude that some calibration designs are superior.

Abstract Title **Introducing Analytical Method Transfer (AMT) in the Undergraduate Laboratory**

Primary Author Kimberly Chichester
St. John Fisher College

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Fang Zhao, Irene Kimaru, Marina Koether

Abstract Text

The concepts of Analytical Method Transfer (AMT) have been integrated in the undergraduate analytical chemistry curriculum at St. John Fisher College (SJFC) and Kennesaw State University (KSU). Students and faculty at SJFC and KSU are developing and validating analytical laboratory methods that are focused on teaching students AMT. The laboratory methods are dissolution testing and HPLC analysis of glucosamine tablets, dissolution and flame atomic absorption spectroscopy of potassium gluconate, and dissolution testing and UV analysis of ibuprofen tablets. These analytical methods are being transferred to the other school to confirm the validation - hence perform an AMT as found in the real world. This transfer will return back to the original school to see if the next group can complete the same validation and accomplish the method transfer. Once they have been validated, POGIL-based lecture and lab exercises using our data to be tested at other schools will be written. The POGIL exercises will walk the students at other schools through the steps of AMT, enabling them to determine whether the transfer was successful or not. We aim to improve student engagement and learning in analytical courses at both schools and to disseminate POGIL-based lecture and lab activities for use at institutions that lack dissolution testers to compare learning gains between classes that have the instrumentation and those that do not. We gratefully acknowledge the financial support of the NSF (DUE: 1141021 and 1141042) for this project.

Abstract Text

Safe handling of hazardous substances cannot be ensured without safety information. The most common means for providing information are the Material Safety Data Sheets (MSDS), and labels. The MSDS are important reference for health and safety information for many chemicals. Container labels provide the basic information that a person needs to know to handle a particular product safely, they show how a chemical dangerous it is, it explains what to wear when using the chemicals, also shows directions for immediate first aid. Also valuable is the National Fire Protection Association labeling system, which shows the type and the degree of a chemical hazard.

There are a number of smartphone Apps which are good resources to find information concerning the hazards of many chemicals, the MSDS and labels. The use of these Apps in the chemistry lab serves as a quick reference and educational tool for students. This paper is based on an ongoing research program examining the implementation of smartphones Apps to help students develop personal safety awareness. Our objective is to explore how students can take advantage of these Apps to react logically to a situation and keep people safe.

There are more than 300 Apps for chemistry. They cover all concepts of chemistry from the basic of naming compounds and writing formulas to more advanced topics like the interpretation of spectroscopy data. Students learn that every chemical is dangerous; chemicals must be handled safely in order to avoid skin, eye or inhalation exposure. Most students made positive comments about what they thought of the use of Apps for learning how to handle hazardous chemicals.

Abstract Text

The impact of a half-semester laboratory project in Analytical Chemistry on student attitudes towards laboratory work was assessed. The laboratory project tasked students with working in small groups to recreate a literature paper. The project allowed students to make experimental design decisions beyond a typical guided laboratory experiment. Before performing the experiment, students submitted a detailed procedure including all calculations for preparation of the standards and samples, choice of glassware, and a data analysis plan. After experiment implementation, students submitted a written laboratory report. The attitude survey was administered at the beginning and end of the project. The 30 questions on the assessment were categorized. Improvement was shown in Confidence, Perseverance, and Value of Collaboration. For example, there was a 24% improvement in both understanding of the lab project and belief in reliability of their results. Minimal change was noted in Value of Work, Value of Learning, Communication and Reading Skills, and Future Plans.

Abstract Text

Persistent organic pollutants (POPs) are a group of chemicals that include brominated flame retardants (BFRs) and polychlorinated biphenyls (PCBs). These chemicals can be distributed throughout the environment through soil, water, and air contamination and once in the environment do not readily break down.

Due to the lipophilic nature of these components they accumulate in the fatty tissue of animals and bioaccumulate up the food chain. According to the World Health Organization human breast milk is an ideal matrix to monitor the levels of POPs in not only the mother and infant, but also as a key indicator of the levels of these chemicals in the local environment.

Current methodology for the analysis of PCBs and BDEs can be expensive, solvent intense and time consuming. The QuEChERS extraction approach coupled to a silica cartridge SPE cleanup may be an attractive sample preparation alternative for biomonitoring efforts for halogenated POPs in milk. Comprehensive two-dimensional gas chromatography (GCxGC) with an electron capture detector (ECD) may also offer a more cost-effective alternative. Method development was done using whole cow milk and later compared to a NIST Standard Reference Material of Human Breast Milk.

Abstract Text

Ammonia (NH_3) is one of the most well-known odorous gas species in the atmosphere. Ammonia is frequently monitored for managing odorous pollution sources and air quality management. It is difficult to accurately measure ammonia concentration in the air due to its reactive, adsorptive, and unstable nature. For the accurate measurement, primary standard gas mixtures (PSMs) should be available to calibrate ammonia measuring instrument. PSMs are prepared in cylinders by gravimetric method in which high purity gas source or liquid sources are weighed. One of the major problems for preparing PSMs in cylinders, especially for reactive gases, is the stability of the target gases in cylinders. However, it is rare to find quantitative information on the extent of stability of $\mu\text{mol/mol}$ NH_3 in the highly pressurized gas cylinder. In this study, we prepared ammonia PSMs at $35 \mu\text{mol/mol}$ in cylinders to evaluate the long-term stability of ammonia PSMs at $35 \mu\text{mol/mol}$ level and compare the stability depending on different cylinder types. Ammonia PSMs at $35 \mu\text{mol/mol}$ were prepared by three steps dilution from the high purity ammonia sources. Results from this study show that ammonia PSMs are consistent within their preparation uncertainties for eight years, although a decreasing trend is observed in PSMs prepared 2006.

Abstract Text

Volatile organic compounds (VOCs) in the atmosphere have been determined to be a human risk factor in urban, suburban, and industrial environments. This study aims to characterize the distribution and concentrations of ambient air toxics in Memphis and identify major sources of VOCs. During four seasons in 2014, about 530 ambient air samples have been collected in various locations in Memphis and surrounding areas for the analysis of VOCs with the TO-15 method. GC-MS was used with a preconcentrator outfitted with a glass bead trap and a Tenax trap in cryogenic mode to analyze the VOCs in scan and/or SIM mode. The ambient air monitoring data showed that there were about 30 compounds that do not belong to the list of TO-15 target compounds that necessitate the preparation of calibration standard mixtures of these non-TO-15 compounds. These include cyclohexene, 3/4-chlorocyclohexene, cyclohexanone, C6-C10 aldehydes, dimethyldisulfide, dimethyltrisulfide, acetonitrile, and 2-cyclohexen-1-one. The improvement in the analytical sensitivity of the non-TO-15 compounds via SIM mode analysis of their fragment ions at specific m/z ratios will be presented. The comparison of non-TO-15 compounds in their concentration levels and emission sources will be highlighted in this project. Also, the Toxics Release Inventory of emission sources near the sampling sites were examined to correlate the air quality profiles with industry-specific chemical releases.

Abstract Text

A method aimed at improved analysis of 73 target volatile organic compounds (VOCs) at trace levels has been implemented for ambient air analysis in Memphis. Analytical instrumentation based on gas chromatography-mass spectrometry (GC-MS) coupled with a preconcentrator outfitted with a glass bead trap, a Tenax TA trap, and cryofocusing capability was used in accordance with the USEPA's TO-15 protocol to achieve detection limits down to 0.1-1 ppbv for the 73 compounds. Method detection limits (MDLs) based on both separate scan mode and selected ion mode (SIM) as well as simultaneous scan and SIM modes were compared to give an indication of their relative sensitivity. Furthermore, the dependence of analytical sensitivity on the ions of different m/z values will be presented. The influence of the preconcentrator parameters on the chromatographic resolution and quantitative precision for closely eluting compounds was evaluated. Data analysis programs such as Automated Mass Deconvolution and Identification System (AMDIS), and Target View were used to resolve the spectra of overlapping chromatographic peaks in order to probe the identity of co-eluting VOCs in the samples. The comparison of quantitative accuracy of co-eluting compounds based on different selected ions for SIM mode analysis will be highlighted. The distribution of TO-15 target compounds detected at various sampling site in Memphis is explained in the context of industrial releases, mobile source emissions, and biogenic emissions.

Abstract Text

The Environmental Protection Agency is about to propose mandatory monitoring of air concentrations at the fenceline of refinery facilities to ensure proposed standards are being met and that neighboring communities are not being exposed to unintended emissions. This will require the multi-point analysis of compounds that are potentially harmful for our environmental, such as benzene, toluene, ethyl benzene and xylenes.

This poster highlights fast analysis of BTEX compounds in air with detection down to low ppm levels using a micro gas chromatograph. A portable field case, equipped with rechargeable batteries and carrier gas, was used to enable on-the-spot measurements. Direct, on-site analyses secures the integrity of the sample. Moreover, it eliminates sample transportation to the lab and direct action can be taken when limits are exceeded.

The instruments small form factor (shoe-box size) allows it to be transported easily to multiple sample points on a refinery facility. Moreover, its low use of operational gases and power simplifies integration in mobile laboratories.

Abstract Text

US Environmental Protection Agency Methods TO-15 and TO-17 list a number of 'air toxics' that must be monitored in urban or industrial locations in order to minimise further ozone depletion and avoid negative health impacts. Due to their hazardous nature, it is vital to obtain comprehensive and sensitive data for an air sample in order to detect all compounds down to the lowest concentrations. Traditionally, the detection of trace-level compounds in a sample is performed by quadrupole MS in either full scan or selected ion monitoring (SIM) mode. However, qMS is a mass filter, with a high percentage of ions being wasted, thus limiting sensitivity. Moreover, in SIM mode, only target compounds can be monitored, meaning that full characterisation of the sample is not possible in a single run, and retrospective searching of data is limited. The use of time-of-flight mass spectrometry (TOF MS) can overcome this issue by providing highly sensitive detection whilst acquiring full-range mass spectra, to allow both target and unknown identification in a single, rapid analysis. Nevertheless, acceptance of TOF technology has been restricted due to large instrument size and the production of spectra exhibiting mass discrimination. This poster describes an innovative, robust TOF MS system that eliminates these problems. The generation of classical EI spectra allows traditional library searching for confident identification of trace-level compounds. The complementary use of GC–TOF MS with thermal desorption is detailed for the analysis of an urban air sample, by means of a cryogen-free, analytical system designed to offer flexibility of sampling methodology, fully compliant with US EPA Methods TO-15 (canisters) and TO-17 (sorbent tubes).

Abstract Text

Thermal desorption (TD) coupled with gas chromatography is a common technique used for the analysis of volatile, semi-volatile and toxic organic compounds in air and soil vapors. Samples are collected by either passive sampling or active sampling by pumping the air sample through a thermal desorption tube packed with appropriate sorbents for the analytes of interest. The samples are subsequently analyzed by heating the sample tube while flowing a carrier gas through the tube to desorb the analytes then directing the outlet flow to a GC column for chromatographic analysis. The thermal desorption tubes can be reused many times but they need to be "conditioned" (or cleaned) prior to each sample collection. Conditioning is a process in which the tube is heated while flow of a high purity inert gas, such as He or N₂, is applied to drive off any residual organic compounds adsorbed on the tube. The PerkinElmer[registered] TurboMatrix[cirumflex O] Automatic Thermal Desorber (ATD) can be coupled with a GC to automate the process of sample desorption analysis and conditioning for up to 50 thermal desorption tubes sequentially. The conditioning process generally takes 1-2 hours per tube and since the TurboMatrix[cirumflex O] ATD works sequentially it can take 50 – 100 hours to condition 50 TD tubes wasting valuable time on the ATD that could otherwise be used for sample analysis. The new PerkinElmer[registered] TurboMatrix[cirumflex O] TC-220 tube conditioner is an offline accessory that can be used to condition up to 20 TD tubes simultaneously which significantly reduces the time required for conditioning and frees up the ATD for analysis of samples. In this case study at Pace Analytical Services[registered] (Minneapolis, MN) we demonstrate the significant time savings as well as improvements in productivity by taking advantage of the TC-220 tube conditioner for offline conditioning as opposed to conditioning tubes on the ATD.

Abstract Text

The focus on water quality in the last decade has increased demands on regulators to monitor and improve pollutant levels. Typical analytical protocols for semi-volatile organic pollutants in water include time-consuming and laborious extraction and enrichment steps, with liquid–liquid extraction being most common. The drive for improved water purity also demands ever-lower limits of detection.

Addressing these challenges, this poster will illustrate the simple and sensitive analysis of semi-volatile organic pollutants in water, by combining enrichment through high-capacity sorptive extraction with modern time-of-flight mass spectrometry (TOF MS). As well as preconcentrating water-borne pollutants, the new high-capacity sorptive extraction samplers are simple to use – they are introduced to the bulk sample, and then directly thermally desorbed, with no further sample preparation required.

Conventionally, trace-level detection of target compounds is often achieved using quadrupole GC–MS methods with selective ion monitoring (SIM), but this protocol prevents retrospective searching of data for contaminants of emerging concern. The poster will show how TOF MS can overcome this issue by providing highly sensitive detection whilst acquiring full-range reference-quality mass spectra, and so allow identification of targets and unknowns in a single, rapid analysis.

Abstract Text

The fragrance of a personal care product plays a major part in marketing and customer satisfaction. Whilst the combination of fragrance compounds creates the unique, pleasing fragrance of a product, their concentrations can span several orders of magnitude in a single sample, and a number of them have been identified as suspected allergens. In addition, whether profiling the fragrance of a product or screening for suspected allergens, samples of shower gels, soaps and other cosmetics are not simple to handle, and typically require cumbersome preparation steps such as liquid-liquid extraction.

This poster will illustrate the application of Markes' sampling, analysis and data-processing solutions to the simple and sensitive analysis of personal care products. With regard to sampling, Markes' high-capacity sorptive extraction samplers provide a simple way of sampling semi-volatile fragrance compounds from complex, difficult matrices. The samplers are introduced to the bulk sample and then directly thermally desorbed, with no further sample preparation required.

Addressing the highly variable concentrations of fragrance compounds, the poster will then describe how quantitative re-collection and automated re-analysis with Markes' thermal desorption (TD) technology facilitates repeat analysis with high and low splits, so extending the dynamic range with a single sample. Finally, the poster will describe how the high data rate of time-of-flight mass spectrometry (TOF MS) can allow fast analysis with detailed spectral information. This, combined with sophisticated data-processing algorithms, enables confident compound identification in complex matrices with high-speed chromatography.

Abstract Text

Results from a Si-microfabricated GC X GC subsystem with each of two different microsensor-based detector technologies are presented. Point-of-care diagnostics or networked environmental sensing applications are envisioned. The separation module includes first- and second-dimension etched-Si columns and an etched-Si dual-stage thermal modulator (μ TM) on which we reported last year. Two novel detectors have now been explored: a 4-element chemiresistor (CR) array employing sorptive nanoparticle interface layers; and a recently developed microfluidic ring resonator (μ OFRR) employing a PDMS interface layer. The 1st dimension comprised two series-coupled column chips with a crosslinked PDMS phase. The 2nd-dimension column chip used a room-temperature ionic liquid (RTIL) phase. The dual-stage μ TM chip had a crosslinked PDMS phase. On-chip heaters heated each modulator stage at ~ 2400 °C/s, and a thermoelectric cooler beneath cooled each stage to -20 °C between modulations. Previously the RTIL phase was too retentive for polar analytes, giving fwhm values up to 2.7 sec for heptanal with FID. This problem has been rectified. A 4 component separation with the CR array showed excessive broadening of modulated peaks due to slow desorption rates from the nanoparticle films and non-ideal flow dynamics in the cell; fwhm values were up to 8X higher than with FID. The effectiveness of a newly designed sensor array with improved fluidics (currently under test) will be demonstrated. Using the μ OFRR, fwhm values of modulated peaks as low as 125 msec were obtained, on par with FID. An 11 component GC X GC separation was achieved with the μ OFRR (see figure).

Abstract Text

Localized surface plasmon resonance (LSPR) in films of thiolate- and dithianate-monolayer-protected gold nanoparticles (MPN) of different core sizes and monolayers probed at multiple visible wavelengths near the LSPR maximum has been exploited to achieve remarkable vapor selectivity from a single sensing film. Solvent cast or spin-coated multilayer films exhibit response selectivity arising from differences in sorption-induced increases in the interparticle distance and the refractive index (RI) of the ligand matrix, which are functions of ligand-vapor affinity, ligand-vapor RI differences, and metal core size. Films of MPNs with core diameters of 4, 5, 20, and 40 nm and 6 different thiolate or dithianate ligands were cast and their visible transmission spectra recorded before, during and after exposure to high concentrations of 6 individual VOCs. For a subset of VOC-MPN pairs we have generated linear calibration curves from 15-100% saturation. Absorbance shifts at 405, 532, and 630 nm were used to create response patterns for all MPN-VOC pairs. Analysis by Monte Carlo simulation coupled with principal components analysis indicated remarkably high degrees of VOC discrimination: 89-100% discrimination with a single 5-nm or 40-nm MPN film of one type. Arrays of just two 4- or 5-nm MPN films were also remarkably selective (> 95% discrimination) even with just a single wavelength response from each film. However, sensitivity is low and replicate films give highly variable responses. Current tests are assessing the influence of film ordering on reproducibility, exploring responses to binary mixtures, and using MPNs films on microfabricated optofluidic ring resonator ([micro]OFRR) sensors.

Co-Author(s) Christopher J. White, Daniel Snow, David S. Hage, Donald Jobe, Elliott Rodriguez, Ellis Kaufmann, So-Hwang Kye, Xiwei Zheng

Abstract Text

A displacement assay based on high-performance affinity chromatography (HPAC) with fluorescence detection was developed for the analysis of drugs in water and biological samples. This assay first involved the application of a labeled analog of the drug phenytoin onto an affinity column containing immobilized bovine serum albumin (BSA) as a binding agent. Samples were then applied to affinity column, resulting in displacement of the labeled phenytoin. One of the applications examined for this assay was for the detection of drugs and emerging contaminants in water. This assay provided detection ranging from low nM concentrations up to μM levels for drugs such as warfarin and carbamazepine. The results for tap water and water runoff samples that were spiked with these drugs showed good agreement with the actual concentration of these drugs. This method was also examined for use in measuring the free, or non-protein bound, fractions of drugs in biological samples. This format was used to examine the free drug fractions in drug/HSA samples containing warfarin, verapamil, or carbamazepine. The results were comparable to those predicted based on the known binding constants for these systems. The information provided by this study indicates that this type of assay can potentially be used as a potential screening tool for environmental contaminants and for the analysis of free drug concentrations in clinical samples.

Abstract Text

The purpose of this research was to investigate the oxidizing capacity of chlorine dioxide for degrading various toxic or odorous organic compounds in both gas and liquid phases. This research project is useful for exploring the potential application of chlorine dioxide for remediation of contaminants in different environmental media. The gas phase reaction was monitored using a 10-meter gas cell and FTIR instrumentation that allows the measurement of reaction products and the chlorine dioxide at the parts-per-million levels. The GC-MS technique was used with a three-trap preconcentrator to characterize the reaction products with greater specificity at lower detection limits than the FTIR method. The degradation trends of five target compounds including cadaverine, cyclohexyl mercaptan, dimethyl trisulfide, methyl disulfide and 2,6- di-tert-butylpyridine were compared. The concentrations of cadaverine and cyclohexyl mercaptan were reduced most effectively. The major byproduct during the reaction between chlorine dioxide and cadaverine was ammonia. The reactions between chlorine dioxide and dimethyl trisulfide or methyl disulfide yielded byproducts that consisted of alkyl halide, sulfone, sulfonate, and sulfur dioxide. The sterically hindered 2,6- di-tert-butylpyridine was more of a challenge for its chemical degradation by chlorine dioxide and showed very slow reaction rate. The GC-MS analysis of the degradation studies via Tenax-based sorbent trap was found to yield confounding results because of the undesirable reaction of chlorine dioxide with the Tenax TA sorbent. The Tenax trap was replaced with a glass bead trap and the analytical results of both preconcentration approaches for achieving low detection limits will be presented.

The funding for this research was provided by the Department of Chemistry, Middle Tennessee State University.

Abstract Text

[b]Purpose[/b]: To develop a simple HPLC/CAD method for the determination of ETU in multiple formulations. The selectivity of the method enabled separation of ETU from a cellulose matrix and background interference from deionized water using a universal detector. This also enabled a simple processing procedure to be used.

[b]Methods[/b]: A Dionex Ultimate 3000 HPLC coupled a Dionex Corona charged aerosol detector was used for the quantitation of deionized water formulations containing ETU. Chromatography was achieved with a YMC Pack ODS-AQ C18, 150 x 4.6 mm, 3 μ m particle-size column (column temperature of 30°C) along with an isocratic elution using mobile phase 90:10 (v/v) 1% formic acid in deionized water: 1% formic acid in acetonitrile (0.5 mL/min). Data acquisition and analysis were performed using Dionex Chromeleon[registered] software version 6.8.

[b]Results[/b]: With the HPLC/CAD method, linearity was demonstrated from 5.00 to 100 μ g/mL. In addition, quality controls (0.0100, 1.00, and 3.00 mg/mL) showed inter-session variability of 1.5% to 6.8% RSD and inter-session accuracy ranging from -3.4% to 4.6% RE. The LOD of ETU was 0.5 μ g/mL and the LOQ of ETU was 5.00 μ g/mL.

[b]Conclusion[/b]: A simple and accurate method was developed and validated for the quantitation of ETU via HPLC/CAD. The method was used to quantify the amount of ETU in deionized water gavage formulations with separation from a cellulose matrix, as well as, background interference from deionized water, with a simple processing procedure.

Abstract Text

The unique chromatographic profiles of petroleum aliphatic and aromatic components are useful for determining oil spill sources, degree of weathering of the spill and the type of oil product released into the environment. These profiles are also useful in determining the petroleum depositional environment and source (petrogenic, pyrogenic, or biogenic). Traditionally, the fractionation of these compound classes was accomplished using column chromatography (i.e. silica gel, alumina, florisil), thin-layer chromatography (TLC), or high performance liquid chromatography (HPLC). Alzaga, et. al. (2004) first reported the use of a mixed bed SPE cartridge for the fast, quantitative separation of the two compound classes in fuel-oil samples. However, the method still requires hands-on manipulation of the fractionation and concentration processes which may affect precision and reproducibility.

The PrepLinc™ SPEi system allows the user to control the conditioning, loading and elution of samples through commercially available cartridges and disks. With the addition of the AccuVap module, the elution and evaporation steps can be linked to obtain analysis ready samples contained in autosampler vials. In this study, the labor-intensive steps of fractionation and concentration were reduced to two steps: 1) loading samples on to the instrument and 2) programming the sequence with saved method parameters. This provided for a fast and simple method for the separation of aliphatic and aromatic components from petroleum related products and petroleum contaminated environmental samples.

Abstract Text

Carbon paste electrode (CPE) belongs to promising electrochemical sensors of wide applicability because of its several advantages such as low background currents, reproducible results, easy fabrication and modification with wide range of compounds. A distinct advantage of carbon paste-based electrodes is their very low ohmic resistance. Hence, the carbon paste electrode has been widely modified with other chemicals. In this study carbon paste electrode mixed with sericite (S-CPE) or sericite modified with hexadecyltrimethyl-ammonium bromide (MS-CPE) was used as a working electrode in cyclic voltammetry (CV) and measured arsenic (As(III) and As(V)) at different conditions such as concentration of arsenic, pH and ionic strength. It was observed that the performance of the resulting MS-CPE possessed significantly high signals in terms of cathodic or anodic current comparing to the CPE and S-CPE. The MS-CPE has been successfully employed for the detection of arsenic in the linear range of 2 - 50 μM with the detection limit of 1.0 μM in synthetic wastewater.

Abstract Text

A new type of Compton camera, Electron Tracking Compton Camera (ETCC), have been extensively developed for imaging and monitoring environmental gamma-ray from contaminated soils. The decontamination of long-lived caesium (Cs) in soils below the regulation level of 0.23 $\mu\text{Sv/h}$, is an issue of great concern at present in Japan. In the decontamination, fine and quantitative imaging capability is required for checking decontamination performance in contaminated areas. The ETCC realized fine imaging to the area by detecting a recoiled electron in the Compton scattering process using a gas (Ar/Ethane) scatterer. Owing to its precise trace capability of incident gamma-rays, the number of incoming gamma-rays can be directly associated with contrast of the reconstructed source image. This means the ETCC has potentials for not only an imaging device but an absolute radiation monitor in a field of view. Furthermore, background particles can be rejected by their energy-deposit (dE/dx) and track length differences in the gas. This enables to measure a weakly contaminated area around 0.1 $\mu\text{Sv/h}$ by improving a signal-to-noise ratio. We carried out performance tests with a prototype ETCC in the contaminated area and proved imaging capability. In the presentation, we will introduce the imaging device, show results of these performance tests, and explain a novel evaluation method to translate Cs distribution to the radiation dose.

Abstract Text

In rural areas, livestock from farmlands are causing negative effects on the environment, and potentially human beings. Farmers pump their livestock with many different classes of antibiotics to keep them healthy and improve feed efficiency. Many of these antibiotics are excreted from the livestock still in their active forms. The surrounding area, including the water supply, can become contaminated with these active antibiotics. Identification of the antibiotics and their concentrations in the environment is important in understanding how extreme the negative effects are.

Extraction methods from solid and liquid samples, as well as identification of the antibiotics present in the environment will be presented. These proposed methods will be used to determine concentration of the antibiotics present in a nearby farmlands and their surrounding water supplies using HPLC.

Abstract Text

Non-renewable energy sources have been widely studied in recent years, though they tend to run out and cause major environmental impacts such as global warming. In this scenario, the search for renewable energy sources is a necessary alternative. The biomass potential renewable energy sources are becoming attractive alternative. The waste generated in the process of wastewater treatment is also seen as good option for energy reuse, driven by the National Solid Waste Policy, which highlights its energy recovery. The city of Araraquara / SP stands out on the national scene by having a modern system of dewatering and thermal drying of sewage sludge. In this study the residue from the Sewage Treatment Station of Araraquara was characterized after dewatering and thermal drying process, and conducting biological H₂ production with anaerobic sludge from the sedimentation ponds tests. The results obtained with these residues shown high organic matter content, calorific value and generation of H₂, opening new possibilities for their application as potential to generate clean, renewable energy.

Abstract Text

Contamination of fluoride ion in drinking water has caused serious health problem such as mottled teeth in developing country. Therefore, simple fluoride analysis has been desired. As one of the effective on-site analyses, colorimetry has been used, because it is unnecessary analytical instrument for judgment of sample concentration. However, this method causes individual difference of analytical result, because of judge of concentration by color contrast. Recently, we have found the binary color reaction (ON-OFF color reaction) when aluminium ion mixed with Lanthanum alizarin complexone (La-ALC) which is color reagent for fluoride. Moreover, number of discoloring is changed with fluoride concentration using this binary color reaction. Based on these findings, we have already reported visual analysis for fluoride by counting number of discoloring using this binary color reaction. However, this method has a problem in operability and portability because this method is required solution reagent. In this study, we attempted to development of fluoride analysis paper with ON-OFF color reaction.

Abstract Text

The analysis of Total Organic Carbon (TOC) in seawater can be both challenging and expensive. The concentration of organic carbon in sea water is of considerable interest. The effect this matrix can have on TOC analyzers can lead to rapid consumable turnover, costly maintenance and repairs. Laboratories are continually looking to increase sample throughput, decrease overall cost of analysis, and improve ease of use while maintaining reproducibility. This poster will demonstrate the ability to maximize throughput of seawater samples using a high temperature combustion analyzer for TOC analysis.

Abstract Text

Phenols are widely used in various domestic and industrial applications; they are often released into the aquatic systems through wastewater discharges. Phenols have been reported to have harmful effects on man and the environment, hence the need to ensure their removal during wastewater treatment processes. This study assessed the potential of activated grape leaf litter (AGL) for the removal of 2-nitrophenol (2-NP) and 4-nitrophenol (4-NP) from wastewater. Batch adsorption studies were carried out on simulated wastewater. Adsorbent concentration, pH, contact time and temperature were optimised to achieve equilibrium adsorption conditions. Langmuir, Freundlich, Temkin and Dubinin-Radushkevich isotherm models were used to describe the adsorption process. Thermodynamic parameters were also evaluated. The optimal adsorption pH was 8 for the sorption of 2-NP and 4-NP. A further increase in initial pH resulted in decreased adsorption capacity. The adsorption equilibrium of 2-NP and 4-NP onto AGL was attained in 30 min. The adsorption kinetics for the sorption of 2-NP and 4-NP is best described by pseudo first order model ($R^2 > 0.999$). Freundlich isotherm best described the adsorption process. Thermodynamics studies revealed that removal processes were exothermic and that contaminant uptake was unfavourable at high temperatures. The optimum capacity of AGL for removal of 2-NP and 4-NP were 103.10 mg/g and 102.09 mg/g respectively. This study suggests that activated grape leaf litter may be utilized for the removal of nitrophenols from wastewaters in industrial processes.

Abstract Text

In this study, we aimed to investigate the removal and decolorization of dye bearing textile effluents by urea-formaldehyde resins admixed with various proportions of modified Chitosan, Starch, eggshell, powder, rice husk, etc. Different textile effluents were collected and treated with these various mixtures. The resultant liquids were almost colorless with very low COD. The sludge can also be used as filler for plastic manufacturing, road paving or brick making. The produced adsorbent mixture may find its use in environmental science. The adsorption properties of these adsorbents were investigated under different adsorption conditions with different initial dye concentrations, contact times and pH values. The adsorption equilibrium data were analyzed with Langmuir and Freundlich models. The adsorption behaviors of various textile effluents onto the resin mixtures were better described by the Freundlich model.

Abstract Text

Since the 1950s mankind has produced billions of tonnes of polymers, with the rate of production increasing significantly on an annual basis. Handling of the disposal of used materials is becoming a major problem and increasing amounts are finding their way into the river system, coastal waters and eventually into the World's oceans. The majority of plastic materials will degrade slowly. This process of degradation due to wave, wind and UV light can generate small particulates, called microplastics that can accumulate and, through digestion, enter the food chain.

In order to combat and identify the source of the pollution, identification of the bulk and microplastics is extremely important. Infrared spectroscopy is the primary analytical technique for the identification of polymers. If the samples of the plastics are greater than 50 microns in size then they can be analysed using an FTIR instrument equipped with an Attenuated Total Reflectance (ATR) sampling accessory. For microplastics, where the particles are below 50 microns in size, an infrared microscope or infrared imaging system can be deployed for the rapid measurement and identification of the plastic types. The microplastics for the infrared microspectroscopy were collected on filter membranes.

This study shows the application of ATR spectroscopy and infrared microscopy for the measurement of plastics and microplastics collected from European waterways from the river source to the river estuary.

Abstract Text

The determination of dissolved solids has long been a key parameter for water quality measurements. Water having high dissolved solids content could be unsuitable for use in industry. Water with concentrations greater than 500 mg/L usually ranks very low on a taste scale and can produce particularly adverse reactions amongst those who are not native to that water source. The test generally consists of evaporation in a tared dish of a known filtered volume of the water with subsequent weighing of the residue. These dishes need to be stable at the temperatures used as well as nonreactive to the matrix of the sample. Traditionally these dishes have been made of borosilicate glass, porcelain, or platinum. The difficulty often presented by these traditional materials is the weight difference between the container and the mass of residue produced. Most methods limit the mass of residue to be between 2.5 and 200 mg. They further require that the measured mass be reproducible to ± 0.5 mg. With such a large percentage of the mass being contributed by the dish the analyst is often confronted by unnecessarily long and drawn out testing sequences. The development of a lighter weight evaporation container will be discussed.

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s)

Abstract Text

The current Contract Laboratory Program (CLP Method SOM01.1) and Environmental Protection Agency (EPA Method 3640A) Gel Permeation Chromatography cleanup procedures utilize 70 gram S-X3 Biobead columns, at a flow rate of 5mL/minute with dichloromethane as the mobile phase. The maximum lipid load on these traditional columns is 1 gram in a 5mL injection. With a run time of 1 hour, to carry out the separation of co-extracted, higher molecular weight interferences from the analytes of interest, the methods require 300mL of dichloromethane per sample injection. Both methods have between-peak resolution (85% and 90%), and analyte recovery range requirements.

The PrepLinc GPC-MAXX feature allows the user to control the GPC dump, collect and wash operations through 2 columns connected in-line. By allowing the guard column dump fraction to act as a molecular filter, the amount of material transferred to the second separation column is minimized which allows for more material to be loaded on a dual column system. Comparisons between the J2 GPC-Guard/Express column configuration and the traditional 70g columns will demonstrate a 1/3 savings in chlorinated solvent usage and run time. This study will also demonstrate the effectiveness of the GPC-MAXX feature by analyzing several different types of sediment and tissue extractions, with comparisons between analyses from traditional GPC Cleanup techniques and alternative column technologies. Finally, the usefulness of alternative column packing materials, to further increase co-extracted interference removal while decreasing overall runtime and chlorinated solvent usage, will also be demonstrated. In all cases, the peak resolution and recovery requirements were maintained to meet both CLP and EPA method requirements.

Abstract Text

In this Abstract we will discuss the different methods for on site water quality testing. Items covered will be the different types of chemistry used and their introduction methods, known interferences, typical applications and data management. The purpose of this abstract will be to better understand the options available to professionals in multiple industries when it comes to water quality sampling and testing, along with any known issues that may arise, thus giving the attending professional a good idea of the correct testing methods needed for his or her specific application.

Abstract Title **Development of 4-Channel LED-Based Reflective Photometer for Determination of Trace Elements in River Water Samples with Membrane Filter Extraction**

Primary Author Yasutada Suzuki
University of Yamanashi

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Susumu Kawakubo

Abstract Text

For sensitive determination of various substances with easy operation, a reflective photometer using light-emitting diodes (LEDs) was developed. LEDs wavelengths were 430, 525, 635, and 740 nm, respectively, and they were turned on and off sequentially. Fiber optics was used to merge the LEDs emission and to illuminate the surface of a filter (sample), and another was used to collect the light reflected by the filter. The reflected light was detected by a photodiode (PD) and its intensity was acquired by a controller, synchronized with blinking of LEDs. Reflectance (R) against blank was calculated for each LED and it was converted to reflective absorbance ($\log_{10} R$) and Kubelka-Munk function $\{(1 - R)^2 / 2R\}$.

Copper(II) was determined with bathocuproine chelating reagent. The chelate was collected on a filter and its reflective absorbance was measured at 525 nm. A calibration curve was linear between 0 and 0.1 mg/L and detection limit (DL, 3 σ of blank, $n = 5$) was 5 $\mu\text{g/L}$. Recoveries for 1 μg of copper added to 10-mL river water samples were measured and they were from 98 to 102%. Another application was phosphorous as phosphate determination by molybdenum blue method. A calibration curve (740 nm) was linear between 0 and 7.5 $\mu\text{g/L}$ and DL was 0.2 $\mu\text{g/L}$. River water samples were analyzed by this method and official analytical method. Their results were in good agreement within 10% errors. Thus, the performance of the photometer could be successfully demonstrated.

Abstract Text

We present a new design for a portable paper-based sensing device for the colorimetric detection of Bisphenol A (BPA) in household dust. A rapid procedure for dust collection is used with a sensitive method for BPA detection, based on the formation of a greenish color on the test zone of the sensing device. The color results from the formation of a Schiff base compound, quinine-imine, formed by reaction of chitosan with the enzymatic product of tyrosinase, o-quinone, on paper coated in a layer-by-layer (LbL) assembly approach. The designed system includes a paper-based sensor disk with a diameter of 0.6 cm as a test zone for BPA detection, and the air-sampling cassette with a diameter of 37 mm as a collection area for household dust. A color database based on sRGB color space was designed specifically for BPA detection in household dust. Color intensity was evaluated using a statistical histogram provided by Photoshop. Colorimetric response was concentration dependent with a detection limit of 0.28 $\mu\text{g/g}$. The color started to appear within the first 60 s and stabilized after 30 min. Data from Gas Chromatography (GC) was validated our colorimetric data. Real household dust specimens were collected from four different homes and a day care center in Potsdam, NY, USA. Results showed a linear regression ($R^2 = 0.9743$) for real samples measured by both of the calorimetric and GC methods. In this work, BPA ranged in concentration from 0.05 to 3.87 $\mu\text{g/g}$ in 57 samples of dust when both methods were used.

Abstract Text

There is a growing demand for in-field analysis for many applications from environmental monitoring to defense. Handheld mass spectrometry brings a powerful tool to bear on these challenges and has been enabled through the development of high pressure mass spectrometry (HPMS). Operating miniature cylindrical ion traps ($r_0 < 1$ mm) at elevated RF drive frequencies ($f > 6$ MHz) and pressure ($P \approx 1$ Torr), yields conditions where a turbomolecular pump is not required. In our lab, HPMS has been demonstrated with a variety of ionization sources including thermionic filaments, glow discharge, and electrospray ionization. However, there remains the need for a miniaturized ionization source that reduces size and power relative to previously developed sources.

The microionizer is a planar, silicon-based field emission source developed for minimal size, weight, and power, as well as compatibility with HPMS conditions. It has dimensions of $1\text{ cm}^2 \times 500\ \mu\text{m}$ thick; decreasing volume by 90% relative to a glow discharge source. Field emission is controlled with voltage pulses between 10 to 100 V, generating electric fields on the order of 0.1 to 1 MV/cm with less than 10 mW power draw. Emission currents have been studied under HPMS conditions at 1 Torr of ambient air to confirm Fowler-Nordheim field emission. The current density was also shown to be sufficient for HPMS by collecting mass spectra of volatile organic compounds.

Funding for this project is provided by the Defense Threat Reduction Agency-Joint Science and Technology Office for Chemical and Biological Defense.

Abstract Text

Microfluidic paper-based devices (PBDs) have received significant attention for biochemical and medical diagnostics, but the applications to environmental testing are also significant, particularly for use in developing countries. This poster presents a new paper-based microfluidic device to measure the cadmium in water samples by titration with using colorimetric reagents. The reagents, based on a sulfonated naphthoquinone with a thiosemicarbazone moiety, react stoichiometrically within the wax-printed channels giving a color change whose intensity and area correspond to the cadmium concentration. We demonstrate that measuring both parameters can improve the calibration model and increase the sensitivity.

Abstract Text

We report on the thickness degradation of deposited silicon nitride layer, mainly used as passivation layer in the semiconductor manufacturing process, caused by airborne molecular contamination inside front opening unified pod (FOUP). An artificial contamination inside FOUP by airborne molecules was introduced to investigate the influence of contamination on the wafer surface. The concentration of fluoride ions artificially contaminated inside FOUP was 6,420 ppbv which was 400 times higher than that of a clean FOUP. The thickness degradation of the silicon nitride layer did not occur when bare wafers had been stored in a clean FOUP before the silicon nitride deposition process. Otherwise, the rate of thickness degradation of the silicon nitride layer gradually increased in the range of 6 Å to 11 Å according to the degree of decreasing layer thickness when the bare wafer had been stored in a contaminated FOUP. It appeared that some of remaining fluoride ions on the wafer surface that contaminated the wafers during etching process diffused in FOUP when the wafers are transported and stored. Then, the residual fluoride ions in FOUP migrated to the bare surfaces of the other clean wafers. These migrated fluoride ions could inhibit the formation of a silicon nitride layer. From this study, the cleaning and monitoring processes are essential and should be applied not only to the processed wafers but also to FOUPs after each chemical etching step.

Abstract Text

High-resolution oxygen and hydrogen stable isotopes of surface snow and snow pits at the Greenland Environmental Observatory, Summit (GEOSummit), were measured by an Off Axis Integrated-Cavity Output Spectrometer (Los Gatos Research DLT-100). The year round, high temporal $\delta^{18}\text{O}$ and $\delta^2\text{H}$ in bi-weekly sampled surface snow during 2012-2014 showed clear seasonal variations. Enriched ^{18}O and D values were observed in summer, while depleted values were measured in winter and spring samples. The greatest $\delta^{18}\text{O}$ and $\delta^2\text{H}$ variability was observed in the 4th quarter, whereas the 1st quarter showed less variability. $\delta^{18}\text{O}$ and $\delta^2\text{H}$ co-varied with air temperature when the most positive $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values in late July 2012 corresponded to unusually warm weather caused by snow melting resulting in post-depositional modification of isotopes. Since water isotope fluctuations are governed primarily by atmospheric conditions, i.e. air temperature and associated air-mass trajectories, long term monitoring of interannual oscillation and magnitude provides insight into source, depositional, and post-depositional processes associated with hydrologic cycles and climate changes in the region. The $\delta^{18}\text{O}$ and $\delta^2\text{H}$ relationship in surface snow shows a slope similar to the global meteoric water line, at 7.97, compared to 8.0. Overall, $\delta^{18}\text{O}$ and $\delta^2\text{H}$ are well preserved in snow pits, with no to minimal post-depositional modification at GEOSummit, as $\delta^{18}\text{O}$ and $\delta^2\text{H}$ patterns lined up well over monthly snow pits. That is, isotope signals from surface layers corresponded to deeper layers in the proceeding months' pits, except a few centimeters' shift in depth. This offset matched well with the presumed weekly snow accumulation rates in different seasons (Banta et al. 2009). Our data support the previous assumption that no significant post-depositional processes occur in the high latitude high elevation of GeoSummit.

Abstract Text

A simple, novel electrochemical method for the detection of arsenic has been developed. The optimized method employs square wave anodic stripping voltammetry (SWASV) and does not require complicated or expensive electrode fabrication, as it utilizes a bare glassy carbon electrode. The co-deposition of copper greatly increases the sensitivity of the electrode allowing for detection limits in the low parts per billion. The method has successfully been used to detect arsenic in various aqueous samples that demonstrate the significance of this technique in environmental and industrial settings.

Abstract Text

Great Lake Coastal Wetlands are essential ecosystems. They provide a variety of services including water quality control, wildlife habitat, flood, pollution, and erosion control, and carbon sequestration. They are continuously storing and emitting greenhouse gases (GHG) such as Methane (CH₄), Carbon Dioxide (CO₂), and Nitrous Oxide (N₂O). My project is monitoring how the GHG flux between the wetland atmosphere interface changes when the wetland experiences drying.

Abstract Text

In the environment, trace metals are aggressive environmental pollutants due to their rapid mobilization and transportation. The bio-availability and toxicity of these metals are controlled by their complexation with different ligands. Most environmental analysis techniques assume the equilibrium of these complexation processes, but these reactions are often not at equilibrium. A real-time detection technique which measures free metals is necessary to characterize dynamic metal complexation. Traditional analytical methods are very sensitive but do not measure in real time. We developed a real time detection technique to characterize metal complexation using Fast scan cyclic voltammetry (FSCV). Due to its well established thermodynamic complexation properties; we used Cu (II) complexation with different known ligands to verify our paradigm. We developed a hydrodynamic model to explain the complexation and compared it with a thermodynamic model for further verification. The ultimate goal of our project is to use our FSCV method as an *in situ* real time diagnostic tool for metal toxicity in the environment.

Abstract Text

Trace metals are highly toxic pollutants in environment and have caused major concerns to public health. Our earlier work found Fast-Scan Cyclic Voltammetry (FSCV) coupled with carbon fiber microelectrodes (CFMs) particularly powerful in real-time detection of Cu[1] and Pb[2] in aqueous environmental samples. Now we functionalize CFMs to improve selectivity by a covalent scaffolding strategy. We employ two schemes in our modification: the first one is creating scaffolds on CFMs via electrochemical reduction of silylated ethynylaryl diazonium salts, making the density of the scaffolds dependent on the silyl spacers. The second scheme is attaching ionophores to the desilylated scaffolds via Copper Catalyzed Azide-Alkyne Cycloaddition (CuAAC), rendering CFMs selective to copper. Moreover, we optimize the parameters for the two schemes and conclude a modular process to graft a variety of functional azides onto CFMs. We evaluate the modified electrodes' sensitivity, selectivity and stability. Our covalent functionalization strategy for CFMs makes FSCV extremely effective for real time environmental trace metal detection with high selectivity.

Abstract Text

The color is a physical characteristic in the water produced by organic and inorganic substances found in a solution or colloidal particles. In natural waters, color is generally associated with metallic salts and organic substances; in this respect the color varies from yellow to brown while in wastewaters color is considered as an associated pollutant with industrial processes. The currently method for measuring natural water color is the Hazen method, because it produces colors, similar to those found in natural waters. When the water's color is produced from industrial waste, the test of color with the platinum-cobalt method does not prove applicable because the hue does not fit the yellow-brown scale. Because of the previously mentioned issue, this investigation was focused on testing the ADMI method as an alternative of color measuring in industrial discharges in Medellín (Colombia).

As a result, a correlation was established among ADMI, pH, turbidity, conductivity, suspended solids, total solids, COD (chemistry oxygen demand) and BOD (biological oxygen demand) taken from 526 samples of wastewaters from ten industrial sectors that flow into The Medellín river. It is important to highlight that during this investigation none of the initial conditions of the analyzed samples were modified, so that the typical characteristics of color could be tested in every one of the industrial sectors that were tested.

Abstract Text

Endocrine disrupters (EDs) are compounds that specifically interfere with the normal functions of the body's endocrine system (system of glands for hormonal secretion) by causing adverse effects in both human and wildlife. Therefore, the routine, sensitive, reliable and cost effective detection methods for EDs are highly demanded.

In this work we present the selection and characterization of ssDNA aptamers that exhibit high affinity, specificity and sensitivity to progesterone (P4), 17 β -estradiol (E2) and, norethisterone (NET). The aptamer selection was conducted by in vitro selections by incubating a huge ssDNA library of about 1.80×10^{15} random sequences with the target analyte which has been previously immobilized on agarose beads. After certain cycles of selections, the enriched aptamers pool was cloned and sequenced. The dissociation constants (KD) of the selected aptamers were determined by fluorometry and by electrochemical impedance spectroscopy (EIS) methods. The KD values are in the low nanomolar range. Cross-reactivity tests for each aptamer demonstrated the high specificity to their target analyte. Additionally, circular dichroism (CD) spectroscopy measurements of the selected aptamers showed a remarkable conformational change upon binding the target analyte. The change in the conformation was exploited to design a biosensing platform to get a measurable signal after binding the specific analyte by following the redox process of a couple composed for $[\text{Fe}(\text{CN})_6]^{3-}/4-$. For first time, an impedimetric aptasensor to detect progesterone was developed by yielding a limit of detection of 0.90 ng/mL; for other analytes, the data will be presented and discussed in the programmed session of the conference.

We believe that the continuous selection of high affinity aptamers for other EDs and their integration in a biosensing platform will facilitate the routine monitoring of EDs in environment as well as clinical and medical diagnosis purposes.

Abstract Text

Highly selective and sensitive phosphate sensors have been fabricated by constructing a solid membrane disk consisting of variable mixtures of aluminum powder (Al), aluminum phosphate (AlPO₄) and powdered copper (Cu). Both binary and ternary electrode systems were produced. The ternary membranes exhibit greater selectivity over a wide range of concentrations. The ternary electrode with the composition 25% AlPO₄, 25% Cu and 50% Al was selected as our preferred electrode. The ternary membrane electrodes exhibited linear potential response in the concentration range of 1.0×10^{-1} to 1.0×10^{-6} mol L⁻¹. The mechanism for the selectivity of phosphates by the electrodes includes adsorption, absorption and ion exchange processes. An understanding of these processes reveals that the composition of the membrane material and its molecular structural framework are all important. The layered double hydroxides which form within the interstitial layers of the phosphate selective membranes contribute to the selectivity of the ions.

Abstract Text

Chromium is a naturally occurring element present in water, rocks, soils, and in biological organisms. Chromium exists in various oxidation states, however, the only biologically and environmentally stable forms are trivalent Cr(III) and hexavalent Cr(VI) chromium. While Cr(III) is an essential nutrient for metabolism, Cr(VI) is toxic and a known carcinogen. Inhalation or ingestion of contaminated air, water, or soil, by Cr(VI) is a major concern for industries using chromate painting, electroplating and welding. Therefore, monitoring Cr(VI) levels to protect workers at various working environment is a priority. Filters commonly used for sampling in industrial hygiene all have some limitations, in particular, stabilizing Cr(VI) for a period of time before analysis. At High-Purity Standards we are investigating how to extend the stability of low levels of Cr(VI) on various filter media. A variety of source materials for Cr(VI) are used to deposit on different filter media. Various conditions are tested for pre-treatment of filters before use, preparation of Cr(VI) on filter, digestion methods, and appropriate packaging and storage. Total chromium, and speciation of Cr(III) and Cr(VI) are determined by analytical techniques with comparison and spiking methods using proper instrumentations. The evaluation of the effectiveness on the stability of Cr(VI) filter associated with analytical results, precision, and bias will be discussed.

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Andrew Robson, David S. Kosson, Mara L. Knapp, Rossane C. DeLapp, Warren T. Corns

Abstract Text

Smouldering remediation is capable of achieving 99.9+% destruction of coal tar and hydrocarbon contaminants in porous materials. These porous materials experience temperatures in the range of 500-1100°C for periods of minutes or hours depending on contaminant type and operating conditions. Often, contaminated materials contain potentially toxic element (PTE) co-contaminants such as mercury and arsenic. High temperatures and smouldering reactions affect physical and chemical properties of materials subjected to remediation, which, in turn, affect the presence and fate of PTEs in those materials.

The Leaching Environmental Assessment Framework (LEAF) provides a collection of tests, data management tools, and assessment approaches to develop source term release profiles for a wide range of materials. LEAF tests were recently added to the USEPA SW846 compendium as standard methods 1313-1316.

The two materials in this study were a field-obtained soil artificially contaminated with coal tar and a field-obtained made ground from a coal tar contaminated site in the USA. These materials were subjected to smouldering remediation in the laboratory. Mercury and arsenic fate and speciation were studied through the application of cold vapour and hydride generation atomic fluorescence spectroscopy (AFS) in conjunction with LEAF testing and geochemical speciation modelling using LeachXS. Total PTE content seemed to be reduced through volatilisation during remediation. After remediation, changes in soil composition and chemistry affected aqueous release of mercury and arsenic from these soils as well as speciation. This knowledge can be applied to the design of engineering approaches to reduce PTE contaminant levels or availability at contaminated sites.

Co-Author(s) Adeyao Adeleye, Godfred Darko

Abstract Text

Several regulatory bodies including WHO and USEPA have listed Polychlorinated biphenyls (PCBs) and Organochlorine pesticides (OCPs) among the potentially toxic compounds. Some of the hazardous health risks in humans include reproductive failures, nervous system dysfunction and cancers. In current study, we evaluate the mean concentrations of PCBs and OCPs in plasma samples of several humans residence in Lagos as well as in water samples of Lagos lagoon, Nigeria employing various extraction techniques (solid and liquid phase extraction) and analysed with gas chromatography coupled to electron capture detector. Mean concentrations of PCBs and OCPs (ng/ μ l) in plasma samples are as follows: PCBs 28 (0.0432-1.3249); 52 (0.0039-0.1678); 101 (0.0064-0.0511); 137 (ND-0.0329); 153 (ND-0.0665); 180 (ND-0.0397); 194 (ND-0.0730); lindane (0.00286-0.0481), chlorothalonil (0.00805-0.0148), heptachlor (0.00224 - 0.00318), aldrin (0.00099 - 0.0821), BHC (0.000310-0.0168), heptachlor epoxide (0-0.0006), endosulfan (0.00105 - 0.1653); dieldrin (0.00104 - 0.00926); P,P'DDD (0.0128 - 0.9499); endrin (0.01198 - 0.02315); P,P'DDT (0.01501 - 0.06697); methoxychlor (0.01016-0.09181); lambda cyalothrin (0.04103-0.06402) and permethrin (0.05572-0.48793). Mean concentrations of PCB 28 and lindane were highest while those of PCB 180 and heptachlor epoxide were lowest. The values in plasma samples were below the maximum concentration limits (MCL) approved by European Union (EU) for organochlorines.. The concentration levels in this study were compared with the levels detected in other parts of the world. The study confirms PCBs and OCPs persistence in Lagos, despite its ban several decades ago.

Abstract Text

Environmental contamination has been at the forefront of government policy and regulation since the USEPA was established in 1970. Over the years the US EPA has developed, published, and updated multiple methods for analysis of environmental pollutants, and single-quadrupole gas chromatography-mass spectrometry (GC/MS) has long been the technique of choice for determination of volatile organic contaminants (VOCs). As efforts to provide dependable analytical methods has progressed, the GC/MS instrumentation has evolved, with improvements in sensitivity, reliability, and user experience, but there haven't been any significant advancements in the overall methodology since the mid-1980s.

The USEPA is currently in the process of developing a revision to USEPA Method 624, which was first promulgated in 1984 and specified the use of packed columns as part of the protocol to collect data on the proposed pollutants. As part of the revision, the USEPA is evaluating up to 30 additional pollutants for inclusion in the method.

This poster will provide examples from a purge-and-trap method validation study conducted to evaluate operating conditions for the existing VOC list plus the proposed list of 30 new analytes. Column selection and GCMS instrumental recommendations will also be addressed to bring the method in line with modern methods. Calibration levels along with QC criteria will also be presented.

Abstract Title **Parts-per-Trillion SVOC Air Analysis with Novel Optical GC Detector**

Primary Author Martin L. Spartz
Prism Analytical Technologies, Inc.

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Alice E. Delia, Anthony S. Bonanno, Stacey E. Beyer

Abstract Text

Ambient air analysis is now performed widely in homes and small businesses as well as the more traditional industrial locations as the general public and businesses wish to better understand their air quality. These ambient air methods customarily look for VOCs, more volatile SVOCs, mold VOCs, and combustion gases like NO_x, CO, and CO₂. SVOCs are normally measured by collecting dust samples, which are subsequently extracted and/or prepared for analysis, instead of air samples because the concentration in ambient air is too low for traditional environmental analytical methods. Unfortunately, dust samples are generally not representative of the sample location due to the large area that needs to be evenly sampled, much of which may be inaccessible due to furniture or other structures. If an air sample could be collected and analyzed with appropriate sensitivity and selectivity, a more representative level of SVOCs in the home or business could be determined.

A novel optical GC detection system (MAX™) has been developed that provides both quantitative and qualitative determination of 100s of SVOCs at or below the single digit parts-per-trillion range (airborne concentration) from a single sample. The MAX™ detection system utilizes optical spectroscopy to provide a one-time permanent calibration so many compounds can be quantified in every sample. Increasingly costly helium is not required as a carrier gas, and the system can be setup and running very quickly since high vacuum is not required as in the more traditional GC-MS based analyses. The novel MAX™ detection technology and its application to SVOC air analysis will be discussed.

Abstract Title **Formation of Disinfection Byproducts and Associated Bromine Substitution Factors Upon Chlorination/Chloramination of Seawater**

Primary Author Haiting Zhang
Missouri University of Science and Technology

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Honglan Shi, Huiyu Dong, Yinfang Ma, Zhimin Qiang

Abstract Text

Due to the high concentrations of inorganic ions (e.g., Cl⁻, Br⁻) and the complex sources of organic materials, the chemistry associated with disinfection of seawater is more complicated than that of fresh water. However, up to date little is known about the concentration levels, species distributions, and influential factors about the disinfection byproducts (DBPs) formed during aquarium seawater disinfection.

In this study, the effects of organic precursor, Br⁻ and pre-ozonation upon chlorination/chloramination of Beijing Aquarium seawater on the formation and associated bromine substitution factor (BSF) values of several typical classes of DBPs, including trihalomethanes (THMs), haloacetic acids (HAAs), and haloacetamides (HACams) were investigated. The results indicated that, with an increased dissolved organic carbon concentration, the formation of THMs and HAAs increased by 3.2-7.8 times upon chlorination and by 1.1-2.3 times upon chloramination. An increase in the Br⁻ concentration substantially increased the concentrations of THMs and HACams and the BSF values of all detected DBPs, while the total yield of HAAs changed slightly upon both chlorination and chloramination. Pre-ozonation treatment (1.0 mg L⁻¹ ozone dose) obviously suppressed the formation of all studied DBPs during subsequent chlorination, but promoted to some extent the DBPs formation during subsequent chloramination. The BSF values of all studied DBPs increased after pre-ozonation treatment even at a low ozone dose.

In summary, for aquarium seawater disinfection, chloramination produces much less DBPs than chlorination. However, if chlorine is adopted as disinfectant, pre-ozonation can substantially reduce the formation of studied DBPs.

Abstract Title **Determination of Endocrine Disrupting Chemicals in Ground Water in Herkimer County**

Primary Author Elaina Zito
St. John Fisher College

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Kimberly Chichester

Abstract Text

The development of a method to determine the amount of endocrine-disrupting chemicals (EDCs) in drinking water using Gas Chromatography- Mass Spectrometry (GC-MS) and Liquid Chromatography will be presented. EDCs can be harmful to aquatic life and humans in specific concentrations potentially causing developmental, reproductive and neurological effects. I aim to quantify the concentration of Estrone (E1), 17 β -ethinylestradiol (EE2) and Estriol (E3) from water samples collected in Herkimer County, NY and further determine how to safely remove these chemicals from the water.

Abstract Text

The inertness of a GC column has prime importance in the analysis of active sample compounds. Active sites on a GC column or on a stationary phase interact with the sample components having acidic, basic or hydrogen bonding properties. Due to such interactions, compounds can be adsorbed on the active sites, which results in decomposition or peak tailing or reduction in peak response and non-reproducible results for run-to-run analysis. Consistency and accurate analysis of environmental and other samples consisting of basic, acidic and alcohol groups containing compounds is very important to assess the true toxicity of a particular sample. In the current investigation, two inert columns were developed and evaluated for the analysis of active components containing samples specified in USEPA Method 8270. Also, pesticide samples were analyzed on the inert columns and results were compared with standard GC columns. Lower detection limits, peak tailing, and linearity range for active and neutral components in a standard mixture were studied using inert and standard GC columns. The comparison of the data illustrates the importance of inertness of the column for the accurate determination of active groups containing compounds by GC and GC/MS.

Abstract Text

Water quality laboratories across the nation are faced with both a rising level of water quality awareness amongst the general public, as well as rising costs in water quality monitoring. As a result, laboratories are looking for more efficient ways to provide higher quality monitoring.

This study compares US EPA methods 524.2 and 524.3, as well as 8260B and 8260C, all on a single system. This study focuses on considerations for sample volume and purge parameters for the US EPA 524 methods, and considerations for quality control parameters for the US EPA 8260 methods.

Abstract Title **Improved Siloxane Measurement in Air Using Ultra Inert Stainless Steel Vacuum Sampling Canisters**

Primary Author Thomas X. Robinson
Entech Instruments, Inc.

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Daniel B. Cardin

Abstract Text

Siloxane measurement in biogas samples has become important to prevent the destructive deposition of silicon dioxide on power generation systems during siloxane combustion. Filters are available for removing siloxanes in the biogas, but monitoring of the inlet and outlet feeds is necessary to verify that filter breakthrough is not occurring. Generally, filter breakthrough occurs slowly enough that occasional sampling and analysis is sufficient to reliably determine when filter replacement is needed.

Canisters provide one of the simplest collection techniques for monitoring air, as the contained vacuum simply pulls in more than enough sample needed to quantify levels of contaminants in the laboratory. Unfortunately, SUMMA passivated and other types of canisters used previously were not inert enough to store and recover the full range of siloxanes quantitatively. A new canister is presented that uses a more inert ceramic lining on the internal surface of the canister that allows the full range of siloxanes to be recovered up to 2 weeks after sampling. A laboratory preparation system automates the GCMS analysis of up to 20 canisters, with optional heating up to 150 deg C prior to sample extraction. Data for Siloxanes with a molecular weight out to L5 and D6 will be presented, including calibration curves, method detection limits, and holding time studies that demonstrate the effectiveness of these new sampling canisters and laboratory sample preparation systems.

Abstract Text

Isocyanates are a main component in the production of polyurethane (PUR) materials. Exposure to isocyanates can put workers at risk for respiratory disorders like "occupational asthma". It is important to include monomer and oligomer isocyanate species when performing environmental health and safety exposure assessments as many paints, coatings and spray foams formulations contain multiple species of isocyanates. The measurement of isocyanate urea derivatives by LC-MS-MS with sub 2 μ m HPLC column can provide fast analysis with optimum resolution and low detection limits. Columns packed with high purity, totally porous, monodisperse silica particles were used in this study and allowed for improved UHPLC performance and higher efficiency separations. Isocyanate monomers and oligomers were measured in one single injection into the UHPLC C18 column packed with 1.9 μ m size particles. The chromatographic results will be pictured and evaluated. The study was done for multiple isocyanates including HDI, HDI oligomers, 2,4-TDI, 2,6-TDI, MDI, MDI oligomers, IPDI, and IPDI oligomers.

Abstract Text

Due to potential adverse health effects of certain chemicals used in consumer products, alternative chemicals are routinely introduced in the market. Understanding human exposure to these chemicals is necessary for risk assessment. Biomonitoring measures the body burden of chemicals through the quantification of the concentrations of the chemicals or their metabolites in biological matrices. Therefore, identification of metabolites which can be used as exposure biomarkers is important. In-vivo and in-vitro metabolism have been used routinely to identify metabolites during drug development. We used a similar approach to identify metabolites of emerging environmental chemicals to investigate the in-vivo metabolism of di-2-ethylhexyl tetrabromo phthalate, an emerging flame retardant, and cyclohexane di-isononyl ester, a phthalate alternative, in rats after administration of the chemical intravenously or by gavage. Similarly, we also investigated the in-vitro metabolism of di-2-ethylhexyl terephthalate and di-2-ethylhexyl-adipate using human liver microsomes. We monitored the differences in elution patterns of chemicals in the urine of dosed vs. control rats and the human liver microsome suspension with and without the parent chemical. We used mass spectrometric fragmentation patterns after HPLC separation to tentatively identify the in-vivo and in-vitro metabolites. Upon obtaining analytical standards of the metabolites that are specific to the chemicals studied, we are able to incorporate some of these newly identified biomarkers into ongoing biomonitoring programs such as the National Health and Nutrition Examination Survey.

Xylem/OI Analytical

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Cynthia Elmore, Steven J. Skalski

Abstract Text

Total organic carbon is an important indicator of water quality throughout the water treatment process. Raw source water is progressively treated to remove particulate matter and natural organic matter (NOM). Humic acid and fulvic acids contained in the residual NOM of water undergoing disinfection by chlorination react with chlorine to form disinfection by product compounds such as trihalomethanes (THMs) and haloacetic acids (HAAs), which have been linked to cancer. THMs continue to form during drinking water distribution due to excess chlorine levels required to maintain microbial disinfection.

TOC analysis is a quick and effective indicator of NOM and THM levels in source water and finished water. However, TOC analysis cannot be substituted for THM analysis and THM analysis requires significantly more time. The relationship between TOC from natural organic matter (NOM) in raw water, TOC levels reduced during treatment, TOC and THMs in finished drinking water, and TOC and THMs from points in the distribution system must be established in a timely manner for effective operation of the water treatment process.

This poster will present comparative data from TOC analysis employing the heated sodium persulfate oxidation technique in USEPA-approved method SM 5310C, and an improved approach to THM analysis using USEPA-approved method 524.4. Any relationship between TOC and THM concentration will be demonstrated and an understanding of the influence of chlorine dosing, time and other factors on each measurement parameter investigated.

Abstract Text

Since medical marijuana (MM) was legalized in California in 1996, 23 states and Washington, D.C. have passed laws allowing its use for a variety of medical conditions. From a consumer safety point-of-view, quantitation of the pesticide residues in MM products has begun to attract wide interest. There are several problems associated with analysis of pesticide residues in MM. First and foremost, there are very few regulatory guidelines established to define which pesticides to include or what the detection limits should be, and secondly the matrix is very complex with significant interferences. Finally, sample load is growing exponentially, so the chosen method must be quick and easy to perform. Trace level pesticide analysis in complex food matrices have been done for many years with similar challenges, thus many of the analytical protocols emerging for the MM matrix are based on these well-established techniques.

Gas Chromatography mass spectrometry (GCMS) is well established for trace level detection of pesticides in complex matrices. Triple-quadrupole GC-MS/MS operated in MRM mode provides significant improvements in both sensitivity and selectivity, but method development can be expensive and time consuming.

This poster describes streamlined screening of pesticide residues in MM using a QuEChERS sample preparation method, followed by analysis using a commercially available GC-MS/MS method package, which includes simultaneous Scan/MRM acquisition methods, second-column confirmation, and pre-registered calibration curves for semi-quantitative results for 478 pesticides. Tools for quick development of a fully quantitative Scan/MRM method for custom pesticide lists will be discussed in detail.

Abstract Text

Geochemical analysis of the <150 μm fraction of surface soils by neutron activation analysis and X-ray fluorescence spectrometry revealed that in general, strongly weathered soils overlying Miocene White Limestone Supergroup in large sections of Central Jamaica are characterized by unusually high levels of Cd. The source of the Cd remains controversial but is presumably natural (geological) since there are no sources of contamination in the area large enough to account for the widespread high levels. Here, we determined the Cd isotopic composition of soil samples, a cadmiferous phosphorite soil concretion, African dust and volcanic ash deposits ($n = 21$) to investigate the source of Cd in this region. The samples were appropriately digested and a portion of each digest double spiked (^{110}Cd – ^{111}Cd) to correct for mass bias and experimental induced fractionation. Spiked samples were then purified by anion-exchange chromatography in order to pre-concentrate Cd in the samples, remove major elements and avoid isobaric interference before Cd isotopic determination using a multi-collector ICP-MS. The isotopic composition of the samples varied widely, with $^{114}/^{110}\text{Cd}$ values ($^{114}/^{110}\text{Cd} = \frac{(^{114}\text{Cd}/^{110}\text{Cd})_{\text{sample}}}{(^{114}\text{Cd}/^{110}\text{Cd})_{\text{JMC Cd Münster}}} - 1 \times 10^4$) ranging from +0.2 to +9.0, suggesting that these soils do not solely reflect the underlying karstic geochemistry of the region. Although not precisely defined, there is also good evidence to suggest two distinct sources of Cd, which, do not include the cadmiferous phosphorite soil concretion as previously suggested.

Abstract Text

Electro-organic synthesis has received great interest as a new environmental compatible synthesis route to produce unique structures. Different monomers especially substituted aromatic compounds have been utilized to produce electrochemical conducting and non-conducting polymers. Functional polymers are attractive candidate for use as a chelating agents for the determination of heavy metals in water samples. [1-3]

We demonstrate here, the application of electro-reduction product of 4-nitrophenol coated on the activated surface the multi-wall carbon nanotubes (MWCNTs). The modified MWCNTS is successfully applied as dispersive micro solid phase extraction (DMSPE) to preconcentrate the Ni²⁺ from water prior to flame atomic absorption spectrometry (FAAS).

The 4-nitrophenol is reduced in a separated electrochemical cell in aqueous medium containing sodium acetate and NaCl on lead cathode and dimensional stable anode. The electro-reduction is conducted under constant current (17 mA). After electrochemical synthesis, a dark brown precipitated powder is washed by double-distilled water and subsequently dried. Furthermore, the product is characterized by analytical technique (GPC, DSC, TGA, FT-IR, ¹H-NMR and cyclic voltammetry). After that, the product is coated on the surface of carbon nanotubes in water-methanol (1:1) medium. In the end, the dried electro-product modified carbon nanotubes is applied to determine the trace amount of Ni²⁺ by DMSPE -FAAS.

The recovery percentage and the detection of limit are obtained 98.7 % and 0.26 µg/L respectively. Finally, the method is employed for the determination of Ni²⁺ ions in some industrial fluids and petrochemicals waste waters.

Abstract Title **A Guide to BFB Tuning for VOC Analysis**

Primary Author Brahm Prakash
Shimadzu Scientific Instruments, Inc.

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Di Wang, Laura Chambers, William Lipps

Abstract Text

One requirement found in all USEPA methods for volatile organic compounds (VOCs) is that specific GC/MS tuning criteria must be met before analyzing actual samples. The GC/MS is tuned using the traditional tuning compound, PFTBA (perfluorotributylamine), and the tune is evaluated every 12 hours by injecting BFB (4-bromofluorobenzene) and measuring the intensity of key mass fragments. The MS tuning procedures adjust PFTBA ion responses to achieve the desired BFB response ratios. The relative ion abundance of the BFB mass fragments must meet specific criteria established in the methods to ensure that the GC/MS instrument operating conditions are adjusted and optimized for analysis of VOCs, and the criteria must be met every 12 hours to ensure that the instrument performance remains stable enough for continued analysis.

The BFB tuning criteria for the three most common USEPA VOC methods (8260, 524, and 624) are very similar, although there are a few important differences. In addition, there are many factors that can affect the instrument's ability to meet the specified criteria, including cleanliness of the ion source, GC oven temperature and column flow rate, threshold setting, and the tuning parameters themselves. This poster summarizes the differences in BFB tune requirements for the 3 most common USEPA VOC methods, and discusses the variables critical to meeting BFB tuning criteria. Recommended tuning conditions are included, as well as results from a long-term stability study.

Abstract Title **Applications of Supercritical CO₂ as a “Green” Solvent in the Textile Industry**

Primary Author Rolf Schlake
Applied Separations

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Al Kaziunas, Anand Anand, J Peter Hobbs

Abstract Text

It is well recognized that the textile industry is one of the world's largest users of potable water. Supercritical CO₂ (scCO₂) solvent characteristics can allow it to replace water in many textile operations such as scouring and dyeing, thereby significantly reducing or eliminating water demand.

Having built our first commercial scCO₂ textile dye system in the 1997, we are again focused on further development and scaling up the use of scCO₂ as a solvent in the textile industry.

This paper will focus on the application of scCO₂ to the following textile operations and the accompanied reduction in water, energy and chemicals use and waste generated.

Scouring: Nylon and cotton fabrics were scoured using with scCO₂ and showed extraction efficiencies > 95%. Scouring of cotton with scCO₂ was also comparable to better than conventional water based scouring. The scCO₂ scoured fabrics were tested for mechanical properties and for dyeing by conventional means and were found to be acceptable.

Dyeing of fabric and garments : Polyester and nylon yarn, fabric and garments were dyed in scCO₂ using raw or non-formulated disperse dyes, and mixtures of raw dyes. The color uptake in the fabric was measured using a Datacolor colorimeter. A novel dye vessel design and process cycle have been developed which allows reproducible and uniform dyeing in a < 2 hour cycle. Commercial scale-up continues.

Dye Recovery : We have demonstrated in a potential new application in which a significant portion of a dye or dye mixture infused into polyester or nylon can be recovered for re-use by extracting with scCO₂. This is not possible in the dyeing process practiced today.

Abstract Text

A novel thiourea-based sorbent was prepared from N-{2-[Bis(2-aminoethyl)amino]ethyl}aminomethyl-polystyrene resin by chemical modification of resin with 3-pyridyl isothiocyanate. The new sorbent was characterized with FT-IR and examined for solid phase extraction of noble metals, including Au(III), Ir(III), Pd(II), Pt(II) and Ru(III). Sorption efficiency was studied via both off-line and on-line solid phase extraction (SPE). ICP-MS analysis of the aqueous solutions indicated that the sorbent possessed high selectivity allowing quantitative sorption (93–99%) of Au(III), Ir(III), Pd(II), Pt(II) and Ru(III) from relatively acidic solutions (pH: 1.0-2.0). The sorption of common transition metals, such as Cu, Co, Ni, Fe, Mn and Zn was insignificant. The analytes retained on the sorbent at pH 2.0 were eluted with 0.05 M thiourea in 0.1 M HCl and measured by ICP-MS. The procedure was successfully applied for SPE determination of Au, Ir, Pd, Pt and Ru in geological and soil samples by ICP-MS.

Co-Author(s) Ismet Basaran, Md. Alamgir Hossain, Zikri Arslan

Abstract Text

A new chelating resin of N-{2-[Bis(2-aminoethyl)amino]ethyl}aminomethyl-polystyrene polymer was prepared by anchoring salicylaldehyde onto the resin via -C=N- group. The salicylaldehyde functionalized resin was characterized by FT-IR, and then used as packing for separation of uranium(VI) and thorium(IV) in seawater and sludge samples by means of solid phase extraction (SPE) approach for ICP-MS determination. The influences of various analytical parameters, including load pH, eluent concentration, sample and eluent flow rates have been investigated on the sorption of U(VI) and Th(IV) on the chelating polymer. The U(VI) and Th(IV) radionuclides were quantitatively retained on the column at pH 6.0, eluted with 2.0 mL of 5% (v/v) HNO₃ and then determined by ICP-MS. The column possessed very selectivity to the radionuclides. No significant retention was noted from transition metals ions or rare earths metals by ICP-MS analysis. The developed method was validated by analysis of certified reference materials of Nearshore Seawater (CASS-4) and domestic sludge (SRM 2781), and successfully applied to the determination of U(VI) and Th(IV) in coastal seawater and estuarine water samples.

Abstract Text

Isocyanates are a main component in the production of polyurethane (PUR) materials. Exposure to isocyanates can put workers at risk for respiratory disorders like "occupational asthma". Dry air sampling devices were used in this field study of exposure assessment during the simulated spray paint coating. The dry air sampler allows sensitive and reliable detection coupled with convenient and safe use. The unique design of the dry sampler allows replenishment of the derivatization agent to the particle filter that allows longer sampling time (more than 8 hours). Low detection limits can be obtained by the analysis of urea derivatives by LC-MS-MS in the testing laboratory.

The sampling device will derivatize both the isocyanate monomers and oligomers. Monomers and polymers of isophorone diisocyanate (IPDI), and 1,6-hexamethylene diisocyanate (HDI) were detected in this study. HDI polymeric species included HDI-Isocyanurate, HDI-Uretidone and HDI-Biuret. The IPDI polymeric form IPDI-Isocyanurate was also detected. Quantitative analysis of the isocyanates was possible by using the available deuterated internal standards. The quantitative results indicated that HDI-Isocyanurate and IPDI-isocyanurate were present at the highest concentration in the air during spraying.

Abstract Title **Mercury Speciation by Selective Pre-Concentration and Liquid Chromatography Cold Vapour Atomic Fluorescence Spectrometry (Prec HPLC-CV-AFS) - An Efficient Method for Many Sample Matrices**

Primary Author Cornelius C. Brombach
University of Aberdeen

Date: Tuesday, March 10, 2015 - Afternoon

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Bin Chen, Eva Krupp, Jorg Feldmann, Warren T. Corns

Abstract Text

Mercury is recognized as one of the most toxic elements in nature and its toxicity, bioavailability and transport is dependent on the specie. Organic mercury compounds are known as the most toxic species of mercury and show the highest bioaccumulation. The concentrations of the species in environmental samples can vary from really low concentrations in water (pg L⁻¹) to high concentrations in predator fish and cetaceans (mg kg⁻¹) and can be challenging for analytical scientists. Speciation in low concentrated samples is nearly impossible with most instrumentation without any preconcentration of the mercury species. In this work, we use an online preconcentration based on the strong interaction of mercury with sulfur compounds and the subsequent separation and analysis via HPLC-CV-AFS. The method was applied for water samples (e.g. urine, crude sewage, sea water) and MeHg⁺ was found in spiked samples with recoveries from 91 to 102 %.

Different environmental relevant samples were digested/extracted to different protocols and analyzed with this method: Estuarine sediment ERM[®] CC-580, various marine materials (e.g. TORT-2, DOLT-4, DORM-2) and hair reference materials. Satisfactory recovery was found ranging from (90 - 105 %). Additionally, a method comparison was performed with the standard speciation method isotope dilution ID-GC-ICP-MS for rice samples and different tissues of long-finned pilot whales and good correlation coefficients (0.9663 R² and 0.9728 R², respectively) obtained. The developed method requires a minimal amount of sample pretreatment, is low in costs, achieves a LOD of 0.04 ng L⁻¹ for MeHg⁺ producing reliable and good results.

Abstract Text

The EPA proposed new rule (40 CFR, part 423) is an attempt to reduce the amount of toxic metals and other pollutants discharged to surface water from power plants. Previous regulations do not consider the additional burden of water discharge pollutants from air pollution control systems such as flue gas de-sulphurization (FGD), selective catalytic reduction (SCR) and flue gas mercury control (FGMC).

The main pollutants of concern include metals (e.g mercury, arsenic and selenium), nitrogen and total dissolved solids (TDS). Toxic metal discharges have a huge impact on the environment as they bio-accumulate in wildlife and cause a wide array of human health issues. The new ruling would establish new and additional requirements for wastewaters associated with FGD wastewater, fly and bottom ash transportation water, flue gas mercury control water, combustion residual leachates from landfill and surface impoundments, metal cleaning wastes and gasification wastewater. Depending on the final options the best available technology (BAT) that is economically achievable will need to be applied to reduce pollutant discharges. This is particularly challenging for dissolved forms of As, Se and Hg as they are not removed by surface impoundments.

PSA have a number of online and laboratory measurement based on AFS and sampling solutions to confirm the efficiency of the wastewater treatment processes and for compliance monitoring. These are outlined with recent experiences and data from the field.

Abstract Text

In the past decade, an emerging branch of science called exposomics has shown that for many non-communicable diseases, the impact of the environment on the human body can account for as much as 90% of factors influencing onset and progression of diseases. This has given rise to toxin measurements in children and adults with diseases such as autism, ADHD, asthma, and many others. The ultimate goal of the new field of exposomics is to assess the effects of exposure on the epigenome and assess epigenetic modifications. Assessment of toxins and their origins has become a very important aspect of exposomics so that origin and dose, either acute and or chronic, from the air in the environment and indoor exposures can be measured and health implications assessed. To help answer exposomic questions, improved methods of solid phase adsorption have been developed in this work to quantify the volatile and semi-volatile toxins in outdoor and indoor air. Under the new methods, analyses of these solid phase extraction collections are performed with thermal desorption and direct isotope dilution (D-ID) mass spectrometry that uses no serial dilutions or external calibration curves. D-ID metrology facilitates calculation of analyte concentrations using a mathematical framework that utilize isotopic abundance ratios between the analyte and isotopically enriched standards. Examples of calibration curve versus direct isotope dilution thermal desorption GC-MS in an automated system is discussed and compared with traditional GC-MS analysis.

Abstract Text

Polyurethane form-like adsorbent(PUF) was successfully prepared using polypropylene glycol(PPG), 4,4'-Diphenylemethane diisocyanate(MDI) and Tri-n-octylamine(TnOA), and then PUF was impregnated with hydrochloric acid. The resulted adsorbent (HCl-PUF) used to remove Cr(VI) from environmental water samples, and Cr(III) was not adsorbed on HCl-PUF. Chromium exists widely in nature as both trivalent and hexavalent forms. Although, Cr(III) is an essential element for humans at trace levels, Cr(VI) has great toxicity and carcinogenicity at low concentrations. Cr(VI) is typically present in aqueous solutions, such as CrO₄²⁻ anion. Therefore, HCl-PUF is an anion exchange adsorbent.

In this study, the preparation conditions of HCl-PUF and the adsorption conditions of Cr(VI) on HCl-PUF were investigated, such as the amounts of reagents, the adsorption time, the solution pH, and coexisting ions. Cr(VI) was quantitatively adsorbed on HCl-PUF at a pH range 1.0-6.0 from aqueous solutions and their adsorption isotherms were fitted by the Langmuir equation. The maximal adsorption capacity of Cr(VI) is 1.48×10⁻³mg/g. The property of HCl-PUF was extended to the recovery of Cr(VI) in the environmental water samples.

Abstract Text

Rice (*Oryza sativa*) is a staple food for many people and is grown around the world. In US it is grown in Gulf Coast States (Louisiana, Mississippi and Texas) as well as Arkansas, California, and Missouri. Many metals in low concentrations can present adverse health effects, and, hence, the concentration of metals in rice is important for risk assessment. This work presents the results and comparison of a study of selected metals (As, Cd, Cu, Cr, Fe, K, Mg, Mn, and Zn) in rice from Gulf coast states as well as a comparison from selected areas from around the world (India and Bangladesh). Results were determined using inductively coupled plasma-optical emission spectrometry as well as anodic stripping voltammetry for selected species of metals, particularly arsenic and chromium.

Abstract Text

In this presentation, the use of abandoned mine drainage (AMD) for irrigation of lettuce, sunflower, and tomato will be presented and discussed. The use of AMD for irrigation of crops has been explored; yet, much of the available information appears to deal with acid mine drainage and its treatment with lime to raise its pH to near neutral levels. The purposes of this investigation are: 1) to examine how the use of untreated, near-neutral-pH AMD from southwestern Pennsylvania for irrigation of tomatoes, lettuce, and sunflowers affects the growth of these plants; and 2) to determine the concentrations of iron, aluminum, manganese, and arsenic in the irrigated plants. A group of tomatoes, lettuce, and sunflowers are presently being grown at the Lowber, PA AMD passive treatment facility and irrigated with AMD from the settling ponds and wetlands. A second group of the same plants are currently being grown at the residence of one of the authors and watered with tap water spiked with 10 ppm each of Fe, Al, Mn, and As. Control plants, watered with uncontaminated water, are being grown in each group. The plants will be harvested, sectioned, wet-ashed, and analyzed for the aforementioned metals by flame (FAAS) and hydride generation (HGAAS) atomic absorption spectrometry. Results for Fe, Al, Mn, and As in the plants from each group grown in this study will be presented and discussed, as will plant growing and harvesting, sample preparation, analytical methods, and future plans for this project.

Abstract Text

Milk is heat-treated or pasteurized prior to distribution to destroy potentially dangerous bacteria. Heat treating milk also converts or degrades lactose to epilactose and lactulose. There are benefits to the presence of these breakdown products. First, they allow the milk industry to monitor carefully milk degradation. Second, the indigestible disaccharides have pharmaceutical benefits. For example, lactulose is used to treat constipation. Further, epilactose has beneficial prebiotic effects for the treatment mal-digestion. Thus, detailed chromatographic separation and analysis of these sugars are abundant in literature including the USP.

The HPLC separation of lactose, lactulose and epilactose is outlined in the United States Pharmacopeia Convention (USP). However, it is difficult to separate these saccharides completely.

Recently, the effective, simultaneous separation of lactose, lactulose, and epilactose was demonstrated using the new Shodex HILIC column (4.6 mm x 250 mm). The polymer based polyvinyl alcohol packing material is modified with tertiary amino functional groups to provide separation. The separation of these disaccharides takes a total of 15 minutes with resolution greater than 1.6. The calibration curves have demonstrated linearity between 500 µg/L and 10 g/L with RI detection.

Abstract Text

In contrast to trends towards miniaturised and portable instrumentation to be used out of the laboratory (on-site, in-field), portable liquid chromatography (LC) instrumentation for rapid on-site analyses has not progressed towards routine applications. In previous studies on portable LC, most of the designs relied strongly on in-house fabricated components, thus significantly limiting the availability of such portable systems for other users.

Here we investigated a design philosophy of a portable medium-pressure LC system based on using off-the-shelf easily accessible components. The basis of the system is a modular microfluidic platform with the components assembled in a flexible manner on a breadboard (Fig.1). The components are syringe pumps and switch valves, joined with capillaries and microfluidic fittings, complemented with other components, including an injection valve and on-capillary detectors, all controlled by a PC. The pumping system is formed by miniaturised syringe pumps (5, 20 and 100µL options). Two pairs of pumps were used for each mobile phase to enable gradient elution capability, connected with two microfluidic switching valves, and then connected together through a Y-connector, thus providing a low hold-up volume for gradient formation. A 4 or 20 nL nano-LC sampling valve was used for the injection system, connecting to a capillary LC column (100 µm i.d., 50- 250 mm length, C18 RP monolith). Photometric detection was conducted through the capillary (100 µm i.d. PTFE-coated fused silica) with an LED-based UV-vis-NIR photometric detector, and/or an end-column electrochemical detector (amperometric and/or potentiometric). The characterisation of this portable LC system was conducted theoretically and experimentally, including the operating pressure, the performance in gradient mode and the performance of the detectors. The initial test analytes included primarily charged and uncharged food dyes of varying hydrophobicity.

Abstract Text

Diabetes is a metabolomic disease that affects many people in the world and in the United States. One of the major health effects associated with diabetes is the elevated levels of glucose in the bloodstream, which can lead to non-enzymatic glycation of serum proteins such as human serum albumin (HSA). Sulfonylurea drugs are a class of anti-diabetic drugs used to treat diabetes. Second generation sulfonylurea drugs are most commonly used to treat type II diabetes because of their effectiveness and ease in excretion from the body. The purpose of this study was to use high-performance affinity chromatography (HPAC) to examine the binding of various second generation sulfonylurea drugs to HSA with various stages of in vitro glycation. Frontal analysis was used to provide data on the overall affinity and number of binding sites for HSA and glycated HSA with various sulfonylurea drugs. Zonal elution competition studies were used to detect any changes in site-specific interactions that may have occurred as a result of glycation for the same sulfonylurea drugs at major drug-binding sites on HSA. The results of these studies should aid researchers in pharmaceutical development and in personalized medicine for the treatment of diabetes, as well as provide a better understanding of how the metabolomic effects of diabetes can affect drug binding in the body.

Abstract Text

In this study, the effect of random versus site-directed immobilization techniques on the performance of antibody-based HPLC columns was investigated using a single-domain camelid antibody (VHH) directed against methotrexate as a model system. First, the high flow-through support material POROS-OH was activated with disuccinimidyl carbonate (DSC), and the VHH was bound via random amines located on the protein's surface. The resulting column was characterized by Frontal Affinity Chromatography (FAC). Then, two site-directed techniques were explored that were expected to increase column efficiency by immobilizing the antibody via its C-terminus, i.e., away from the antigen-binding site. In one approach, a poly-lysine tail was added, and the antibody was immobilized onto DSC-activated POROS. In the second site-directed approach, the VHH was modified with the Avitag peptide, and a biotin-residue was enzymatically incorporated at the C-terminus. The biotinylated antibody was then immobilized onto Neutraavidin-derivatized POROS. While FAC analyses showed that both of the site-directed approaches yield better results than the random immobilization, the by far highest efficiency was determined for the immunoaffinity column based on Avitag-biotinylated antibody.

Abstract Text

Contamination and adulteration of heparin (HEP) have elevated the importance of separation and detection of glycosaminoglycans (GAGs) to ensure product quality and safety. Being a natural product, HEP extracts can contain other GAGs, such as chondroitin sulfate (CS) or dermatan sulfate (DS) but unnatural adulterants such as oversulfated chondroitin sulfate (OSCS) must also be checked. The current HPLC/UV method, established by the FDA and USP, for separating and detecting HEP and other GAGs is performed on a low capacity strong anion exchange column with gradient elution using a concentrated sodium perchlorate eluent. Despite the ability to separate HEP from OSCS, this method tends to suffer from long run times and broad peaks. Previously, we have shown ion exclusion chromatography can be effective for the separation of hyaluronic acid (HA) from either HEP, CS, or DS. Resolution of HEP and OSCS was incomplete. To the best of our knowledge, weak anion exchange (WAX) chromatography has not been explored in depth to separate HEP from OSCS and other GAGs. We adopted for use a commercially available 4.6 mm x 50 mm column packed with 5 micron DEAE derivatized methacrylate mono-disperse porous polymer particles. The following gradient mobile phase of initially 80% A [2.6 mM sodium di-hydrogen phosphate (pH 3.0)]-20%B [1 M sodium perchlorate in A] was changed to 10%A-90% B in 60 min at various flow rates ranging from 0.2 to 0.8 mL/min with detection at 202 nm. Using 0.8 mL/min, resolution of HA, CS or DS, HEP, and OSCS was possible in less than 30 min. HA, evident as a sharp peak, eluted in less than 1 min, CS or DS and HEP were resolved at about 12 and 17 min, respectively, and OSCS was retained at 29 min but with a baseline peak width of less than 6 min. Lowering the flowrate did not change peak resolution significantly. Raising the pH to change the ion exchange capacity of the column and changing the type of weak anion exchange column are under study.

Abstract Title **Determination of Ammonia in Tobacco Filler from 24 Brands of Little Cigars and Cigarillos Using Ion Chromatography**

Primary Author Shakia Smith
Centers for Disease Control and Prevention/ORISE

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Christina Watson, Clifford H. Watson, Roberto Bravo

Abstract Text

Little cigars and cigarillos (LCC) are widely available in the U.S. and historically have been less costly than cigarettes. Unlike cigarettes, LCC are offered in a variety of flavors including vanilla, wine, cherry, and raspberry, which could appeal to novice smokers. During manufacturing, a variety of chemical additives are added to the tobacco to affect the flavor, taste, and marketability of the products. Ammonia is an additive that may increase nicotine bioavailability and addiction potential by boosting the relative amounts of the free-base form of nicotine in smoke, as well as increasing the "harshness" or "mouth feel" typical of cigar smoke. For this study, tobacco from 24 brands of LCCs was analyzed for ammonia content. Ammonia levels were determined using ion chromatography coupled with conductivity detection. Of the 24 brands, ammonia levels in little cigars and cigarillos spanned 0.8 to 3.7 mg/g. This range of ammonia is similar to reported values for cigarettes (0.15 to 2.4 mg/g). Despite their visual-physical differences, LCCs and traditional cigarettes are similar with respect to ammonia levels in the brands tested. The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Abstract Title **Determination of Collagen Content in Eggshell Membrane Products through Analysis of Hydroxyproline Using Microwave Digestion and HPLC**

Primary Author Ken Bolda
NOW Foods

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s)

Abstract Text

Eggshell membrane is a novel dietary supplement containing naturally occurring glycosaminoglycans and fibrous proteins such as collagen type I that has a potential of becoming a new natural therapeutic for JCT (joint or connective tissue) disorder. Since collagen type I is a primary constituent of the eggshell membrane, quantitation of collagen in raw materials and finished dietary supplements could serve as an appropriate quality control measure. The analytical methodology for determination of collagen in eggshell membrane is very limited; therefore we developed and validated a simple method for analysis of collagen in raw materials and finished dietary supplements. Collagen containing products are hydrolyzed in sulfuric acid using microwave digestion. The hydrolyzed material is then diluted in water and derivatized with 6-Aminoquinoline-N-hydroxy-succinimidyl carbamate. Amino acids are separated using reverse phase chromatography with UV detection at 260 nm. Target amino acid hydroxyproline is quantitated using a primary grade standard. Based on the amount of hydroxyproline, collagen content can be determined using known/published conversion factors.

The University of Tokyo

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Makoto Tsunoda, Takashi Funatsu

Abstract Text

Low-molecular-weight biothiols play important roles in biological processes. Although many analytical methods for biothiols were developed, simultaneous determination of multiple biothiols has not been successful because of the difficulty in retaining biothiols on reversed phase chromatography (RLC). Hence, in this study, we developed an analytical method for multiple biothiols based on HPLC-fluorescence detection under hydrophilic interaction chromatography (HILIC) conditions, where the retention and separation of highly polar compounds is easily achieved. Thiols were derivatized with thiol-selective fluorogenic reagent, ammonium 7-fluoro-2,1,3-benzoxadiazole-4-sulfonate (SBD-F). Among the six HILIC columns examined (bare silica, amide, amino, diol, phosphorylcholine, and sulfoalkylbetaine columns), the sulfoalkylbetaine column proved to be the best for the SBD-thiols separation. Eight thiols ([i]N[/i]-acetylcysteine, cysteamine, homocysteine, cysteine, cysteinylglycine, glutathione, [gamma]-glutamylcysteine, and internal standard, [i]N[/i]-(2-mercaptopropionyl)glycine) were well separated within 10 min. The detection sensitivity was 30-300 times higher compared to RPC methods, partly due to the enhancement in the SBD-thiol fluorescence owing to the acetonitrile-rich mobile phase used. The method successfully quantified six biothiols in a human plasma sample with good precisions. This method should be a useful tool for investigating the relationship between sulfur metabolism and related diseases.

Abstract Title **Separation of Coumarin in Skincare Cream on PHEMA Column by Using HTLC**

Primary Author Sema Akay
Aksaray University

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Berkant Kayan, Murat Sener, Yu Yang

Abstract Text

Coumarin is an active principle found in several vegetable species with a characteristic smell of vanilla. It is widely used as a perfume fixer, paint and spray additive, skin-care-related consumer products and in cleaning products. It also possesses clinical value due to antibiotic and analgesic properties, besides its potential use in the treatment of cancer and AIDS(1,2). High temperature liquid chromatography (HTLC) deal to liquid chromatography separations performed at elevated temperatures using organic solvent-water mixtures as the mobile phase. The consumption of organic solvent in HTLC mobile phase is considerably reduced with increasing temperature (3). In this study, 1-naphthylamine (NA) attached PHEMAH (NA-PHEMAH) beads were prepared by diazotization of 1-naphthylamine (NA) and covalent coupling of it to the PHEMAH beads for stationary phase. Then Vaseline cocoa butter lotion sample was separated on PHEMA column by using HTLC. HTLC results revealed that NA-PHEMAH stationary phase yielded reasonable separations of skincare cream with symmetrical peak.

Abstract Text

Non-mammals, such as [*Tribolium castaneum*] - flour beetle, [*Danio rerio*] – zebrafish, and [*Aiptasia pallida*] – sea anemones, offer new model systems and thus new challenges for the measurement of signaling molecules. To further understand the molecular changes of amino acid and phytoestrogen release associated with behavior, separation methodologies were developed for high-performance liquid chromatography. Amino acid neurotransmitters were derivatized by bonding an alkylthiol-isoindole to the amino acid amine using O-phthalaldehyde (OPA) and sodium sulfite. The high pH sensitivity of each derivative limited the use of phosphate buffers, typically used at neutral pH. Instead, the effects of a citrate-acetate based mobile phase were investigated to not only allow resolution of these species but also increase their sensitivities when using an electrochemical-based detection system. For the detection of phytoestrogens such as isoflavones, which have been known to affect reproduction of sea life, solid phase extraction and a formic acid-acetonitrile gradient for high performance liquid chromatography was developed. Three isoflavones: diadzein, genistein, and biochanin A were measured in sea waters containing symbiotic and aposymbiotic sea anemones. It is hypothesized that the symbiotic relationship between these anemones and their algal counterparts may regulate the method sea anemones reproduce, specifically the algae release compounds that decide whether the anemones reproduce sexually or asexually. It is hoped that the methods described here will provide greater insight into how behavior is affected by the development of signaling pathways in these species.

Abstract Text

Retention behavior of pyrazine derivatives on various types of alkylsilane stationary phases was studied in reversed-phase liquid chromatography (RPLC). The retention factors of pyrazines were measured with changing column temperature. With an acetonitrile/water mobile phase, an abnormal temperature effect of the pyrazines' retention was observed. The retention factors of all the alkylpyrazines studied were increased with increasing column temperature on an octadecylsilica (C18) stationary phase. To discuss the thermodynamics for the retention of pyrazines, van't Hoff plots were prepared. The slope of the plots indicates the standard enthalpy of transfer for the solute from the mobile phase to the stationary phase. Non-linear van't Hoff plots were obtained for some pyrazines, indicating that the retention mechanisms for the pyrazines were not constant over the temperature range studied (20-60[degree]C). Similar trends were also observed on all other stationary phases including butylsilica (C4), octylsilica (C8) and triacontylsilica (C30) phases. In contrast, no similar temperature-dependence was found with methanol/water mobile phases, suggesting that the abnormal temperature effect on the retention of the pyrazine derivatives might be mainly induced by acetonitrile-based mobile phases. Although further theoretical studies should be carried out, the results contribute to a better understanding of the retention mechanism of pyrazines in RPLC.

Abstract Text

Vitamins play vital roles in the metabolic activities of the body. However, because they cannot be synthesized in sufficient quantities in the body, if at all, they must be ingested either in our meals or by other means, such as tablets. Vitamins can be classified into two groups, water-soluble and fat-soluble, and their analysis is generally conducted by high-performance liquid chromatography. The water-soluble type consists mainly of highly polar basic components which exhibit weak retention in analysis by reversed-phase liquid chromatography. Since they exhibit weak retention, the analysis is typically conducted using ion-pair reagents. That makes it difficult to apply gradient elution. On the other hand, the fat-soluble type consists of hydrophobic components. They are usually analyzed by reversed-phase liquid chromatography with organic solvent mobile phases or normal-phase liquid chromatography.

In this study, a Shim-pack MAqC-ODS I was used to analyze water- and fat-soluble vitamins in a single method. This column contains ODS-modified and metal-doped stationary phase, so it was able to retain the weakly-retained components without ion-pairing reagents. In addition, by using a 100% organic solvent mobile phase after water-soluble vitamins were eluted, fat-soluble vitamins were also able to be analyzed.

Abstract Text

We developed an easy-to-use analytical method for amyloid fibrils by high-performance liquid chromatography (HPLC) with post column fluorescent labeling. Thioflavin T (Th T), which was used as a labeling agent for amyloid fibrils, is a traditional probe for the confirmation of amyloid fibril formation. Amyloid fibrils play important roles in several neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease. Although it had been previously known that the amyloid fibril formation takes place as a result of conformational change of the proteins from a stable α -helical structure into a β -sheet structure, the details of the amyloid fibril formation process are not completely understood. The traditional fluorescence spectroscopy measurement is used for monitoring the aggregation reaction, but only the total amount of the amyloid aggregates such as amyloid fibrils and fibrillar oligomers were measured in this method. In order to understand the fibril formation process, the development of an efficient method enable to separate and detect the amyloid aggregates is required.

In this work, the Th T labeling of the amyloid fibrils in sample solution was performed following the separation of the different-sized amyloid fibrils by a reversed-phase column with the mobile phases containing hexafluoroisopropanol. The fluorescence was monitored at 482 nm, with a maximum excitation wavelength at 450 nm. The developed method detected overlapping peaks of the amyloid fibrils within 3 min. In addition, the novel method showed its sensitivity for the detection of the amyloid aggregates was several-fold higher as compared to the traditional fluorescence spectroscopy measurements. These results suggest that this analytical method may be used to analyze the amyloid fibrils and identify an inhibitor of the fibril formation.

Abstract Text

A new method has been developed for determining the organic impurities in Ext. D&C Violet No. 2 (monosodium salt of 1-hydroxy-4-(o-sulfo-p-toluidino)anthraquinone). The color additive is listed under 21 CFR 74.2602a for use in externally applied cosmetics and is required to be batch certified by the U.S. Food and Drug Administration (FDA). The impurities determined are the intermediate starting materials (p-toluidine, 1-hydroxyanthraquinone, and 1,4-dihydroxyanthraquinone); subsidiary colors (mainly the disodium salt of 1,4-bis(o-sulfo-p-toluidino)anthraquinone); and sodium salts of sulfonated p-toluidines. The new method uses ultra-performance liquid chromatography (UPLC) with a 1.7- μ particle size C-18 column, 0.1 M ammonium acetate and acetonitrile as eluants, and photodiode array detection. The method was validated by measuring linearity, accuracy, precision, and limit of detection for each impurity. Six-point linear regression calibration curves had r² values that were all greater than 0.999. Recoveries of impurities were 99 to 101%. Samples from 20 previously certified lots of Ext. D&C Violet No. 2 were analyzed with the new method, and the results are comparable with the results previously obtained by gravity column chromatography, thin-layer chromatography, and isoctane extraction. The new UPLC method determines all of the impurities in a single analysis, uses green technology by reducing organic waste generation, and saves time and labor.

Abstract Text

Carbohydrates are important food components affecting taste and nutrition. The determination of the types and levels of carbohydrates in foods is important for energy evaluation, nutritional labeling, quality control and for identifying any possible product adulteration.

Carbohydrate analysis can be problematic since they are very polar compounds, exhibit similar structural characteristics and do not have a suitable chromophore. Their analysis can be performed after suitable derivatization using techniques such as gas chromatography, capillary electrophoresis, HPLC with ultraviolet (UV) or Fluorescence (FL) detection or HPLC with mass spectrometry (MS). These methods utilize derivatization to improve the chromatographic resolution and detector sensitivity; however they can lead to increased assay variability. Direct methods that do not require derivatization include HPLC with refractive index (RI), High-Performance Anion-Exchange Chromatography with Pulsed Amperometric detection (HPAE - PAD) using a high pH mobile phase or HILIC mode chromatography with charged aerosol detection. This poster presents approaches for carbohydrate analysis that solve the challenges for separation and detection of carbohydrate analysis without requirement for laborious derivatization: HPLC with pulsed amperometric detection (HPLC-PAD), HPLC with charged aerosol detection (HPLC-CAD).

When the PAD option on the electrochemical detector is coupled with a gold working electrode, it provides high sensitivity and selectivity for the measurement of carbohydrates in complex food sample matrices. The charged aerosol detector is a mass-sensitive detector that can measure all non-volatile, and many semi-volatile compounds in a sample. The method has a limit of detection of <10ng, on column and a wide dynamic range that covers nanogram to microgram levels with high reproducibility. Application examples for various juice samples, milk and other dairy products, syrup and honey will be discussed.

Abstract Text

There is considerable interest in botanical supplements due to their purported health benefits. Mangosteen (*Garcinia mangostana* L) is a tropical fruit that is indigenous to Southeast Asia, where it has been historically used to treat abdominal pain, diarrhea, dysentery, inflammation, wound infection, suppuration, chronic ulcer and as a homeopathic therapy in the treatment of Parkinson's disease. Such therapeutic benefits have been mostly attributed to a unique family of compounds referred to as xanthonenes that are most abundant in the pericarp of the fruit. Five major xanthonenes present in mangosteen pericarp, include 6-mangostin, 3-isomangostin, gartanin, 8-desoxygartanin and 9-hydroxycalabaxanthone.

Chromatographic analysis of the xanthonenes and other important analytes contained in this supplement presents is challenging. Reversed phase HPLC with UV detection is widely used for the analysis of xanthonenes, but such methods lack analyte resolution and/or require exceedingly long analysis time. Improving these issues, by using UHPLC may still require >25 mins to complete since the flow rates required to achieve optimal column efficiency generate exceedingly high back pressures, typically beyond UHPLC system limits. This situation is addressed by the new Vanquish UHPLC system, which consists of a binary parallel pump capable of operating at pressures up to 1500 bar, autosampler and diode-array detection.

Consequently, UHPLC columns containing smaller particle size can be operated at high flow rates to improve analyte resolution and sample throughput. The analytical power of the Vanquish system is typified by the improvements in analyte resolution and reduced run time shown for the analysis of mangosteen pericarp.

Abstract Text

Flavan-3-ols, known also as proanthocyanidins or condensed tannins, after lignans are the second most common class of natural phenolic substances found in nature. Single linked, B-type procyanidins occur in many foods, with those from apples and cocoa being the most prominent in western diet. A possible connection between procyanidins and cardiovascular disease is particularly interesting. The double linked, A-type procyanidins occur in cinnamon and cranberries and are believed to contribute to anti-diabetic and anti-UTI properties of these foods. Procyanidins form chains containing polymerized subunits of epicatechin and catechin, with the number of subunits being between 2 and 30. With the ever increasing interest in determining their significance as dietary antioxidants and pharmacologically active components, better analytical techniques allowing their standardization in dietary supplements are required. We developed a sensitive and selective gradient HPLC method combining photodiode array and coulometric electrochemical array detection to resolve and quantify numerous procyanidins in different foods/supplements. This approach also enabled the estimation of standard purity and abundance of contaminants. A second method, using charged aerosol detection, was used to determine the presence of impurities that either lack a chromophore or are not electrochemically active. A third method was developed using gradient UHPLC with UV detection. This approach significantly shortened the analysis time from 30 to <5 minutes, while maintaining analyte resolution.

Abstract Text

It has been estimated that less than 1% of all bacteria have been cultured in the laboratory environment. To understand the intricacies of microbial ecology, we need isolates that can be easily characterized and cataloged. Traditional methods for characterization utilize biochemical methods and molecular techniques allowing for identification down to the species level. However, most of these methods are either too costly or not rapid enough for analysis of large groups of isolates. This work sought to develop a reverse phase HPLC method for identification of pink bacterial carotenoids unique to the genera [i]Deinococcus[/i] and [i]Hymenobacter[/i]. [i]Deinococcus[/i] strains are the only known producers of deinoxanthin lending to the notion that the presence of deinoxanthin suggests that the strain must be [i]Deinococcus[/i]. [i]Hymenobacter[/i] strains are known to produce many derivatives of the carotenoid flexixanthin, with 2'-hydroxyflexixanthin being the common carotenoid observed. Bacterial cultures were isolated from submerged freshwater substrates. Pink colonies were then isolated for testing and analysis. To verify the identity of putative [i]Deinococcus[/i] and [i]Hymenobacter[/i] species, 16S-rRNA analysis was used. A total of 122 isolates were analyzed using our method resulting in positive identification of 7 deinoxanthin and 72 2'-hydroxyflexixanthin producing bacteria with 43 isolates exhibiting unidentified carotenoids. The method developed was highly effective in not only determining the genus of a given isolate, but also in denoting chromatogram differences indicative of species divergence, such as additional minor carotenoids. Future work will focus upon expanding our method to search for carotenoids unique to other genera.

Abstract Text

When analyzing serum or plasma, the very nature of the matrix can cause problems with the analytical methodology. Endogenous components such as salts, proteins and phospholipids are all present and can have a marked effect on instrument response in terms of ion suppression or enhancement effects. This variation in signal can lead to quantitation issues and method reliability problems. In recent years a number of filter plates have been developed to address these specific interferences. This poster evaluates the performance of a novel 96-well filter plate for the simultaneous removal of proteins and phospholipids prior to LC-MS/MS analysis. Protein removal was compared via gel electrophoresis using a NuPAGE Novex 12% Bis-Tris mini gel with MOPS SDS running buffer. Phospholipids and recovery and signal intensity for a variety of acidic, basic and neutral analytes were analyzed using a Waters 2795 liquid handling system coupled to a Quattro Ultima Pt triple quadrupole mass spectrometer. Analyte monitoring involved positive ion acquisition using electrospray ionisation in the MRM (multiple reaction monitoring) mode. For each analyte protonated molecular ions were fragmented to the most intense product ion. Phospholipid analysis involved monitoring MRMs of the most intense phospholipid ions (selected from full scan, SIR and precursor ion monitoring), fragmenting to the common 184 production.

Rough protein quantitation of the precipitated extracts showed greater than 99% protein removal for a 1:3 matrix:ACN crash ratio. Phospholipid free extracts were obtained when using 1:3 or 1:4 matrix:ACN crash ratios. Using 1% formic acid in ACN as the precipitant also resulted in good removal of phospholipids. Recovery experiments for a variety of analytes with varying logP and pKa values demonstrated recoveries greater than 60%. Full results, discussion and conclusions will be presented in the final poster.

Abstract Text

Laboratories are tasked with making blended formulations for use in environmental, pharmaceutical and biopharmaceutical applications for use with HPLC, gas chromatography and LC-MS. These formulations are often developed without a full Health Safety and Environmental (HS&E) review. The hazards can come from the neat chemicals used to prepare the formulation, blend or buffer. They can also come from the new hazards associated with the formulation. HS&E groups tend to focus on the neat chemical or ingredient used to make the formulation. HS&E issues from the process of making buffers and chemical solutions can reduce productivity and create hidden cost within a company.

The poster will examine the hazards associated with preparing formulations in the lab. One focus will be the hazards associated with the neat components used to make formulations. The other focus will be on the lesser understood hazards of the new formulation for use in an application. These unknown dangers can have a direct impact to worker safety, chemical inventory management and productivity. A solution to this dilemma is to utilize commercially prepared formulations. Honeywell LabReady Blends by Burdick & Jackson is an example of an offering that is specifically suited to address these factors. When organizations choose to “buy” versus “make” their formulations, they are able to have a clearly defined product that meets the various requirements of governing bodies of lab chemical hygiene. The poster will demonstrate how adopting Honeywell LabReady Blends can decrease the hazards of preparing formulations in-house. The poster will also show how risk can be mitigated through the purchasing of commercially prepared formulations.

Abstract Text

Glyphosate is part of a group of herbicides referred to as phospho-herbicides and is the most commonly used herbicide worldwide with around 25% of the global herbicide market. In 2001, the EPA estimated that Glyphosate was the most commonly used active ingredient in pesticides with between 85 to 90 million pounds applied per year. It undergoes rapid microbial degradation in plants, soil and water to the metabolite aminomethylphosphonic acid (AMPA). In Europe, the following limit values were inferred for glyphosate: ADI (acceptable daily intake): 0.3 mg/kg of bodyweight; AOEL (acceptable operator exposure level), systemic: 0.2 mg/kg bodyweight/day. In addition, Codex alimentarius has defined a MRL (maximum residue limit) of 0.05mg/Kg in meat or milk and 30mg/Kg in cereals.

As very polar molecules, the analysis of Glyphosate and AMPA is still a challenge. Indeed, they are difficult to extract with organic solvents and common solid phase extraction (SPE) sorbents. A new SPE sorbent based on Molecularly Imprinted Polymers (MIP) was developed for Glyphosate and AMPA. A MIP is a synthetic material with artificially generated three-dimensional network which shows affinity for a target molecule. SPE results have shown a good ability of the sorbent to catch both molecules with good recoveries in elution without salts interference problem in different water matrices (mineral water; natural groundwater) and FOOD and FEED cereals matrices. This sorbent will also be tested in the framework of the development of integrative passive samplers (POCIS) for Glyphosate & AMPA.

Abstract Text

In the past decade, QuEChERS procedures have become standard methods for analysis of pesticides due to their cost-effectiveness and excellent performance. In many cases, the methods were developed and validated using spiked samples. However, evaluation of the methods for extraction of existing pesticide residues is necessary to fully confirm the methods' performance. In this work, the QuEChERS procedure was performed for the extraction of existing pesticide residues from a number of produce and/or food samples. The shaking of the samples was done either by hand for 1 minute, as written in QuEChERS methods, or by using a simple shaker/vortexer for 10 minutes. The extraction efficiency for both procedures was compared. The use of the shaker resulted in 10-15% higher yield of existing pesticides for the tested food samples. Introduction of the simple and inexpensive shaker to the laboratory workflow can result in significant improvement in pesticide yields and measurement accuracy.

Abstract Text

We invented a QuEChERS salts tablet, which made the QuEChERS extraction method for pesticides in fruits and vegetables even easier as regards dispensing the phase-separation salts. However, difficulties in making the tablet inhibited its production. Recent breakthroughs in the manufacturing process on a bench scale have enabled a better performing tablet that is easily handled and yields quantitative results comparable to commercially available QuEChERS salt packets. This presentation will share some promising results from this research.

Abstract Text

Extraction techniques are plentiful; however, determining which technique to implement for analysis can be difficult. Percent recovery, selectivity, ease of extraction, and ruggedness, must all be considered. It is the goal of this study to investigate three different extraction methods: QuEChERS (Quick, Easy, Cheap, Effective, Rugged, Safe), IL-SDME (ionic liquid single drop microextraction), and SPME (solid phase microextraction). In this discussion, the use of QuEChERS will be emphasized. QuEChERS is a liquid-liquid microextraction combined with a dispersive solid phase extraction cleanup. Primarily used for the extraction of pesticides from food products, QuEChERS has not yet been thoroughly investigated for forensic samples. This study will serve to determine if QuEChERS is a viable extraction method for the analysis of drugs in urine as well as compare this extraction method to the use of IL-SDME and SPME. In IL-SDME an ionic liquid drop is suspended above the sample until such a time that equilibrium has been reached. The drop is then desorbed in the GC inlet. This method is very similar to that of SPME except for the use of an ionic liquid drop rather than a coated fiber as the extraction media. The optimization of these techniques for the extraction of amphetamine, methamphetamine, morphine, benzoylecgonine, methadone, oxazepam, secobarbital, phencyclidine, 11-nor-9-Carboxy- Δ^9 -THC, and nortriptyline from urine will be discussed as well as the sensitivity and selectivity of the method via gas chromatography-mass spectrometry (GC-MS).

Abstract Title **Application of Extraction Induced by Emulsion Breaking in the Determination of Chloride in Brazilian Crude Oils by Ion Chromatography**

Primary Author Ricardo J. Cassella
Universidade Federal Fluminense

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Alessandra R. Cassella, Fernanda N. Feiteira, Nicolle F. Robaina

Abstract Text

Chloride occurs naturally in crude oil, since petroleum is in constant contact with saline waters and sediments that contain large concentrations of this anion. Therefore, the concentration of chloride (reported as NaCl) in crude oils depends on the geographical region where it is deposited and also on the oilfield region where it is found. The presence of chloride in crude oil can lead to the formation of HCl during refining, which provokes corrosion of metallic pipelines and other unities. Additionally, chloride can deactivate Ni- and Pd-based catalysts widely used in catalytic cracking. This work proposes a novel methodology for the determination of chloride in crude oil samples by ion chromatography (Dionex ICS-2100 equipped with an AS15 column) employing the extraction induced by emulsion breaking (EIEB). In fact, we are proposing a new way to perform EIEB, in which oil-in-water emulsions are employed instead of oil-in-water ones. The method was based on the formation of w/o emulsions between crude oil (1.0 g) with a Triton X-114 solution (5 mL). After formation, the emulsions were broken and the aqueous phases containing the extracted chloride were collected for analysis by IC. Several parameters that could affect the performance of the method were evaluated. Under optimum conditions, a 2.5% m/v Triton X-114 solution must be used for emulsification with 0.5 g of crude oil diluted with 0.5 g of mineral base oil. The emulsion must be agitated for 60 min before its breaking. After breaking by centrifugation, the extracts were filtered through a 0.2 [micro]m pore diameter membrane and diluted to fit the analytical curves (0.05 to 2.5 mg/L). The optimized method was applied in the determination of NaCl in five samples of Brazilian crude oils and the results were in good agreement with those obtained by the ASTM D6470 method. Recovery testes were also performed, yielding recovery rates in the range of 78 - 108%.

Abstract Text

The demand for analysis of drugs of abuse in human urine, plasma and blood continues to grow each year throughout the world. As this demand increases many forensic and clinical laboratories struggle to analyze the large number of samples submitted and often seek high-throughput methodologies in order keep up with the workload. Quantitative determination for drugs of abuse in urine is commonly conducted by a solid phase extraction (SPE) to clean-up and concentrate the sample followed by LCMS analysis. The SPE sample preparation is normally the bottle neck in this process and often represents a significant portion of the time and man hours required for the analysis. The PerkinElmer[registered] Zephyr[registered] is a compact liquid handling workstation that can be specifically configured for SPE on the 96-well plate format for high-throughput parallel sample preparation. We have developed a series of SPE methods for drugs of abuse classes such as opiates, benzodiazepines, cannabinoids and amphetamines as well as the common metabolites in urine to demonstrate the time savings and precision of the Zephyr[registered]. These methods utilize the PerkinElmer[registered] Supra-Clean[cirumflex O] spherical silica and Supra-Poly[cirumflex O] spherical polymeric SPE sorbents packed in 96-well plates to produce excellent recoveries and reproducibility. Final analysis of the samples was conducted on the PerkinElmer[registered] SQ300[cirumflex O] LCMS.

Abstract Text

Liquid-liquid extractions have long been performed manually and are used to extract and concentrate analytes from aqueous matrices. Inclusion of liquid-liquid extraction in many official methods attests to the wide acceptance of the technique. Following solvent extraction it is also common to include an evaporation and reconstitution step to improve detection limits or exchange solvents for compatibility with subsequent chromatographic separations. Modern analytical labs are looking to automation to help reduce solvent usage and increase sample throughput while ensuring the high quality of the resulting data.

A single robotic X-Y-Z coordinate autosampler commonly used for sample introduction in GC or HPLC can be used to perform a wide variety of sample preparation techniques using a single instrument and controlling software. The sampler can be configured as part of a GC or LC system or can be configured as a bench-top workstation and can also include a six position evaporation station.

In this report, the automation of liquid-liquid extractions by the robotic autosampler is discussed. Examination of a new, automated vortexing option that allows samples to be rapidly and effectively mixed using speeds of up to 3000rpm is described. Automated liquid-liquid extractions methods for a variety of analytes from different matrices are examined and resulting precision and accuracy data are provided.

Abstract Text

The last 15 years have shown an increasing requirements for the use of coatings to improve analytical results obtained in systems used for mercury and sulfur sampling. New flare monitoring regulations, sub part –Ja, go into effect in 2015 and require inert flow paths for low level sulfur analysis. New regulations for mercury emissions from coal fired boilers are now enacted and industry sampling initiatives for natural gas and oil wells drives a renewed need for inert sample paths. As a result of increased regulation, sampling system performance must be rugged and stable, even in challenging and corrosive environments, while also reliable to meet frequent calibration inertness checks. To meet stringent standards, the use of coatings has been specified or highly recommended.

This presentation will address and summarize reports to date on how coatings have been used to effectively improve the accuracy and reliability of sampling systems across many applications and industries. Industries and application data presented will range from flare gas and stack gas sampling to gas and oil exploration. All of these industries have unique challenges which must be addressed and solved by high durability, inert coatings that are designed for chemical compatibility.

Abstract Text

Pharmaceutical discovery research labs are a fast pace, high throughput environment where quality and efficiency are balanced for a fit-for-purpose approach. Typically, detailed lab work would need to be performed by skilled hands to ensure the accuracy and precision of standard curves and sample dilutions. This time consuming work is also a benchmark of quality in bioanalytical labs that only experienced staff can perform. We show that by using a bioprinter the quality and efficiency are increased while devoting time to other duties thereby increasing workflow productivity. The bioprinter performs the arduous tasks of preparing standard curves for bioanalysis and research compound dilutions for in vitro screening assays. While doing so with accuracy, reproducibility, relative ease, and speed. Utilization of a bioprinter has increased our DMPK lab productivity by 25% over manual labor and offers more possibilities that can be explored in the future.

Abstract Text

Improving sensitivity and working with limited sample volumes without compromising the efficiency of the workflow is a challenge for many bioanalysts. In order to achieve the required detection limits many analytical methods utilize dry down and reconstitution steps to remove the dilution effects necessitated when using traditional scale SPE and operating with very low sample volumes.

Low bed weight SPE offers a potential solution to this problem by allowing users to take advantage of low elution volumes. As a result, dilution of low volume samples in the final eluent can be avoided. This means that sample usage can be reduced and issues caused by evaporation can be eliminated without compromising the sensitivity of the assay. Additionally larger sample volume can be used to achieve a concentration effect directly during the SPE process.

This poster presents a novel approach to low volume sample preparation. Reproducibility, robustness and ease of use at low elution volumes can be achieved by utilizing the revolutionary SOLA, Solid Phase Extraction (SPE) technology. This removes the need for frits delivering a robust, reproducible format which ensures highly consistent results at low elution volumes compared to traditional SPE and micro elution technologies.

The poster will demonstrate how this new approach will allow users to:

- Achieve a high level of confidence in analytical results at low elution volumes due to high reproducibility at low elution volumes
- Increase sensitivity by increasing sample loading and reducing elution volumes
- Improve productivity by removing requirement for lengthy evaporation and reconstitution
- Process samples which are limited in volume or compromised by evaporation procedure

Abstract Text

Epilepsy affects approximately one percent of the world population. Of these patients, 70% experience local or focal seizures which occur in only one region of the brain. Epileptic patients are diagnosed after having two or more non-provoked seizures. By giving an animal multiple seizures within one experiment, the model more accurately represents epileptic patients, improving on the animal model for local epilepsy. Additionally, epilepsy is believed to result in oxidative stress in the body. By monitoring oxidative stress biomarkers as well as neurotransmitters, we hope to gain a better understanding of how epilepsy correlates to oxidative stress. In this study, microdialysis was used to locally dose the hippocampus of a rat with an epileptic agent, 3-mercaptopropionic acid (3-MPA), while simultaneously collecting extracellular fluid for analysis. Samples were analyzed for the excitatory and inhibitory responders, glutamate and GABA, via liquid chromatography coupled to fluorescence detection. Changes in these amino acids indicate that a seizure occurred and give information on seizure strength. Catecholamine neurotransmitters norepinephrine and dopamine were also monitored using liquid chromatography coupled to electrochemical detection. Monitoring the both amino acid and catecholamine neurotransmitters gives additional neuronal information about epilepsy. Biomarkers of oxidative stress such as malondialdehyde were also monitored showing the oxidative effects of epilepsy. Various time regimens were explored in order to study seizure strength and duration in response to the epileptic agent. It was determined that there was approximately a twofold decrease in glutamate response to a secondary epileptic episode. It is possible that desensitization to the epileptic agent is occurring which may be indicative of glutamate depletion, a neuronal protective response, or changes in neuronal plasticity which could be caused by oxidative stress.

Abstract Title **Automation of EPA Method 526: Determination of Selected Semi-Volatile Organic Compounds in Drinking Water by SPE and GC/MS**

Primary Author Leticia D. Brown
J2 Scientific

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Jeff Wiseman, Mike Tanner

Abstract Text

EPA Method 526 is used to determine selected water-soluble, semi-volatile pesticides, herbicides and additives in raw and finished drinking waters. One(1) liter water samples are passed through polystyrene-divinylbenzene solid phase extraction (SPE) cartridges and the analytes of interest are recovered with ethyl acetate and dichloromethane elutions of the dried sorbent bed. The sample are then concentrated and analyzed by gas chromatography/mass spectroscopy (GC/MS).

The PrepLinc™ Large Volume Injection (LVI) system allows the user to pass large volumes of aqueous sample matrix through commercially available SPE cartridges and disks. The autosampler will accommodate 1 liter sample jars, therefore sample is taken directly from the container used to collect the water in the field. The analytes of interest can be eluted to collection tubes or to an AccuVap module for concentration directly to autosampler vials. In this study, the labor intensive steps of SPE conditioning, loading, elution and concentration were reduced to two steps: 1)loading on to the instrument and 2) programming the sequence with saved method parameters. This provided for a fast and simple automated method for the labor intensive process of manually loading 1 liter of water to an SPE, subsequent elution and concentration for analysis.

Abstract Text

Escherichia coli (E. coli) is a non-traditional platform for producing antibodies that offers potentially higher production yield and rapid fermentation process development compared with its counterpart Chinese Hamster Ovary cells (CHO). However, the expression platform comes with its own challenges such as the requirement of cell lysis for product retrieval due to the lack of protein secretion and often minimal folding fidelity, necessitating refolding procedures. Because of these factors, the analytics associated with the development of E.coli derived antibodies can be challenging, especially for expression screening and fermentation optimization. Here we describe an automated platform developed and established for the rapid analysis of whole cell broth. This includes the initial lysis of the cells, analysis of the resulting yield, downstream affinity purification, and further analytics such as SEC and icIEF. We have developed a high throughput platform with an integration of automation, information and analytical technologies. The platform is able to produce fast data enabling just-in-time decision making for process development.

Abstract Title **Storage Stability Considerations for Vet Drugs Analyzed by LC-ESI-MS/MS**

Primary Author Andrew J. Tigchelaar
University of Guelph Laboratory Services AFL

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Heather McCormick, Jurek Samoluk, Perry Martos

Abstract Text

This study explores the stability of veterinary drug target analytes, from several compound classes in a variety of tissues stored at different of temperatures under a range of conditions. Despite common understanding of storage condition requirements, e.g. -80°C vs. -20°C, there are many situations where sample temperature control is not adequate, potentially placing the sample integrity in question. Given the number of variables required to optimize LC-ESI-MS/MS for multi-residue / multi-class analyses, including matrix considerations from the bench to the instrument, it is important not to overlook the quality of the sample following storage prior to the analytical procedure.

This work was initiated following the observation that coccidiostats spiked into turkey liver were differentially affected during storage at temperatures of -20°C and -80°C, where the greatest loss of analyte was observed at -20°C. This is evidenced in the accompanying figure which shows overlaid chromatograms for monensin extracted from turkey liver which had been freshly spiked at 50ppb (control), and samples which had been spiked at 50ppb and then stored at -20°C and -80°C respectively. The response for the sample stored at -20°C was about 30% as compared to the control and the sample stored at -80°C.

These findings inspired an in depth evaluation of sample storage conditions required for regulatory samples and tissues to be used in method development. Evaluation was carried out with design of experiment (DOE), including fractional factorial with ANOVA for variables such as sample size, spike or incurred analyte concentration, storage time, temperature, tissue type, and species such as turkey and chicken.

Abstract Title **Using SPE to Achieve a Twenty Fold Pre-Concentration without the Need for Evaporation and Reconstitution**

Primary Author Ken Meadows
Thermo Fisher Scientific

Date: Tuesday, March 10, 2015 - Afternoon
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s)

Abstract Text

Despite advances in analytical detection technology, achieving required limits of assay sensitivity can still be challenging for many bioanalysts. In order to improve limits of detection analysts are looking to sample preparation not only for increased sample cleanliness but also to pre-concentrate their sample prior to analysis.

Traditional scale SPE facilitates clean up of the sample to minimize matrix effects, however in order to pre concentrate the sample a lengthy dry down and reconstitution step needs to be employed. This process is not only time consuming but can have a detrimental effect on the recovery of the analyte often due to volatility or non specific binding.

This poster presents a low elution volume sample preparation protocol for the analysis of niflumic acid in human plasma, which allows users to achieve a twenty fold pre-concentration without the need for evaporation and reconstitution. The results demonstrate that this level of sample pre-concentration can be achieved without sacrificing reproducibility, robustness and ease of use.

Abstract Text

Proposed EPA Method 325 uses the technique of passive sampling to collect air samples along the fence line of petroleum refineries. The target compounds include Hazardous Air Pollutants (HAP) such as; 1,3-Butadiene, Benzene, Toluene, and Xylenes. The samples are analyzed using Thermal Desorption and Gas Chromatography. The proposed method provides an economical way of determining the annual average concentrations of VOC's emitted from the refinery along its perimeter.

The passive air sampling device used in this method is comprised of a stainless steel thermal desorption tube packed with a single bed of graphitized carbon. The inner surface of the stainless steel tube is specially treated with a protective inert layer to mask the active sites which could be present on the inner surface of the tube.

In this work we evaluated a number of different adsorbents for their background levels of target compounds, including benzene. We tested the adsorbent's ability to retain a broad list of compounds under dry and humidified conditions. The chosen graphitized carbon has the unique capabilities to retain all analytes.

Abstract Text

Pharmaceuticals and Personal Care Products (PPCPs) have been found in many surface water systems throughout the world. Concentrations are typically reported in the ng/L range so sample preparation and preconcentration are required for detection. Manual off-line solid phase extraction (SPE) is one method for sample preparation and is specified in EPA Method 1694. Though up to 1L of sample can be extracted in this way, the manual aspect requires a great deal of operator time and several hours of laboratory time. On-line SPE has also been developed using a trapping column ahead of the analytical column. In the on-line version much smaller sample volumes are used but the system requires complete integration with the analytical system. The alternative developed here involves using a valve block system with multiple semi-preparative columns for automated parallel SPE. The extract is then evaporated to reduce volume for analysis. Results from this method using a Semba Biosciences Octave 100 system to prepare 1L samples for analysis of PPCPs by LC-MS/MS will be presented.

Abstract Text

Analysis of Volatiles Organic Compounds (VOC) in water is a growing field of interest, due to the need of a continuous confirmation of the quality of drinking water and the control of the contaminants in waste water.

The Environmental Protection Agency (EPA) strictly regulates this kind of analysis through the method 8260 in which detection limits and instrumentation requirements are established.

This work presents the GC analysis of VOC in water, in compliance with EPA method 8260, obtained with the use of Purge and Trap coupled with TOF-MS. The DHS-P&T guarantees the complete VOC extraction from water without any sample carryover or cross contamination and the TOF-MS allows to reach the Minimum Detection Limit required working with extended mass range. Moreover, its high acquisition rate, coupled with a new approach to deconvolution, provides a proper compound identification even when compounds are co-eluted, assuring a proper identification of any VOC present.

In addition, the possibility to overlap sample incubation in the DHS-P&T and to perform Fast GC, results in an increased laboratory productivity.

The results obtained show that the Purge & Trap technique provides the sensitivity needed to exceed the low-level threshold required by the latest regulations. Data will be reported including chromatographic parameters, calibrations and method detection limits.

Abstract Text

Extraction of Poly Aromatic Hydrocarbon (PAH) compounds from water involves using a large volume of solvent. The advent of more sensitive Mass Spectrometers (MS) coupled with Large Volume Injection (LVI) onto the Gas Chromatograph (GC) has aided in better detection of PAH compounds. In consequence, micro-extraction of PAH compounds from water has become a viable solution for sample preparation. Micro-extraction reduces sample size, and solvent usage, thus decreasing laboratory costs and sample preparation time. This application will investigate an automated liquid-liquid extraction technique for the preparation of PAH water samples.

Abstract Text

In an effort to improve product performance and/or make products safer, certain compounds are added. Phthalates, used to make plastic more pliable, and flame-retardants, are two prime examples. Unfortunately, some of these are environmentally hazardous, and therefore toxic to humans, so require monitoring. Certain phthalates are banned in children's toys and child care articles in the US; and brominated flame retardants, widely found in indoor and outdoor environments, and shown to have adverse health effects are also banned in the US and EU. Other newly developed additives may yet have unknown health risks. Even residual components used to make a polymer (like styrene from polystyrene and bisphenol A from polycarbonate) may be left on the polymer or leach from the polymer with aging and wear. Analysis often of requires lengthy sample preparations, like solvent extraction. The solvent itself becomes a problem, as it may also be environmentally hazardous, and requires proper disposal.

A simpler way to analyze such compounds would be thermal extraction. Requiring no solvents, a sample is simply heated. At lower temperatures (like 300°C) semi-volatiles, such as phthalates and other additives are removed from the product in question, transferred directly to the gas chromatograph. At higher temperatures, like 750°C or greater, nonvolatile molecules, like polymers or larger additives, can be broken down into volatile fragments which, in turn, can also be analyzed using a gas chromatograph. In this presentation, consumer products will analyzed for potentially toxic compounds like phthalates and flame-retardants using thermal extraction techniques. Both thermal desorption and pyrolysis will be used to study these known toxic and potentially toxic compounds.

Abstract Text

The Environmental Protection Agency has proposed new legislation for US petroleum refineries to control emissions from storage tanks, flares and coking units. When fully implemented, the rule will result in an estimated reduction of 5600 tons per year of toxic air pollutants and 52,000 tons per year of VOCs, improving air quality and protecting public health for workers and surrounding communities. Integral to the new law will be the requirement to monitor air concentrations of benzene at the perimeter fence-line. Diffusive monitoring has been widely used in a range of air monitoring scenarios, i.e. occupational hygiene, as well as plus indoor air and ambient air monitoring. By eliminating the requirement for a sampling pump, diffusive monitoring provides a simple and cost-effective method of collecting the large number of samples required in many air monitoring programmes. Key applications include personal exposure monitoring, large-scale environmental studies, and indoor air monitoring. Widespread use over many years has resulted in over 100 published uptake rates (e.g. ISO-16017 part 2). This simplifies matters for new users, as often uptake rates are available without the need to determine them experimentally.

This poster will discuss the application of passive sampling with industry-standard sorbent tubes and factors that need to be taken in to account when deploying them.

Abstract Text

Pseudomonas aeruginosa is one of the leading causes of gram-negative bacterial infections in hospital settings. *P. aeruginosa*'s antibiotic-resistant character has results in great concern within the scientific community. Given its prevalence and impact on people with compromised immune systems and cystic fibrosis, developing a novel means of detecting *P. aeruginosa* is a top priority. One such method targets *P. aeruginosa*'s production of pyocyanin, a quorum sensing molecule (QSM) that is unique to this species. As pyocyanin is redox-active, it can be detected electrochemically using standard electrochemical techniques, such as differential pulse voltammetry (DPV), where the sensitivity of the measurements is limited by the concentration of pyocyanin present in the sample. Use of up-regulatory molecules to increase *P. aeruginosa*'s production of pyocyanin has yet to be utilized for early and rapid detection in complex samples. Therefore, the aim of this study is to electrochemically detect and optimize the up-regulation of pyocyanin production, leading to a better understanding of how this bacterium grows at the onset of infection as well as improving this sensing strategy.

Different amino acids, iron compounds, metal halide salts, and simple sugars were explored as a means of regulating *P. aeruginosa* cell growth. Cultures of *P. aeruginosa* were grown overnight and inoculated into separate liquid media. Samples were taken at set time intervals, loaded onto a disposable, carbon-based screen-printed electrode, and DPV was performed to determine the concentration of pyocyanin. The data from this study provides a better understanding of how pyocyanin production is linked to the up-regulation of biofilm formation in *P. aeruginosa* and supports the use of electrochemical techniques for early infection identification. This approach can be extended to other pathogens by identifying and regulating other unique QSMs.

This work was supported by the NSF under grant no. 1125535.

Abstract Text

Reference electrodes are used in almost any electrochemical measurement. In many reference electrodes, the electrolyte solution that forms a salt bridge between the sample and the reference electrode are contained in nanoporous glass plugs (such as Vycor or CoralPor glass). Although these reference electrodes are frequently used, their use is limited to solutions with high ionic strength, because at low ionic strength, the half-cell potentials of reference electrodes are not sample independent and depend on the sample composition.¹ The variations in the reference potential cannot be explained by the liquid junction potential between two miscible electrolyte solutions, and they result from the surface charge density on the glass surface and the resulting electrostatic screening of ion transfer into the glass pores when the dimensions of the pores are comparable to or smaller than the Debye length. To overcome this issue, nanoporous polymeric materials that bear no surface charge were synthesized and the performance of the reference electrodes equipped with these plugs were tested. Porous polystyrene with average pore diameter of 10.0 nm was shown to be a proper material for construction of reference electrodes for organic solvents. Poly(ethylene oxide)-block-poly(styrene-co-divinylbenzene), which is more hydrophilic compared to polystyrene, is synthesized for use as plugs in reference electrode for aqueous solutions.

Abstract Text

It has been previously shown that fluorinated membrane based ion-selective electrodes (ISEs) have improved selectivity and an improved resistance to biofouling compared to those with conventional plasticized polymeric membranes, such as polyvinyl chloride. Most previous fluorinated membrane ISEs have relied on a fluorinated liquid deposited into a porous poly(1,1,2,2-tetrafluoroethylene) support. This has the advantage that any type of fluorinated liquid can be tested readily as ISE membrane matrix but it limits the mechanical stability of these sensors and the ability to miniaturize them. One previously introduced approach to address this problem was the introduction of plasticized poly[4,5-difluoro-2,2-bis(trifluoromethyl)-1,3-dioxole]-co-poly(tetrafluoroethylene) as the ion-selective membrane matrix [1]. To test the possibility of eliminating the plasticizer and the need for solvents in the device fabrication, we have recently shown highly fluorinated polymers with low glass transition temperature, such as poly[(1H,1H,2H,2H-perfluorooctan-1-yl)styrene], can function as ion-exchange membranes with a wide selectivity range similar to that of ion-exchange membranes based on fluorinated liquids and as highly selective silver ISEs. However, these electrodes still required a porous support. In this work, we present ion-exchanger electrodes and silver ISEs that have been fabricated using self supported membranes of crosslinked highly fluorinated polymers. These electrodes show a Nernstian response, and show a wide selectivity range or are highly selective for silver. These sensors show improved mechanical stability and an ability to be miniaturized compared to that of previous fluorinated membrane ISEs.

Abstract Text

Polycyclic aromatic hydrocarbons 9,10-diphenylanthracene (DPA) and rubrene (RUB), along with tris(2,2'-bipyridine) ruthenium (II) species $[\text{Ru}(\text{bpy})_3]^{2+}$, have shown excellent electrogenerated chemiluminescence (ECL) at ~410, 550, and 620 nm, respectively. Their use as ECL labels for multiplexing detection of biomolecules, however, is limited, as both DPA and RUB are very insoluble in water. We report herein the electrochemical and ECL studies of individual sulfonated DPA and RUB (synthesized in our lab) and $[\text{Ru}(\text{bpy})_3]^{2+}$ as well as their mixtures in aqueous media. Data obtained from various anodic and cathodic ECL coreactants including 2-(dibutylamino) ethanol, tri-*n*-propylamine, persulfate, and hydrogen peroxide at different working electrodes (glassy carbon, Pt, and Au) were compared. Correlation between the individual ECL emitter's concentration and its ECL peak intensity from the mixed systems under optimal experimental conditions (i.e., type and concentration of the coreactant, type of the working electrode etc.) was established. This study provides us the basis of ECL based multiplexing detection of biomolecules in aqueous media.

Abstract Text

The novel structured - layered potentiometric potassium- or copper-selective photopolymerized polyacrylate membranes (containing the same contents of ionophore and ion-exchanger, in each layer) were studied. Thus a traditional single membrane characterized by one diffusion coefficient can be replaced by ordered structure of a few layers with different diffusion coefficients. It was shown that this approach allows to control the overall primary ion diffusion rate in the membrane. The ultimate result is slowing down the full saturation of the membrane phase with primary ions. In this way it was possible to obtain improved potentiometric responses of the tested sensors.

Abstract Text

Metal nanoparticles of various size, shape and composition are the catalysts of choice for a wide range of energy technology applications. Typically, measurements made from nanoparticle catalysts are the averaged responses from an immobilized ensemble on an electrode and can depend on the spatial organization and the number of particles present. Understanding what effect size and shape have on the intrinsic catalytic activities of individual nanoparticles is fundamentally important, yet remains a significant challenge.

Using the technique of Fast Scan Cyclic Voltammetry (FSCV) we are able to measure the specific electrocatalytic activities of individual metal nanoparticles for the fuel cell relevant Hydrazine Oxidation Reaction (HOR). FSCV enables us to measure many Cyclic Voltammograms (CVs) from each nanoparticle, as they collide with an inert electrode, and are used to determine the electrocatalytic activity and Electron Transfer (ET) kinetics. We observed the oxidation of the HOR shifts to more positive potentials as the particle size decreases, possibly due to stronger surface binding of the nanoparticle ligands and the increasing mass transfer rate of reactant, requiring a higher potential to overcome these effects. From the ET kinetics, the smallest sized nanoparticles were found to possess the largest value for the heterogeneous electron transfer coefficient which was used to calculate the Gibbs free energy of activation. We found the change in Gibbs free energy follows a thermodynamic model where it is dependent on the radius of the nanoparticle and can be ~ 11.8 kJ/mol smaller than the bulk metals.

Abstract Text

Over the past decade, several reports have emerged describing collisions of different types of particles (i.e., metals, oxides, polymers, emulsion droplets, and liposomes) on ultramicroelectrodes. The collision frequency and shape/size of the collision events can yield insight into concentration, shape, and size distribution of the specific colloid. A method using electrochemical collision techniques for the specific determination of the murine cytomegalovirus will be presented, and future directions will be discussed.

Abstract Text

Heterogeneous catalysts are often optimized by substituting monometallic nanoparticles with multimetallic alloys for their enhanced stability and selectivity. Current state of the art nanoalloy synthesis techniques involve the chemical reduction of metal ions in a solvent containing organic surfactants or stabilizing agents, which prevent aggregation of the resulting nanoparticles. Chemical reduction synthesis may lead to unintended core-shell formation, agglomeration of nanomaterials, or support degradation upon removal of stabilizing agent.

Herein we report a complimentary approach to synthesizing metal nanoalloys directly from individual bulk metals by dissolving them in molten lithium; avoiding the use of stabilizing agents, metal salts, or bulk metal alloys. Two systems will be discussed. First, palladium-platinum (PdPt) was chosen for Pd and Pt's similar crystalline structure (face-centered-cubic, atomic radius of 137 and 139 pm, respectively). This was then expanded to include metals with dissimilar structure such as PdZn in which zinc displays hexagonal close-packed crystalline structure with an atomic radius of 134 pm. Alloy formation was confirmed and insights into the mechanism of nanoalloy synthesis were explored using multiple x-ray techniques including powder x-ray diffraction (PXRD), extended x-ray absorption fine structure (EXAFS), and x-ray absorption near edge structure (XANES). Electrochemical measurements were performed to investigate the characteristics of as-prepared PdPt nanoalloys as well as the catalytic activity towards methanol electro-oxidation. Electrochemical studies show that the PdPt nanoalloys exhibit a 72.0% increase in specific activity for the methanol oxidation reaction when compared to as-prepared Pt nanoparticles.

Abstract Text

The development of better catalysts for oxygen reduction reaction (ORR) and other electrocatalytic processes requires detailed knowledge of reaction pathways and intermediate species. Here we report new methodology for detecting charged reactive intermediates and its application to mechanistic analysis of ORR. A nanopipette filled with organic phase immiscible with the external aqueous solution was used as a tip in the scanning electrochemical microscope (SECM) to deliver neutral redox species (O_2) to the electrocatalytic surface. The transfer of a negatively charged intermediate of ORR (superoxide, O_2^-) to the organic solution produced ion transfer (IT) current across the liquid/liquid interface. The time required for an ion to cross the nanometer-thick gap between the catalytic surface and the pipette orifice was $<1 \mu s$ —sufficiently short to detect and quantify O_2^- and other short-lived intermediates. The detection is highly selective because the IT current is insensitive to neutral molecules, and different ionic species can be distinguished based on their charge and standard IT potential. The developed approach is suitable for mechanistic studies of numerous electrocatalytic processes and other heterogeneous reactions involving ionic intermediates.

Abstract Text

Electrochemical biosensors have been explored as a novel approach for DNA detection because of their portability, low cost, and high sensitivity. Here, we present a four-way junction electrochemical sensor developed using screen printed gold electrodes. The sensor is comprised of a stem loop oligonucleotide (SL) immobilized via a gold-thiol bond to the electrode surface and two synthetic adaptor oligonucleotide strands used for hybridization to target analyte. The adaptor strands, one labeled with methylene blue, have a segment complimentary to the SL and to the analyte. A four-way junction is preferred over a two strand DNA detection system due to its improved selectivity and the potential for using one universal optimized reporter for detection of any DNA or RNA sequences.¹ Square Wave Voltammetry (SWV) was used to detect hybridization of target microRNA (miRNA) by analyzing an increase in current caused by electron transfer between the methylene blue and the electrode surface. No electrochemical signal was observed in the absence of the target miRNA strand. The sensor has been optimized to produce maximum signal intensity using 0.1 mM solution of the SL, producing a surface probe density of 5.78×10^{11} molecules/cm². Altering the sequence of one segment on each adaptor strand allows this electrochemical sensor to be used for a variety of target analytes, offering the possibility for a universal sensor format.

Abstract Text

A novel scheme for the spatially-resolved detection of lithium ions in aqueous solutions was developed. We utilize cyclohexane for the facilitated ion transfer of lithium ions across the water/(1,2-dichloroethane + cyclohexane) interface supported at laser pulled micro- and nano-quartz pipettes. This ITIES system is highly sensitive and produces steady-state electrochemical signals that depend on the local concentration of lithium ions.

The ITIES pipettes are used as probes for high resolution scanning electrochemical microscopy (SECM) imaging of active TiO₂ substrates, which are known to insert lithium ions when biased at reducing potentials. SECM imaging with ITIES pipettes is able to discern site-specific surface phenomenon and demonstrate heterogeneity in the electrochemical performance of TiO₂ substrate electrodes for insertion of lithium ions in real-time. The insertion efficiency for lithium is known to vary based upon the crystalline phase of the TiO₂ [sup]1[/sup]. ITIES-SECM imaging is used to study the spatial diversity in local ionic concentrations for lithium as a function of the crystal structure of TiO₂ and electrode potential. The images produced by ITIES-SECM are corroborated by optical microscopy and Raman imaging for identification of electrochemically active structures and regions. The Raman and optical microscopy has been reported previously [sup]2[/sup].

ITIES-SECM has been shown to be a highly promising platform for lithium ion detection and high spatial resolution imaging of energy materials for evaluation of their electrical storage performance.

Abstract Text

Ion transfer at the interface between two immiscible electrolyte solutions (ITIES) allows for the detection of non-electrochemically redox active species using traditional electrochemical techniques. This can be especially useful in the detection of neurotransmitters such as acetylcholine, which is difficult to be detected directly using a traditionally used carbon electrode, where the modification of the electrode surface is often required. In this work, quartz capillary pipettes were laser pulled to form a pore on the nanometer scale, and were filled with 1,2-dichloroethane to create an ITIES interface when immersed in artificial sea water. We were able to detect several neurotransmitters both qualitatively and quantitatively at the nano-ITIES. Additionally, we investigated the transfer behavior of these neurotransmitters and compared these findings to those at larger interfaces. The steady state current obtained by the transfer of the neurotransmitters allowed for their quantitation at physiological conditions relevant to our model animal, [*Aplysia californica*]. Furthermore, the small size of these nanopipettes means that they may be used as amperometric probes for the high resolution imaging of the neurotransmission process using scanning electrochemical microscopy.

Abstract Text

Ion Selective Electrodes (ISEs) are widely used to determine the concentration of a specific ion dissolved in aqueous solution. The goal of this project is to design a carbonate ISE in which a perfluoroalkyl ketone serves as the ionophore in a fluorinated liquid phase membrane. Perfluoroalkyl ketones are potential ionophores for the doping of membranes of ion selective electrodes due to the proposed superiority of binding with carbonate ions. NMR dilution and titration experiments were used to estimate the binding constant between an analogous ionophore and carbonate. Trifluoroacetophenone (TFAP) was used as a suitable analogue of perfluoroalkyl phenyl ketones because of the limited quantity of perfluoroalkyl ketone ionophore available. Cryptand-2, 2, 2 was applied in this system because we employed potassium carbonate as the carbonate source and because it strongly binds potassium cations and thereby minimizes ion pairing with carbonate. In the NMR dilution experiment, a series of NMR samples of TFAP, K_2CO_3 and cryptand in deuterated methanol were diluted with the TFAP: carbonate ratio of 1:2, 1:1 or 2:1. A NMR titration experiment was performed holding the concentration of host constant while varying the concentration of guest. The complex formation was further studied by Job plots and species plots. Non-linear regression was carried out using Mathematica 9.0. From the NMR dilution experiments, the logarithm of the binding constant for a 1:1 guest to host ratio was calculated to be 2.77 ± 0.03 while for a 2:1 complex, the binding constant was 1.9 ± 0.2 . So far, from the data of the dilution NMR experiment, we can conclude that binding of the potassium ion with cryptand-2, 2, 2 increases the stability of the complexes between carbonate and the perfluoroalkyl phenyl ketone ionophore.

Abstract Text

Trifluoroacetophenone derivatives have been known to selectively bind to carbonate through covalent bond formation and are commonly used as ionophores in carbonate ion selective electrodes. Heptadecafluorooctyl phenyl ketone was previously synthesized as a new ionophore designed to selectively bind to carbonate. Synthesizing a carbonate compound lipophilic enough to determine this new ionophore's affinity for carbonate by way of a NMR titration experiment, however, was unsuccessful. Instead, potassium carbonate was tested to determine its suitability for determining carbonate binding. Spectroscopic methods were used to study the interaction between carbonate and a widely-available, fluorophilic analog to heptadecafluorooctyl phenyl ketone, trifluoroacetophenone. NMR dilutions, titrations, and a Job plot coupled with original Mathematica programs specifically designed to simultaneously fit data from multiple experiments provided binding constants for both 1:1 and 2:1 trifluoroacetophenone-carbonate complexes as well as chemical shift values for each complex formed. In addition, for the NMR dilution experiments, the binding constant results made it possible to prepare speciation plots describing the concentrations of free ionophore and each complex formed throughout the course of the dilution experiments. Results indicate weak binding between trifluoroacetophenone and carbonate with 1:1 and 2:1 log scale binding constants of 1.70 ± 0.15 and 1.59 ± 0.35 , respectively. From these results, using a Mathematica file to concurrently fit multiple NMR experiments produced reliable binding constants for the trifluoroacetophenone-carbonate complex, confirming both 1:1 and 2:1 ionophore-carbonate complex formation. We are planning to apply this optimized method to the new fluorophilic carbonate receptor, heptadecafluorooctyl phenyl ketone.

Abstract Text

All-solid-state ion-selective electrodes and reference electrodes are miniaturized electrochemical sensors with an intermediate layer between a sensing membrane and an underlying solid electron conductor. In this work, colloid-imprinted mesoporous (CIM) carbon with a low content of redox impurities and high double layer capacitance is investigated as intermediate layer to construct all-solid-state ion-selective electrodes and reference electrodes. These sensors exhibit superior electrochemical performance including excellent ionic response, excellent resistance to common interfering agents such as O₂, CO₂, light and water, as well as outstanding potential stability. When combined with a redox couple as internal reference species, calibration-free all-solid-state ion-selective electrodes and reference electrodes can be fabricated. In view of mass production, the synthesis of CIM carbon and fabrication of the corresponding sensors are straightforward and employ inexpensive precursors, making CIM carbon a promising component for commercialized all-solid-state electrochemical sensors.

Abstract Text

Despite the importance of the second dimension separation in determining the overall performance of two-dimensional liquid chromatography (2D-LC) separations, the characteristics of the second dimension separation bear little resemblance to what most would consider mainstream liquid chromatography. Second dimension separations must be faster and more repeatable (in absolute time units) than what is typically required of conventional 1D separations. From a theoretical point of view, these requirements push us to the edges of both understanding and practice – we want to use short narrow columns, packed with small particles, and operated at high pressures and temperatures, and very high eluent linear velocities; at the same time we want to inject hundreds of fractions of first dimension effluent with volumes on the order of the column volume per hour.

In this presentation we will share some of our observations made when dealing with this chromatographic quagmire. Specifically, we will discuss the impact of the demanding conditions associated with the second dimension on column lifetime, and steps that can be taken to slow the deterioration of column performance to a practically tolerable level. We will also discuss the impact of the first dimension effluent composition on the performance of the second dimension, both for non-ionizable and ionizable solutes in terms of detection sensitivity and choices related to column selection and method development.

Abstract Text

A good deal of progress has been made in developing the instrumentation to do fast, two-dimensional chromatography (2D-LC) and understanding the factors needed to optimize its resolving power. Although there have been a few notable experimental and theoretical studies of peak quantitation we do not fully understand, as yet, why the reproducibility of the peak size in 2D-LC is poorer, and sometimes considerably poorer, than in 1D-LC. Some recent results that clarify the source of this problem will be presented.

There is a great deal of unfulfilled potential inherent in the higher order data structure of two-dimensional liquid chromatography when done with a multi-variate detector. Methods such as parallel factor analysis (PARAFAC), the generalized rank annihilation method (GRAM) and multivariate curve resolution-alternating least squares (MCR-ALS) approaches possess many advantages relative to conventional quantitation methods. These will be discussed here.

Abstract Text

The use of elevated column temperature has long been viewed as a practical solution to achieving greater separation speed. While increased column temperature reduces eluent viscosity and increases analyte diffusivity, both attributes that enhance separation quality, higher column temperature often requires a commensurate reduction in the elution strength to maintain solute retention. Thus, high-temperature reversed phase separations are frequently performed using nearly aqueous mobile phases. This presents a major problem for fast, high sensitivity measurements of modestly hydrophobic solutes in capillary liquid chromatography: inadequate preconcentration. Large volume injections of aqueous samples onto high efficiency capillary columns operated with nearly aqueous eluents results in volume overload-induced losses in column efficiency. We are developing temperature-assisted on-column solute focusing (TASF) to address this problem. TASF mitigates precolumn dispersion by cooling a small segment of the column head to sub-ambient temperatures. Following the injection, the focusing segment is rapidly heated to match the temperature of the analytical segment. The use of active temperature control to enhance preconcentration and decrease volume overload effects has proven effective in a series of applications: 1) rapid separations of moderate and high polarity small molecules and peptides, 2) augment the typically used solvent-based focusing method and 3) facilitating the use of large volume injections of strong elution strength samples.

Abstract Text

Once a good comprehensive two-dimensional liquid chromatography (LC×LC) method has been developed it may offer great advantages. Structured chromatograms may be obtained for very complex, non-volatile mixtures with potentially high peak capacities in reasonable analysis times. LC×LC systems are hardly more complex than common one-dimensional LC systems and they exhibit a similar high robustness.

It is generally true that the development of chromatographic methods requires more knowledge and skills than their application. Developing, improving and optimizing LC×LC methods requires amplified skills, as indicated below.

1. The analyst needs to select and (partly) develop two one-dimensional methods that offer very different (“orthogonal”) selectivities;
2. The individual separations stages need to be optimized within the constraints of time and pressure, as well as possible constraints of the sample and the detection system;
3. Losses in resolution (peak capacity) due to first-dimension “undersampling”, second-dimension band broadening and incompatibility of the first-dimension effluent with the second-dimension system need to be minimized, as does the dilution of the sample during the two separation stages;
4. The operating parameters in both dimensions must be optimized as a function of time (implying that the LC×LC is more than the product of two one-dimensional LC methods).

To help chromatographers make full use of the fantastic possibilities of LC×LC we are developing efficient, user friendly strategies and software tools. In this lecture the development of successful LC×LC methods will be illustrated with practical examples.

Abstract Text

Over the last decade the pharmaceutical industry has been inundated with ultrahigh pressure liquid chromatography (UHPLC) and all of the speed, efficiency and cost savings it theoretically affords. While powerful for many applications, a decade after its introduction UHPLC is still in a staggered phase of implementation within many pharmaceutical companies. Laboratories running standardized assays have experienced a higher uptake than development and quality control laboratories, where integration of UHPLC must be balanced with internal/external resourcing capabilities and regulatory requirements for method transfer/validation. Nevertheless, the impact that UHPLC has had on pharmaceutical method development cannot be ignored. In addition to hundreds of new HPLC columns, UHPLC has catapulted technologies such as 2D HPLC and online HPLC to go from customized lab-built systems to "off the shelf" analytical tools.

In this presentation, we will present our experiences applying UHPLC method development strategies and the challenges we have encountered installing them in various phases of development. We will also discuss technologies enabled by UHPLC that we have implemented to expand upon our current capabilities, focusing on decreasing the time to turn data into information enabling decision making.

Abstract Text

W. W. Coblenz, during his post-doctoral studies at Cornell University, and at the Bureau of Standards in the early 1900's, did the basic studies that defined the analytical applications of infrared spectroscopy. The data he produced using instruments he constructed are remarkably good.

The Coblenz Society was founded in 1953 "To foster the understanding and applications of infrared spectroscopy". As an example of the Society programs, high quality reference spectra have been generated in accordance with specifications established by the Society. These specifications are currently undergoing revision to take into account the current state of modern instrumentation. The Society supports training courses. It also supports symposia at national meetings to recognize developments in the field and presents a number of awards to leaders in the field. Current programs will be briefly described.

Abstract Text

Practical applications of liquid/solid interface chemistry including catalysis, selective adsorption of molecules, chromatographic separations, and environmental remediation, generally employ porous support materials for immobilizing ligands or reactive sites. The high surface area of porous particulate materials provides large capacities for adsorption, reaction, or catalysis. While flat surfaces are often used as models for these materials for spectroscopic investigation, the surface chemistry of porous materials cannot be totally understood by study of flat surfaces. The challenge for spectroscopic investigation of porous materials is that most (>99%) of their surface area resides within the porous structure; thus relevant methods to investigate these materials must be capable of interrogating chemistry inside the porous structure. To address this measurement challenge, we employ confocal Raman microscopy to determine the chemical composition, interface structure, and surface interactions of molecules within individual porous particles. The pore structure of these particles is much smaller than the wavelength of excitation or scattered radiation and allows diffraction-limited imaging within the particle interior. The high specific surface area of these particles (>100 m²/g) allows sub-monolayer coverages of molecules to be detected in Raman scattering without any enhancement. Confocal Raman microscopy is capable of unraveling retention mechanisms involved in chromatographic separations. It is also being developed for single-particle, solid-phase extraction to enable rapid, ultra-trace-level Raman scattering detection in sub-fL volumes. The methodology is being applied to measurements of octanol-water partitioning within silica particles whose pores filled with octanol. Finally, the method can be used to determine solute interactions with hybrid-lipid bilayers supported on n-alkyl chain ligands within individual, porous-silica particles.

Abstract Text

New physical phenomena occur when the size of a structure is comparable to physical scaling lengths, <i>e.g.</i> the Debye length in ionic solutions, and these unique physical effects may be usefully exploited to achieve improved control over chemi-cal manipulations, such as (bio)chemical sensing or processing. In particular, we are interested in the effects that accrue from confining reactants and products to the small volumes characteristic of 0-D and 1-D nanostructures. Zero-dimensional architectures are also being studied in two formats: (1) arrays of nanoconfined recessed ring-disk electrodes (RRDEs) in which redox cycling can be carried out at very high efficiency; and (2) electrochemically-active zero-mode waveguides (ZMWs), in which strongly confined optical fields can be coupled to single molecule electron transfer in order to study the dynamics of single enzyme molecules and single redox-active organic chromophores. Nanoscale separation in RRDE arrays allows ultraefficient coupling of counterpoised electron transfer processes at the bottom disk and upper ring electrodes in an attoliter-volume nanopore, processes that can be exploited for improving both sensitivity and selectivity in electroanalysis. In the ZMW geometry the Au optical cladding layer is used as the working electrode in order to couple the local potential to fluorescence dynamics of molecules exhibiting large changes in emission quantum efficiency with redox state. These experiments allow the distributions of single molecule E_{eq} values and other details of electron transfer reactions on a single molecule basis.

Abstract Text

I will present our work in using single-molecule fluorescence microscopy to study the catalytic properties of individual metal nanoparticles at single-turnover resolution and nanometer precision. The single-molecule approach circumvents the intrinsic heterogeneity challenge among nanoparticle catalysts, so that their temporal and individual behaviors can be dissected. I will present the insights we gained into the catalytic activity and dynamics of individual metal nanoparticles, the reactivity differences of various surface sites, and the surprising spatial reactivity patterns within single facets at the nanoscale. This spatiotemporally resolved catalysis mapping also enables us to probe the communication between catalytic reactions at different locations on a single nanocatalyst, in much relation to allosteric effects in enzymes.

Abstract Text

Dopamine (DA) is a highly significant neurotransmitter in the mammalian central nervous system, where it contributes to the control of muscle movements, learning, and mood. DA's significance as a neurotransmitter is heightened by its role in several disorders that adversely affect human health, including Parkinson's disease, schizophrenia, substance abuse, and depression. The DA systems are among the smallest in the brain, comprising only a few thousand neurons of the billions that exist in total, so their ability to impact in so many physiological functions is remarkable. Some evidence suggests that DA's diversity of function is temporally encoded, i.e. that rapid DA transients and slow DA fluctuations have their own discrete functions. Thus, it is highly significant to understand the factors that control the time courses of DA function, including the kinetics of DA release, DA clearance, and DA transport in the extracellular space. Fast scan cyclic voltammetry, especially when paired with electrical stimulation of DA axons, is a proven methodology for investigating these issues. Recently, our laboratory has documented that the heterogeneity of evoked DA responses measured in the dorsal striatum, a brain region that receives the densest DA input within the CNS, is a consequence of a rich, yet previously undocumented, diversity in the kinetic properties of the DA terminal field. We find that the dorsal striatum exhibits 5 statistically distinct evoked DA responses. A single, 4-parameter kinetic model based entirely on first-order rate expressions fully captures the features of the diverse responses. Spatial mapping across the anterior-posterior, dorso-ventral, and medio-lateral aspects of the dorsal striatum is beginning to reveal the size and anatomical distributions of the diverse DA responses and their association with known patch:matrix architecture of this brain region.

Abstract Text

Embryonic stem cells (ESCs)-based cell therapies exhibit great potential for clinical treatment of Parkinson's disease (PD), because they can significantly rescue PD-like behaviors. However, whether the transplanted cells themselves release dopamine in vivo remains elusive. We and others have recently induced human ESCs into primitive neural stem cells (pNSCs) that self-renew for massive/transplantable production and can efficiently differentiate into dopamine-like neurons (pNSC-DANs) in culture. Here we show that after the striatal transplantation of pNSC-DANs, (1) pNSC-DANs retained tyrosine hydroxylase expression and reduced the PD-like asymmetric rotation; (2) depolarization-evoked dopamine release and reuptake were significantly rescued in striatum in situ (brain slices) and in vivo, as determined jointly by microdialysis-based HPLC and electrochemical micro-carbon-fiber electrodes; and (3) the rescued dopamine was released directly from the grafted pNSC-DANs (not injured original cells). Thus, pNSC-DAN grafts release and reuptake dopamine in the striatum in vivo and alleviate parkinsonian symptoms in rats, providing proof-of-concept for human clinical translation.

Abstract Text

Over the past 5 years, the incorporation of optogenetics into the study of brain function has resulted in a tremendous leap in this field, initiating a revolution in our understanding of the networks underlying several cognitive processes. Here, we will present recent breakthroughs in which optogenetics was applied to research in the field of drug addiction and describe the technical approach. The nucleus accumbens (NAc) is a neural substrate involved in integrating sensory and emotional information to initiate reward-directed behavior. We previously demonstrated that dopamine release surges when an animal is presented with a cue that predicts the avoidance of punishment. However, it is not known whether this release is just an epiphenomenon of the behavior or if it has a causal role. Here, we transfected the cell bodies of dopaminergic neurons in the ventral midbrain of rats that express the enzyme cre recombinase in these specific cells, with a virus carrying a light sensitive cationic conductance. Animals were also implanted with voltammetric electrodes in the nucleus accumbens for the measurement of dopamine, and with optical fibers in the ventral midbrain to allow for specific control of these cells and not others. We found that optogenetic release of dopamine was sufficient to improve the animals' behavior by 70%. This was accompanied by a significant augmentation of subsecond dopamine release and of accumbens gamma power at the presentation of the warning signal that introduces the option to avoid. This data suggests that changes in dopamine neuron activity at specific predictors of an outcome are sufficient to produce the motor sequences to obtain it.

Abstract Text

Serotonin is thought to be involved in the regulation of emotion-related behavior and the etiology and treatment of mood and anxiety disorders. However, direct evidence for the encoding of emotionally salient information by serotonin neurotransmission has not been forthcoming largely due to the inability to investigate serotonin signaling in a highly time-resolved manner. We have developed paradigms for measuring changes in extracellular serotonin on the minute-by-minute (fast microdialysis) and second-by-second (fast-scan cyclic voltammetry) time scales. These approaches enable us to record serotonin transmission in brain areas associated with affective and anxiety-related circuitry in behaving animals. We have developed highly resolved chemical, electrical, and optical stimulation procedures for investigating endogenous serotonin release. Moreover, we are investigating behaviorally evoked serotonin release in the context of aversive learning, dysphoria, and stress. Methods, advances, and future challenges will be discussed.

Abstract Text

All nervous systems employ many neuropeptides as chemical messengers. Using a sensitive mass spectrometry (MS)-based platform, more than 300 neuropeptides have been discovered in a well-defined crustacean nervous system, revealing that even a relatively simple neural network contains an unexpectedly-rich diversity of neuropeptides. To further explore the functional consequences of peptide multiplicity, MS imaging techniques and in vivo microdialysis sampling technique are employed to obtain spatial and temporal information of peptidergic signaling, respectively. Furthermore, novel isotopic and isobaric labeling techniques have been developed and employed to produce differential display of neuropeptidomes under different physiological conditions. Examples of neuropeptide regulation of feeding behavior and environmental stress will be highlighted. Collectively, these combined studies will help elucidate the functional roles that neuropeptides play in regulating neural plasticity.

Abstract Text

The evolution of the instrumentation used to detect the Raman effect, from the initial instrument used by CV Raman himself, through to the current use of multichannel detectors on grating-based spectrographs with microscope sampling devices, will be reviewed, while indicating what fields of science have been explored during these time periods. In the earliest period we will indicate how Raman spectra were originally used as an aid to determine molecular structure. During the 1960's it was successfully used to study the physics of semiconducting materials and devices. The introduction of the microscope in ~1974 as a sampling device first simplified experimental conditions, but also provided information on a scale commensurate with many questions of microstructure and with problems of manufacturing defects. Curiously, while the original concept of the microscope in the early 1970's was focused on Raman imaging, technological limitations prevented its practical implementation. As the ability to acquire high quality map data over a region of interest improved, development of multivariate statistical means of treating the data has provided high quality Raman images that are now yielding solutions to problems.

Abstract Text

With the help of surface plasmons molecular chemical reactions can be observed on the nanoscale. Plasmon assisted dimerization of p-nitrobenzenethiol (pNPT) molecules to 4,4-dimercaptoazobenzene (DMAB) has been realized by SERS and tip enhanced Raman spectroscopy (TERS). In the previous study, it was found that the plasmon assisted reaction can be controlled by the molecular concentration and the laser intensity. In principle, if the molecular concentration is very low, the distance of adsorbed pNTP molecules is too large for an intermolecular reaction, independent from laser power. In this case, SERS signals relate to single or several non-interacting molecules. Thus, SERS will provide information on the status of a reaction.

We present a strategy, to detect SM-SERS signals of the plasmon catalyzed chemical reaction of pNTP using gold nanoparticle dimers. When about 10 molecules are absorbed on a single dimer surface the average distance between two molecules is ~32 nm. SERS of pNTP on such a surface can be obtained at such a concentrations. Furthermore our experiments demonstrate an interesting behavior of pNTP molecules at such low concentrations upon radiation. Instead of the dimerization a different reaction can be observed, that will be discussed in detail.

Abstract Text

Current medical imaging modalities rely on differences in tissue properties rather than on chemical-content changes deep inside the body. Consequently, a biopsy is routinely needed for ultimate diagnosis of a malignancy. Thus, we need noninvasive imaging technologies that can be used in vivo and can determine in real time the chemical content of deep-tissue. Vibrational spectroscopy has been a powerful tool for quantitative analysis of molecules in gas phase or solutions and has been deployed for label-free analysis of biological tissues. Yet, applying vibrational spectroscopy to non-invasive in vivo imaging is difficult due to limitations in imaging speed and penetration depth. In this presentation, I will present our persistent efforts in transforming molecular spectroscopy from an in vitro analytical tool to a set of in vivo label-free imaging platforms that have been enabling groundbreaking discoveries and paradigm-shifting diagnosis strategies. This transformation is achieved through development of coherent Raman scattering microscopy for real-time spectroscopic imaging of living cells and development of vibration-based photoacoustic endoscopy/tomography for bond-selective imaging of deep tissues. Potentially transformative applications to cancer metabolism, cardiovascular disease and neuroscience will be presented.

Abstract Text

Electron and proton transport in proteins has been studied using impulsive stimulated Raman vibrational coherence spectroscopy and ultrafast kinetics. Cytochrome c (cyt c) and green fluorescent protein (GFP) are employed as model systems. "Ruffling" distortions of the heme in cyt c alter the electron transport rates by two orders of magnitude. Because this mode can also mix with other delocalized low-frequency modes of the protein, or with binding partners, it offers a potential control mechanism for electron transfer. The ruffling distortion is relaxed upon cyt c binding to the mitochondrial membrane, which suggests that et rates are enhanced in the membrane bound state. In another study, involving proton transfer kinetics, we use Duschinsky mixing of the low-frequency donor-acceptor mode with the high frequency O-H oscillator to explain the kinetic data. This quantum mixing delocalizes the tunneling wavefunction and offers shorter tunnel path-lengths, which control the underlying transport rates.

Abstract Text

Raman spectroscopy is a powerful technique that can be used to obtain detailed chemical information about a system without the need for chemical markers. It has been widely used for a variety of applications such as cancer diagnosis and material characterization. However, Raman scattering is a highly inefficient process, where only one in 10^{11} scattered photons carry the needed information. Several methods have been developed to enhance this inherently weak effect, including surface enhanced Raman scattering and coherent anti-Stokes Raman scattering. These techniques suffer from drawbacks limiting their commercial use, such as the need for spatial localization of target molecules to a 'hot spot', or the need for complex laser systems. Here, we present a simple instrument to enhance spontaneous Raman scattering using elastic light scattering [1]. Elastic scattering is used to substantially increase the interaction volume. Provided that the scattering medium exhibits very low absorption in the spectral range of interest, a large enhancement factor can be attained in a simple and inexpensive setting. In our experiments, we demonstrate an enhancement of 10^7 in Raman signal intensity. The proposed novel device is equally applicable for analyzing solids, liquids, and gases. Real-life applications like monitoring human waste in a pool [2] will be discussed.

Abstract Text

A short overview on general aspects of ultrafast electromigrative separations will be given followed by most recent developments of our group concerning ultrafast capillary electrophoresis coupled to mass spectrometry. The hyphenation of capillary electrophoresis (CE) with mass spectrometry (MS) is an attractive tool of instrumental analysis. However, the combination of conventional CE systems with MS is usually associated with the implementation of rather long capillaries (longer than or equal to 60 cm). Consequently, the window of migration times is typically in the range of 5-10 min or even longer. In order to speed up CE-MS separations much shorter capillaries and rather high separation voltages should be applied. A novel instrumental approach for CE-MS measurements in the time scale of seconds is presented. In addition, very small samples in the nanolitre range can be studied. Samples are handled by means of a microprocessor controlled injection system with an integrated capillary. The injection capillary is moved out of the injection cell for taking up samples from a microenvironment, and after repositioning it is facing the fixed inlet of a short separation capillary (15 cm in length), then a small sample plug is injected onto the inlet of the separation capillary. In this way separations of catecholamines could be carried out in less than 12 s. A very recent development from our laboratory is the concept of two-dimensional separations of ionic species by combining ion chromatography – fast capillary electrophoresis – mass spectrometry. This novel approach of ion analysis will also briefly be discussed.

Abstract Text

Microchip electrophoresis is a powerful tool for the analysis of biological samples. In particular, the ability to perform fast efficient separations makes it possible to monitor several compounds simultaneously with high temporal resolution. The small dimensions of the channels in the chip are compatible with the analysis of microdialysis samples and single cells. In this presentation, two applications of microchip electrophoresis (ME) for biochemical investigations will be presented. The first application involves the development of ME-based methods for the detection of reactive nitrogen and oxygen species (RNOS) in macrophages and immune cells. These are short-lived species that have been implicated in cardiovascular disease and neurodegenerative disorders, including Alzheimer's and Parkinson's diseases. The second involves the combination of microdialysis with microchip electrophoresis for near real-time continuous monitoring of amino acids, catecholamines, and nitric oxide metabolites in awake, freely roaming animals. The goal of this second application is to miniaturize the entire system for simultaneous monitoring of neurochemistry and behavior with on-animal analysis and telemetry control.

Abstract Text

In contrast to UV-detection capacitively coupled contactless conductivity detection (C4D) is readily possible in narrow channels with diameters down to 10 μm . C4D is therefore suitable for lab-on-chip devices as well as for conventional capillary electrophoresis and has frequently been employed for both. Examples for the two platforms drawn from work in our group will be presented. Fundamental aspects of C4D and how these relate to the implementation on the two electrophoresis platforms will be discussed.

In capillary electrophoresis, regardless of the arrangement employed, the speed of analysis cannot be optimized without consideration of other performance parameters, in particular separation efficiency and limits of detection. This interrelationship is not always considered, and often makes a comparison between different reported results difficult.

Other important aspects to consider are the practical handling of the two platforms with regard to flushing with electrolyte and sample injection. Manual use is cumbersome with both platforms, and for automation an external manifold is required in either case.

Abstract Text

Ultrafast capillary electrophoresis (UFCE) is defined as a mode of capillary electrophoresis where the field strength is 1000 V/cm. To maintain this field strength while using the conventional CE power supplies with a maximum of 30 kV, the maximum length of the capillary for the UFCE apparatus is limited to 30 cm. To achieve this high field strength while avoiding excessive Joule heating, narrow capillaries (5 μ m) are utilized. There are three main issues with these narrow capillaries: 1) They are difficult to interface to mass spectrometers without any loss of resolution or sensitivity. Our porous tip interface in conjunction with capillary format has eliminated this difficulty. 2) There is a limited sample volume that can be injected into these short, narrow capillaries, where the total volume of the capillaries is in the range of a few nanoliter or less. To increase the loading capacity of this capillary, the porous tip of the capillary is adjustable. This allows the porous tip to be pulled inside the sheath liquid for sample stacking during injection, or sample focusing in isoelectric focusing (IEF), or, alternatively, pushed outside of the sheath liquid for electrospray ionization (ESI). The adjustable interface preserves electrical conductivity during electrokinetic injection with reverse electro-osmotic flow. Therefore, pre-concentration of analytes at the capillary inlet is achieved without the need to disassemble the interface, improving the throughput. 3) There is a lack of quality control in the production of the narrow capillaries in terms of the uniformity of the inner diameter. Additionally, small particles entering the capillary or precipitation of analyte during the concentration result in frequently clogged capillaries. This issue is currently under study.

Abstract Text

The injection method selected for an electrophoretic separation can have a dramatic impact on the resolution, throughput, sensitivity and quantitation of the analysis. We are developing new techniques that overcome many of the limitations of conventional hydrodynamic and electrokinetic injection approaches. For example, a newly developed microchip sample injector features a pneumatic microvalve that separates a sample introduction channel from a separation channel. The sample introduction channel is pressurized such that when the microvalve is briefly opened, a variable-volume sample plug is introduced onto the separation column. The microvalve is computer controlled and enables sample volumes from picoliters to nanoliters to be reproducibly injected. No quantitative bias is observed and subsequent sample plugs can be injected with minimal latency, opening the door to multiplexing approaches based on, e.g., the Hadamard transform for improved signal to noise. The microchip injector can be incorporated within monolithic microfluidic devices or seamlessly interfaced with capillary separation columns. Detection has utilized both fluorescence and electrospray ionization mass spectrometry. We have also found that samples can be preconcentrated at the closed microvalve by applying a potential across it. A 70-fold enrichment of a model analyte was achieved in just 8 s. The concentrated analyte was then injected as a 1 nL plug for CE. These advances should enhance the performance of both microchip and capillary-based CE and are also expected to lead to greatly improved multidimensional separations (e.g., liquid chromatography-CE).

Abstract Text

Multifunctional nano-carriers enabled a major route for the achievement of theranostics, i.e., simultaneous therapy and diagnostics, where the later can be broadly defined as covering structural (physical) and functional (chemical) imaging, surgery assisting delineation, as well as monitoring of therapy. The mode of therapy can be chemical (e.g. drugs), physical (e.g. radiation), or a combination (e.g. photochemical). Drug targeting, to specific organs, cells, organelles, or cell biomolecules, has been the dream of the biomedical community for a century; it has been transformed into reality only recently, largely with the use of “nano-drugs”. A nanoparticle based platform can include drugs, drug sensitizers, imaging contrast agents, targeting moieties, “cloaking agents” and more. This recent development of nanoplatfroms has made possible such combinations of therapeutic functions, as well as better designed biodegradation and bioelimination. Application examples include: (1) brain cancer optical and photoacoustic imaging, surgical delineation, chemotherapy and photodynamic therapy (PDT), (2) ovarian cancer chemotherapy, (3) optimization of cancer cell photothermal therapy via nuclear delivery of surface modified Au nanoparticles, (4) targeted PDT of arrhythmia causing cardiac cells in-vivo, (5) chemical imaging of hypoxia and acidity by photoacoustic imaging, (6) Cell Magneto-Rotation (CMR) for evaluating the metastatic potential of individual breast cancer cells.

Abstract Text

The great promise of single-molecule/assembly measurements is to understand how critical variations in structure, conformation, and environment relate to and control function.¹ New approaches to imaging and analysis are keys to elucidating these associations. I will discuss current and upcoming advances and will pose the challenges that lie ahead in creating, developing, and applying new tools for biology and medicine. These advances include fusing spectroscopic imaging modalities and freeing up bandwidth in measurements to record simultaneous data streams and to expand our dynamic range. Recent advances in sparsity and compressive sensing can be applied both to new analysis methods and to directing measurements so as to assemble and to converge structural and functional information. Early examples will be discussed.

Abstract Text

A full understanding of the molecular basis of diseases depends on the development of molecular probes able to recognize disease targets of interest. Until very recently, such tools have been absent from the clinical practice of medicine. The newest molecular probe, and one that holds most promise, is a new class of designer nucleic acids, termed aptamers, which are single-stranded DNA/RNA able to recognize specific targets, such as single proteins and even small molecules. Recently, we applied a simple, fast and reproducible cell-based aptamer selection strategy called Cell-SELEX which uses whole, intact cells as the target for aptamer selection. This selection process then generates multiple aptamers for the specific recognition of biological cells, but without the need for prior knowledge about the signature of target cell-surface molecules. The selected aptamers have dissociation constants in the nanomolar to picomolar range. Thus far, we have selected aptamer probes for many different diseases, and used them to carry out studies at the vanguard of biomedical science, including ultrasensitive detection of tumors, molecular imaging, targeted drug delivery, and, most critically, cancer biomarker discovery. Taken together, these molecular level tools form a solid scientific platform from which to pursue advanced studies in molecular medicine. We will report our most recent progress in this exciting research area, especially the molecular elucidation of cancer biomarkers and targeted drug development.

Abstract Text

A novel class of metal-free spherical nucleic acid nanostructures was synthesized from readily available starting components. These particles consist of 30 nm liposomal cores, composed of an FDA-approved 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) lipid monomer. The surface of the liposomes was functionalized with DNA strands modified with a tocopherol tail that intercalates into the phospholipid layer of the liposomal core via hydrophobic interactions. The spherical nucleic acid architecture not only stabilizes these constructs but also facilitates cellular internalization and gene regulation in SKOV-3 cells.

Abstract Text

Nanostructured materials are key elements of energy generation and storage technologies. Their performance, in terms of activity and durability, is critically dependent on composition and structure, the nature of the surface, the interface and its morphology. This presentation will deal with the synthesis and [i]in situ/operando[/i] characterization of novel materials for fuel cells and batteries employing ordered intermetallic phases and nanostructured materials. In the case of fuel cells, we will focus on the oxygen reduction reaction (ORR) using Pt/M (M = Fe, Ni, Co, Cu) alloys as well as ordered intermetallic core/shell nanostructured electrocatalysts (1-3). Variations in electrocatalytic activity will be discussed within a framework of electronic effects and lattice strain. Operando methods, with emphasis on TEM will be presented and degradation mechanisms proposed. In the case of batteries, the presentation will focus on a detailed mechanistic study of the conversion reactions of Mn_3O_4 (4) as an anode material as well as in situ/operando lithiation dynamics of LiFePO_4 (5). The presentation will conclude with an assessment of future directions.

Abstract Text

Recently, we have shown that it was possible to couple a redox flow battery with two external circuits to carry out indirect electrolysis.

The gist of this approach is to store “junk electricity” in a redox flow battery when its prize from the grid or from renewable sources is very low and to use this stored redox energy to carry out indirect electrolysis.

For example, with a vanadium redox flow battery, Vanadium(II) can be used to produce hydrogen whilst Vanadium(V) can be used to oxidise SO₂ to generate protons and sulfuric acid. To perform these reactions in external reactors, it is important to use nanoparticle catalysts.

We shall discuss here nanoelectrocatalysis with nanoparticles supported on silica or other ceramics. Two redox half-reactions take on the nanoparticle, e.g. hydrogen evolution and V(II) oxidation, and we shall discuss both the thermodynamic and the kinetic aspects.

More generally, we shall discuss the role of nanoparticles in the field of redox flow batteries and possible applications for energy storage.

Abstract Text

To better understand the fundamental properties, correlate structure-function relationships of nanoparticles (NPs) and optimize NPs activity for various applications analytical tools that enable precise characterization of individual NPs are of immense importance. The development of "electrocatalytic amplification" is one such method where single NPs are detected by measuring electrocatalytic current (or potential) due to the electrochemical processes (oxidation/reduction of the species present in solution) occurring on the surface of the NP whenever a NP collides with an inert ultramicroelectrode(UME) which otherwise cannot catalyze the reaction. Here we report the influence of ligand, and morphology of the Pt NP on the current-time (i-t) response during single Pt NP collisions with the Hg UMEs. We evaluated the catalytic activity of ~11 nm spherical Pt NPs capped with different ligands(citrate, polyvinylpyrrolidone (PVP), polyacrylate (PA) and tetradecyltrimethylammonium bromide (TTAB)). Pt NPs of different shapes (hexagons and cubes) were also studied,as well as, Pt NPs without ligands referred as "naked Pt NPs". Hexagonal Pt NPs possess (100) and (111) facets where cubic Pt NPs possess (111) planes as preferential surface facets. The integrated charge passed per spike during single NP collision for polyacrylate capped hexagonal and cubic Pt NPs concentrated over a range of (120-210) and (40-120) pC respectively. Whereas, for naked hexagonal and cubic Pt NPs the integrated charge passed per spike during single NP collision concentrated over a range of (180-400) and (60- 200) respectively. Naked Pt NPs displayed higher catalytic activity for hydrazine oxidation compared to polyacrylate capped Pt NPs of similar size and size. Also, hexagonal Pt NPs displayed higher (two times) catalytic activity for hydrazine oxidation compared to cubic Pt NPs.

Abstract Text

Spatially resolved electrochemical experiments at the single nanoparticle level are essential for uncovering relationships between catalyst structure and performance. We used nanometer-sized electrodes and nanopipettes as tips in the scanning electrochemical microscope (SECM) to visualize and quantitatively measure catalytic activities of individual metal nanoparticles. New methodology was developed for detecting charged reactive intermediates and applied to mechanistic analysis of oxygen reduction reaction. A nanopipette filled with organic phase immiscible with the external aqueous solution was used to deliver neutral redox species (oxygen) to the electrocatalytic surface and detect negatively charged intermediate (superoxide). The developed approach is suitable for mechanistic studies of other electrocatalytic processes and other heterogeneous reactions involving ionic intermediates.

Abstract Text

MXenes, a recently discovered large family of two-dimensional (2D) early transition metal carbides and carbonitrides, have shown much promise in electrochemical energy storage applications, such as battery and supercapacitor electrodes. We recently reported on large volumetric capacitance and high rate capability of Ti₃C₂T_x – the most studied MXene to date. Spontaneous intercalation of a variety of single- and multiply charged cations, together with highly reversible electrochemical insertion of the same cations, has been well documented for Ti₃C₂T_x in aqueous electrolytes. Perfect capacitive behavior was observed for Ti₃C₂T_x MXene even at quite high charge and discharge rates, contradicting to slow intercalation of ions in a specific potential range, which is usually observed in layered materials for battery applications.

In order to understand mechanism of capacitance in MXenes we performed characterization of the mechanical deformations of MXene electrode materials at various states-of-charge with a variety of cations (Li, Na, K, Cs, Mg, Ca, Ba, and three tetra-alkylammonium cations) during cycling by electrochemical quartz-crystal admittance (EQCA, quartz-crystal microbalance with dissipation monitoring) combined with in situ electronic conductance and electrochemical impedance. Based on this work, it appears that in MXenes cationic insertion is accompanied by significant deformation of the Ti₃C₂T_x particles, that occurs so rapidly so as to resemble 2D ion adsorption at solid-liquid interfaces. The latter is greatly facilitated by the presence of water molecules between the MXene sheets.

Abstract Text

Carbon nanomaterials have potentially useful electrochemical properties, including fast electron transfer kinetics and high surface area. The use of carbon nanotubes (CNTs) in fabricating large electrodes has been widely demonstrated but the reproducible production of small, sensitive CNTs-based sensors is not as well studied. Our lab has investigated several different techniques for making CNT-based microelectrodes and investigated their response using fast-scan cyclic voltammetry. We have developed vertically-aligned CNTs on metal substrates as microelectrodes with chemical vapor deposition (CVD). The alignment of CNTs and the inherently high conductivity of metal substrates determine the sensitivity of the microelectrodes for nano-molar detection of neurotransmitters. We have also used CNT yarns/fibers as microelectrodes due to their different adsorption/desorption properties for dopamine that allow them to be used with higher temporal resolution without a decrease in sensitivity. Thus, CNT-based microelectrodes are advantageous as high sensitivity and high temporal resolution electrochemical sensors for neurotransmitters. Other types of carbon nanomaterials could be advantageous for microelectrode sensors as well, such as a different type of edge-plane graphene, termed carbon nanospikes. Carbon nanospikes are formed with plasma-enhanced CVD and do not require a catalyst. Preliminary electrochemical tests reveal that they have promising electrochemical properties that depend on the metal substrate they are deposited onto. Overall, this talk will explore the development of carbon-nanomaterial based microelectrodes for neurotransmitters detection. The ease of making different types of microelectrodes will be compared, as well as the electrochemical properties and implications for their use in vivo.

Abstract Text

Conducting polymer electrodes have emerged as an attractive alternative to metal and carbon-based electrodes in a variety of applications. Conducting polymer electrodes are inexpensive, easy to process, and are robust. Additionally, they have electron transfer kinetics appropriate to measure the redox properties of biologically relevant molecules. The poly(3, 4-ethylenedioxythiophene), PEDOT, family of conducting polymers offers the additional benefits of high optical transparency, electrochromism, thermal stability up to 260 °C, and demonstrated biocompatibility. PEDOT is most commonly dip-coated or electropolymerized onto metal or carbon electrodes before being employed for electrochemical measurements. PEDOT-only band electrodes (i.e. those without a conducting metal under-layer) have emerged recently and seen use as an electrochemical sensor. Other applications of structured conducting polymer films include antistatic coatings¹⁰, ITO-free and ITO-containing photovoltaic cells, capacitive touch screens in mobile devices, capacitors, lead-free solder, electrochemical actuators, and flexible displays in organic light emitting devices. Here we fabricate three dimensional PEDOT-based electrode arrays for in vivo monitoring of neurotransmission.

Abstract Text

The brain functions through a series of complex biochemical interactions that underlie organized neuronal circuits. Disruptions in these signaling pathways can result in dysfunction. As such, measuring the dynamic biochemical signaling in the brain is expected to provide critical information for understanding and treating numerous neuropsychiatric disorders. Unfortunately, the tools for measuring dynamic biochemical signaling in functioning tissue are still very limited. To meet this critical need, our group has been creating and adapting microfabricated electrochemical sensors for a variety of applications, effectively expanding the number and type of biochemical measurements that can be made in vivo utilizing electroanalytical techniques. We utilize fast scan cyclic voltammetry, a proven in vivo technology with excellent performance for our analytes of interest. Microfabrication enables the dimensions and geometry of the sensor to be precisely defined, improving sensor-to-sensor repeatability and enabling new sensor geometries to be created and tested. Recent efforts have focused on creating sensors that enable metabolic markers and monoamine neurotransmitters to be monitored on all time scales. This presentation will describe the creation and application of these microfabricated sensors to a variety of biochemical measurements in vivo.

Abstract Title **Electrochemical Quantification of Reactive Nitrogen and Oxygen Species (RNOS) Using Reduced Graphene Oxide**

Primary Author Sabine Szunerits
University Lille 1

Date: Wednesday, March 11, 2015 - Morn

Time: 10:35 AM

Room: 261

Co-Author(s) Rabah Boukherroub, Serban Peteu

Abstract Text

The importance of the so-called reactive nitrogen and oxygen species (RNOS) in biology and food technology has been widely recognized. However when these species are in excess, the steady-state maintained by physiological processes is disturbed leading to nitro-oxidative reactions in food and in living organisms. Analytical methods enabling the assessment of the antioxidant activity of a biological sample is therefore largely sought after. Among these RNOS, peroxynitrite (ONOO₂) is a well-known inflammatory mediator making the development of peroxynitrite specific sensors of urgent demand. Though several strategies have been developed for peroxynitrite detection, electrochemical quantification has come into the forefront of interest when it comes to real-time, label-free and direct measurements of these reactive species

This presentation investigates the electrocatalytic activity of metallophthalocyanine modified rGO hydrides towards peroxynitrite detection. Besides careful functionalization of rGO, strategies for the optimization of the interface design will be discussed.

Abstract Text

Norepinephrine (NE) is released by sympathetic nerves supplying small mesenteric arteries (MA) and veins (MV). We used continuous amperometry with a diamond microelectrode to study temperature sensitive mechanisms of NE release and clearance at the adventitial surface of isolated rat MA and MV in vitro. In this measurement, NE release is evoked by electrical stimulation and a fraction of the released NE diffuses from the release site and is measured as an oxidation current. NE release in MA and MV was blocked by the calcium channel blocker, CdCl₂ and by the sodium channel blocker, tetrodotoxin. NE current at MV was greater than at MA, and NE current at MV exhibited greater temperature sensitivity than at MA. At 37 °C, the rate of NE release was significantly greater at MV than that at MA but NE clearance at MV was slower. At 28 °C, there were no artery-vein differences in NE release or but clearance was slower in MV. The α_2 adrenergic receptor antagonist, idazoxan (1 μ M), increased NE peak current and the rate of rise at MA at 28 and 37 °C but not at MV at either temperature. The Gi/Go protein blocker, pertussis toxin (3 μ g/ml), increased NE current in MA but not MV at 28 and 37 °C. The NE uptake inhibitor, cocaine (10 μ M), increased peak NE currents and their rate of rise in MA at all temperatures. NE overflow in MV was unaffected by cocaine. The decay time of NE current was prolonged at MA but not MV at both temperatures. Guanethidine inhibited NE release through NE transporter in both MA and MV. The blockade of both NET and presynaptic α_2 receptor at the same time in MA increased the current amplitude, rise time and decay time at both 28 and 37 °C, but current rise slope was only increased at 28 °C. The difference of temperature dependent NE current sensitivity between MA and MV disappeared after cocaine treatment with and without idazoxan. We conclude that the NE release and clearance mechanisms are different in sympathetic nerves associated with MA and MV.

Session Title Recent Initiatives by FDA and Compendia: How do They Impact Analytical Development for Pharmaceu

Abstract Title **A Review of Applying QbD Concepts for Analytical Development for Pharmaceutical Drug Products**

Primary Author Shreekant V. Karmarkar
Baxter Healthcare

Date: Wednesday, March 11, 2015 - Morn

Time: 08:35 AM

Room: 269

Co-Author(s)

Abstract Text

The QbD approach including application of design of experiments (DOE) concepts for the development of analytical methods for product characterization, routine product release, and stability studies have recently gained momentum within the pharmaceutical and biopharmaceutical industry. The paper will provide a review of QbD based method development performed for injectable drug products. QbD concepts from ICH Q8, Q9, and Q10 can be applied to analytical method development for pharmaceutical drug products. A method development cycle can be significantly reduced yielding savings in time and money. Potentially, the QbD approach may be applied to non-chromatographic methods. ICH guidance would be useful in streamlining the QbD process and also to alleviate concerns over "How much extra work is needed" to implement QbD.

Abstract Text

There has been a great deal of interest in Analytical Quality by Design (AQbD) and Analytical Method Lifecycle Management in the past few years, including the recent publication of the USP and FDA draft guidances on Analytical Lifecycle Management and Analytical Method Validation, respectively. Additionally, a collaborative group of pharmaceutical representatives was formed from the IQ Consortium to discuss these topics. One outcome of the discussions was the development of a risk-based strategy for assessing analytical method comparability and the management of analytical methods changes. In this presentation, we will highlight the risk-based strategy discussed surrounding analytical method comparability and will share additional discussion topics and activities by the IQ analytical working group surrounding AQbD and Analytical Method Lifecycle Management.

Abstract Text

The lifecycle concept described in ICH Q8, 9&10 is adaptable to analytical procedures. The purpose of applying lifecycle principles to analytical procedures is to holistically align analytical procedure variability with the requirements of the product to be tested, and improve the reliability of the procedure by understanding, reducing and controlling sources of variability. Recently, USP initiates discussion towards to adoption of these concepts in its vision of validation, verification and transfer of analytical procedures (chapters <1224>, <1225> and <1226>). During this presentation, an update of the current state of the discussions will be presented.

Abstract Title **Why the Tolerance Intervals Fill the Gap Between Method Validation and QbD Guidances: The USP Trend**

Primary Author Bruno E. Boulanger
Arlenda

Date: Wednesday, March 11, 2015 - Morn

Time: 10:20 AM

Room: 269

Co-Author(s)

Abstract Text

Regarding the validation of analytical procedures, there are actually two – almost contradictory- trends existing: the ICH Q8 Quality by design thinking and the ICH Q2 guidance. Many dimension do oppose two set of thinking: The QbD has a goal-oriented and risk-based thinking to assure quality of each future outcome while ICH-Q2 is based on the state of the art thinking and evaluation of average performance of an analytical procedure. On one hand the quality of each measure matter, on the other hand only the average estimated performance matter. On one hand the way to develop and to continuously improve is central to the concept of quality while for ICH Q2, development is not part of the picture and improvement is not envisaged either: once a method is validated it is forever.

The USP new guidance aim at filling the gap by giving to the analytical procedure a lifecycle approach and introduce the concept of risk in the decision making process. Central to this idea is the use of the Tolerance interval to make a decision about the future quality of the results. The Tolerance Interval is in reality a prediction interval and it gives an idea about the probability of each measure to fall within the confidence interval. The allows to make the connection between the estimated performance of an analytical procedure (bias, precision) and the future chance or probability that each result in the future will be within the specification limits. In addition, as it will be shown, the tolerance interval has an impact on the lifecycle approach. Indeed the same tolerance interval can also be used to define control limits for future continued improvement of the analytical method. Finally, connections with the concept of uncertainty and risk-based management will be established. Globally, the presentation will attempt to show how UPS current trends in documents such as <1210> is not only providing new insights but allows to fill the gaps between the various concepts in place.

Abstract Text

My research group has been exploring the analytical applications of room-temperature ionic liquids (RTILs) for several years. Recently, we have extended the range of these materials to include analytical applications of similar solid phase materials, i.e. organic salts with melting points of solid ionic liquids (25 °C to 100 °C) and other organic salts up to melting points of 250 °C. Since most of these materials cannot be classified as ionic liquids by the current definition (melting points below 100 °C), we contrast these new materials from RTILs by creating a new acronym, GUMBOS (Group of Uniform Materials Based on Organic Salts). These GUMBOS have the tunable properties frequently associated with RTILs, including tunable solubility, melting point, viscosity, thermal stability, and functionality. However, these materials allow the production of solid phase materials which have a wider range of applications in measurement science, thus extending the task specific properties of ILs to the solid phase. In this talk, I will highlight recent applications of GUMBOS which we have explored in the area of measurement science, including GUMBOS as sensors, imaging agents, stimuli-responsive materials, and for production of nanoGUMBOS. In regard to the latter, we believe that our methodology represents an extremely useful approach to production of nanomaterials since our materials are designed and assembled for task specific uses, rather than adapted for such use as is done for many nanomaterials. Selected examples of such applications will be highlighted in this talk. Particular emphasis will be placed on a novel QCM sensor for measurement of volatile organic compounds with simultaneous molecular weight determination and development of sensor arrays for measurement of analytes in gaseous and aqueous media.

Abstract Text

Recent innovations in speed, accuracy and sensitivity have established mass spectrometry (MS) based methods as a key technology for the analysis of kinetic intermediates and folding mechanism of protein complexes. When complemented with theoretical calculations, Ion Mobility Spectrometry – Mass Spectrometry provides a powerful tool for the identification of structural motifs. We have recently introduced Trapped Ion Mobility Spectrometry coupled to Mass Spectrometry (TIMS-MS) as a high-throughput technique for the study of solution states of biomolecules (e.g., peptides, proteins, DNA and their complexes), as well as the kinetic intermediates involved during their folding as a function of the molecular environment (e.g., pH, organic and salt content). While this description holds true for most contemporary IMS analyzers, the higher resolving power (e.g., $R = 150-250$, 3x larger than traditional IMS systems) and the unique ability to hold and interrogate molecular ions for kinetic studies (e.g., millisecond-second time scale) provides TIMS-MS with unique capabilities (e.g., recently combined with hydrogen-deuterium exchange, HDX-TIMS-MS and selective dopants in the TIMS cell). That is, HDX-TIMS-MS has a significant advantage in the flexibility to interrogate, at the single molecule level, the molecular interactions that define the conformational space.

Abstract Text

Cells carefully control their architecture by restricting the localization of protein components. Both mammalian and bacterial cells are able to do this by enclosing proteins within, or associating proteins with, lipid bilayers. However, membrane proteins are notoriously difficult to analyze due to their hydrophobicity and/or denaturant-resistant properties. Organelle proteomics, which couples biological isolation methods with mass spectrometry techniques, has been successfully utilized to more fully elucidate the composition of distinct subcellular regions. Yet, additional novel protocols are necessary to characterize recalcitrant structures and dynamic internal associations. This presentation will highlight the diversity of innovative approaches developed and used by our laboratory to effectively enrich, identify, and characterize membrane-associated proteins from (1) the gram-negative bacterium [*Caulobacter crescentus*], (2) rodent mitochondria-ER contact sites known as [*m*]itochondria-*a*ssociated ER [*m*]embranes (MAM), and (3) rodent liver microsomes.

Abstract Text

Currently, there are approximately 50 proteins encoded in the human genome that contain the catalytic SET (Suppressor of variegation, Enhancer of zeste, Trithorax) domain, characteristic of nearly all KMTs. Roughly about a fourth of these KMTs have been shown to methylate histone proteins substrates to regulate gene expression. However, despite widespread efforts, only a small number of non-histone protein substrates for any KMT are defined. The significance of KMT activity in both normal physiology and disease is emerging as highly significant, as association of over 25 KMTs with a multitude of different human cancers have been reported. Therefore, an unambiguous determination of KMT activity, target sites and induced cellular responses or phenotypes would be highly beneficial to the chromatin, cancer and clinical biology communities, as this information is severely limited. We have recently developed novel quantitative affinity mass spectrometry (MS) based proteomics approaches to characterize in vivo protein lysine methyltransferase (KMT) activity in human cancers on both histone and non-histone proteins. Discussed will be the methods that we have developed to quantify histone modification patterns and also different methods to identify hundreds of non-histone methylated proteins in human cells, the most comprehensive large scale global analysis of protein lysine methylation (e.g. the "methylome") to date, including KMT specific methylomes.

Abstract Text

As a leading cause of death in developing countries and a persistent problem elsewhere, pathogenic organisms are as ubiquitous as they are dangerous. Significant worldwide resources are directed toward their detection and eradication, leading to a broad coalition of government agencies, healthcare providers, academic researchers, and food manufacturers dedicated to providing the best-available prevention strategies for mitigating exposure risk. At the forefront of this effort is the field of pathogen detection. Our work directly addresses the current lack of simple, rapid, sensitive, and selective pathogen detection methods needed for frontline intervention in the most at-risk populations. To begin, we focused on the common food- and water-borne contaminant, *E. coli*. Using a resonance energy transfer system incorporating a bioluminescent protein and quantum dots, we demonstrated that adjacent hybridization of sequence-specific, labeled probes could detect *E. coli* 16s rRNA at concentrations as low as 2.1 nM in only 5 minutes. Continuing, we developed a novel tuberculosis (TB) biosensor in both microtiter plate and paper-based microfluidic platforms for the detection of two different TB DNA biomarkers. The dual-platform design afforded either quantitative (microtiter plate, 1.0-20.0 nM) or qualitative (paper microfluidic) detection. Finally, we extended the paper-based platform concept to Epstein-Barr virus (EBV) detection using a target-bridged capture scheme in which EBER-1 RNA from EBV linked a tethered probe to a fluorescent reporter probe for a low nanomolar detection limit. While divergent in design and target, these assays achieve the aims of current pathogen detection research while providing cost-effective options for deployment in resource-poor environments.

Abstract Text

Serotonin is a neuromodulator that is most notoriously involved in depression. Depression affects up to 15% of the US population and is particularly prevalent (up to 50%) in Parkinson's Disease (PD) patients. Fast-scan cyclic voltammetry (FSCV) tracks serotonin concentrations in real-time in living mammalian brains. In this work, we direct a voltammetric analysis towards serotonin in mouse models of PD in the substantia nigra (SN). We assess the effects of induced PD and PD therapy (L-Dopa) on serotonin levels and find that serotonin neurotransmission is significantly altered in PD, correlating with time after disease onset. Furthermore, we find that L-Dopa therapy significantly exacerbates this alteration in serotonin neurotransmission. Via mathematical modeling, we propose mechanisms for PD related depression and discuss the relevance of antidepressants to this pathophysiology.

Abstract Text

Most often sensing with nanopores implies monitoring changes in the voltage driven ion flow across a single nanopore that separates two electrolyte chambers as target species are passing through or residing within the nanopore sensing zone. This versatile technique for studying and quantifying nanoparticles of synthetic or biological origin approaches the limits of practical applicability when used for the detection of small ions and polyelectrolytes. Instead of measuring extremely small current pulses here we present new sensing schemes based on using chemically-modified nanopores and potentiometric transduction of the selective recognition reactions within the nanopore. Beside potentiometric detection of ions and polyelectrolytes we are proposing alternative signal amplification schemes for quantification of polyelectrolytes using nanopores modified with selective artificial receptors.

Abstract Text

Ion-selective electrodes have been well established in a variety of analytical applications and a range of selective materials have been developed that allow these systems to exhibit the desired selectivity and detection limits for a range of target samples. Direct potentiometry, however, is prone to potential drifts and does not provide diagnostic information on the type of analyte that is detected. It is also not a technique useful for multianalyte detection.

This talk aims to describe concepts that may result in calibration-free multianalyte detection using ion-selective membranes. The goal is achievable with thin layer voltammetry at ion-selective membranes, where the sample composition is exhaustively altered in the course of the measurement. Diagnostics on the identification of the detected ions is possible by the resulting peak potentials. Early examples of this principle will be presented.

Abstract Text

In this work, two ion-transfer reactions at polymeric membranes are diagnosed voltammetrically to develop ultrasensitive ion-selective electrodes with subnanomolar and picomolar detection limits. On one hand, we demonstrate that perfluoroalkyl sulfonates and carboxylates are readily extracted into an ionophore-free membrane owing to the high lipophilicity of these emerging environmental contaminants. The extraction process, however, is limited by the moderate solubility of the fluorophilic ions in the lipophilic membrane, which explains why no response was obtained in ion-selective potentiometry. On the other hand, polypeptide protamine is only adsorbed at ionophore-based membranes in contrast to the traditional belief that the biomedically important polycation is extracted into the membranes for potentiometric and optical sensing. The voltammetric approach not only leads to the greater understanding of the membrane behaviors of the important analyte ions but also enables their ultrasensitive detection based on stripping voltammetry.

Abstract Text

Photodynamic molecules have far-reaching implications in medicine, forensics and environmental sciences. Advances in photochemistry and synthetic methodology promise molecules with tailored properties which can virtually cater to almost any application. Our interest lies in using reversible meta-stable photoacids in dynamic ion-selective optodes which can be used for the wireless detection of essential and toxic metal ions. The use of photoacids enables the sensor to be switched ON/OFF on demand while providing for spatial and temporal control. Our studies have open three directions of exploration. The first is the modulation of equilibrium response of the sensor by appropriate functionalization of the photoacids with groups having various electron demands. This enables us to tune equilibrium responses tailored to the time frame of the application. The second direction aims to solve leaching issues by covalently linking the photoacid to the sensor matrix. This approach also enables us to tailor the lipophilicity of the photoacid in the matrix. The third direction uses non-ionic photoacids which promises universal compatibility with all types of plasticizers, enhanced lipophilicity and may ultimately lead to pH independent sensing. The sensors we have designed so far are highly selective, have low limits of detection and are activated by visible light. Future work is aimed at miniaturization of these sensors as well as designing photoacid optodes which can be switched on in the near IR region.

Abstract Text

The presentation discusses the hydrophobic properties of different types of ion-to-electron transducer materials. The main focus is on polyazulene (PAz) [1] and polyaniline (PANI) [2,3] based materials, and composites consisting of graphene derivatives and electrically conducting polymers (ECP) [4-6]. In the latter, the ECP takes care of the ion-to-electron transduction while the graphene derivatives improve the pseudocapacitance, hydrophobicity and mechanical stability of the transducer. A few case studies with preliminary results will be briefly presented where PAz and the composite materials have been applied as transducers in polymeric solid-contact ion-selective electrodes. Finally, different strategies will be shortly discussed for reducing and mapping the water uptake of polymeric ion-selective membranes.

Abstract Text

Micro- and nanostructures are reaching considerable attention in context of sensing applications. Either linear dependence of signal on logarithm of concentration within the broad range or sigmoidal shape dependence within rather limited (fixed) range are reported [e.g.1,2,3]. The aim of this work was to investigate the possibility of modify sensitivity and response range of polymeric micro- and nanospheres. To achieve this goal in principle different approaches are available. Optimizing material used to prepare micro- or nanospheres is one of them. For "classical" microspheres change of the polyacrylate material (e.g. from poly(n-butyl acrylate) to poly(lauryl acrylate) can result in substantial differences in ion-permeability and ultimately in optical responses of microspheres.

The alternative is to use other materials like e.g. alternative polymers, to prepare nanospheres, with lipophilic core and ion-exchanging surface. This approach has resulted in fluorimetric sensors of broad responses range. The choice of polymer used of prepare nanospheres is shown to affect the response range and sensitivity of prepared sensors. Potassium or calcium ions sensors prepared were characterized with stable response and broad linear range of emission change accompanying change of logarithm of analyte sample concentration.

Abstract Text

The surface chemistry of nanoscaled plasticized poly(vinyl chloride) and unplasticized poly(methyl methacrylate)/poly(decyl methacrylate) membranes doped with redox molecules such as ferrocene and new hydrophobic cobalt organometallic compounds has been studied using cyclic voltammetry (CV), synchrotron radiation-X-ray photoelectron spectroscopy (SR-XPS) and near edge X-ray absorption fine structure (NEXAFS). This paper will present interesting findings on mass transportation effects to and from and within the nanoscaled membrane films.

Abstract Text

A calibration-free ion-selective electrode measurement requires that only the phase boundary potential at the sample/sensing membrane interface is variable (depending on the activity of the target ion in the sample) while all the other phase boundary potentials in the electrochemical cell consisting of the indicator electrode, the reference electrode, and the sample are constant. Historically, the biggest difficulties lie in establishing a reproducible phase boundary potential at the interface of the sensing membrane and the underlying electron conductor. This talk will address our newest finding using ion-selective membranes doped with redox buffers. It will also address the question on how water affects this phase boundary potential and how the time necessary for conditioning in aqueous sample solutions can be minimized.

Abstract Text

Recently, we developed a label-free detection method of biomolecules using nanostructures [1-3]. This method is based on diffraction of the light of the nanostructures fabricated in a micro device. The refractive-index difference between the samples in the nanostructures and a device substrate brings about change of intensity of the diffracted laser beam. In this paper, we demonstrate a highly sensitive detection of DNA (48 kbp) molecules (detection limit, 0.18 molecules) using our label-free detection method.

Abstract Text

Recently, extracellular vesicles have received researchers attention since the extracellular vesicles contain important cellular components such as RNA, DNA, and microRNA (miRNA). The miRNA analysis in the extracellular vesicles provides of great clinical importance as biomarkers for a variety of disease states. Several methods have been developed to isolate the extracellular vesicles from culture medium or body fluid; however, these methods require expensive facilities and large volume. In this study, we developed nanowire devices to isolate the extracellular vesicles from lower sample volume of culture medium or body fluid. We fabricated ZnO nanowires (100 nm in diameter and 2-3 μm in length) embedded in microchannels. The microchannels were etched using Reactive Ion Etching (RIE), and the ZnO nanowire were grown by aqueous synthesis in low temperature (85 $^{\circ}\text{C}$ for 20 hours). We compared extraction efficiency of miRNA in the extracellular vesicles using the nanowire devices with those using conventional methods. The conventional methods take over 24 hours at 4 $^{\circ}\text{C}$ by introducing agglutinating reagents to isolate the extracellular vesicles in the supernatant. In addition, the isolated vesicles were pelleted by centrifugation at 1500 g for 1 h. The pellets of the vesicles were re-suspended in lysis buffer to extract the miRNA. On the other hand, for nanowire devices, the miRNA could be extracted only by introducing lysis buffer after isolation of the vesicles inside the nanowire devices. Since the ZnO nanowires have positive charge on their surfaces, the negatively charged vesicles in the supernatant are trapped onto the ZnO nanowires by electrostatic interaction.

Abstract Text

Liquid chromatography (LC) columns and column packing materials have been downsized to achieve the high-resolution separation of chemical compounds. These downsized tools prepare a high specific surface area, it causes not only high-resolution separation but high pressure resistance. Large pumps, that can generate high pressure without pump pulsation, are also required to achieve high resolution and fast separation. On the other hand, a miniaturized device for on-site analysis is required for tests of water quality, soil, quarantine and so on. It is necessary to reduce the pressure resistance of LC columns and develop micropumps for achieving the miniaturized LC device.

We have proposed a novel concept of the miniaturized LC columns. The LC columns have incorporated a pumping function based on an electroosmotic flow (EOF). Two kinds of LC columns have been developed to satisfy the criteria; one is capillaries with monolithic materials prepared by organic or inorganic synthesis, and the other one is microfluidic channels with microstructures made by microfabrication technologies. These both columns have a large specific surface area and high porosity. The large specific surface area has possibility to generate fast EOF and high pressure, and high porosity can probably reduce the pressure resistance.

Prepared silica monolithic capillaries have lower pressure resistance than polymer monolithic capillaries. The silica monolithic capillaries also generate sufficient pressure for liquids to flow into it. After the immobilization of silica surface with sulfonate, the immobilized silica capillaries have retention of the cationic solutes. As for microfluidic channels, the reduction of pressure resistance and retention of hydrophobic solutes were confirmed by designing microstructures. These columns can contribute to miniaturize LC devices for on-site analysis.

Abstract Text

This paper reports the condensation and separation method of microdroplet contents by utilizing spontaneous emulsification nanodroplet formation at the microdroplet' interface. In this method, contents of the microdroplets were condensed, or separated depending on hydrophobicity and/or the size of the contents. For high throughput microdroplet-based analysis, versatile spectrometric detection is sometimes difficult to be applied because of its short optical path length. Another difficulty is a lack of in-line separation methods. As a challenge to solving these problems, we propose new condensation and separation method for microdroplets' contents. When spontaneous emulsification occurs at the interface of microdroplets, the microdroplet shrink and nanodroplets are generated. If the contents stay in the microdroplet, the contents will be condensed in it. The condensation was demonstrated in a 100-[micro]m-deep 250-[micro]m-wide channel, where aqueous dispersed phase and organic continuous phase with excess surfactant (Span 80) were used. Then, condensation of tris (2,2'-bipyridyl)ruthenium chloride due to shrinkage of the microdroplets was observed. On the other hand, Fluorescein was partition to nanodroplets and was not condensed. Investigations on these condensation/separation process will be presented.

Abstract Text

Recently, microfluidics are further downscaling to 10-100 nm space, where nanofluidic field is formed. In this field, basic liquid properties are increasingly investigated, while device application is also developed for analysis and energy generation. For this purpose, detection method in this ultrasmall space is essential. In particular, absorptiometry is one of the popular detection method. However, due to the ultrashort pathlength (10-100 nm), the sensitivity was low. Our group developed a differential contrast thermal lens microscope, which detects heat after light absorption sensitively and realized detection in 50 nm space with zmol detectability. In this presentation, we introduce the novel detection method and the unique characteristics (UV absorptiometry by visible light) by combining with optical near-field.

Abstract Text

The distribution of exocytotic activity has been found to be spatially heterogeneous at the surface of a single cell, resulting in hotspots where neurotransmitters are released more frequently. This subcellular heterogeneity across a single cell has thus motivated the design of microelectrode arrays (MEAs) capable of resolving the spatial variation of exocytosis across a single cell. The development of MEAs with electrodes small enough to allow quantitative measurement of released molecules from exocytotic hot spots distributed on the surface of a single cell is highly important to our understanding of the exocytosis process.

Here, we present the fabrication, characterization, and application of microwell-based MEA devices for high spatial resolution of release at single cells. The microwell-based MEAs consist of up to thirty-six 2- μm -width square ultra-microelectrodes, all inside a 40 μm \times 40 μm SU-8 square microwell. The microwell is used for single cell trapping and single cell culturing on the surface of MEAs. Effective targeting and culturing of single cells in the microwell are achieved by these cell-sized microwell trapping and micropipette picking techniques. Imaging the spatial distribution of exocytosis at the surface of a single PC12 cell has been demonstrated with this system. Exocytotic signals from multiple independent ultra-microelectrodes at a single PC12 cell demonstrating the subcellular heterogeneity in single-cell exocytosis.

Abstract Text

Control in crystal shape and/or polymorphisms are essential issue in protein crystal structure analysis and material chemistry field. We found that crystal growth can be controlled in small droplet generated in microfluidic chip [1-3]. This technique is based on decreasing the supersaturation by controlling the protein concentration gradient in a microdroplet after the first nucleation. By this method, we could control generated crystal number within the droplet.

First, we expand this approach to control the shape of protein crystal within small microfluidic chamber, because there is a demand on the controlling morphology and aggregation of protein crystals in order to obtain clear diffraction pattern via on-chip X-ray analysis. In particular, crystal habit of protein effects on the diffraction intensity. We found the potential of microfluidic chip for controlling crystal habit as well as aggregation of protein crystals by changing size and aspect ratio of microchamber on chip.

We also expand this approach to control polymorphism of organic materials. We employed L-glutamic acid, L-phenylalanine, indomethacin, paclobutrazol, as model compounds. In all cases, we were able to obtain the metastable form crystals by using simple droplet-based microfluidics, by decreasing supersaturation within droplet.

These results demonstrate that microfluidic chip is a suitable apparatus for controlling crystal habit and polymorphism.

Co-Author(s)

Abstract Text

In order to establish partitioning methods for high level radioactive liquid wastes, various separation techniques such as solvent extraction and chromatography for actinide and lanthanide ions have been investigated. However, mutual separation of lanthanides (Ln) and actinides (Ac) is difficult, because these f block elements possess relatively similar physicochemical properties. Therefore, this study aims at investigating the adsorption mechanism of lanthanide trivalent ions (Ln(III)) by using non-crosslinked N-isopropylacrylamide (NIPAAm)-based polymers, where brush-like polymers immobilized on silica (SiO₂) beads were employed.

The copolymerization of NIPAAm with N-vinyl-2-pyrrolidone (NVP) or 4-vinylpyridine (VPy) onto SiO₂ beads was performed by using surface-initiated atom transfer radical polymerization (SI-ATRP). The thermo-responsive behavior of NIPAAm-based polymers was investigated for Ln(III). In less acidic aqueous solutions, all the NIPAAm-based polymers exhibited only adsorption behavior with regular selectivity (Eu³⁺>Sm³⁺>Nd³⁺>Ce³⁺>La³⁺) at below the phase-transition temperatures. This tendency suggests that hydrogen-bond network of Ln(III) hydration would also largely contribute to the adsorption mechanism in weak acidic solutions. On the other hand, in more acidic solutions, the NIPAAm-based polymers exhibited adsorption and desorption at below and above the phase-transition temperature, respectively. The absence of desorption phenomenon for VPy copolymers corresponds to the disappearance of LCST caused by the high protonation of pyridine N atoms. Based on the prospect that the entire hydrogen-bond strength is almost unchanged in the low pH region, hydrogen-bond network would not significantly contribute to the adsorption/desorption mechanism in strong acidic solutions. The adsorption mechanism depends on coordination of electron-donating groups in polymers to Ln(III) ions.

Abstract Text

Our novel infrared imaging spectroscopy technology, introduced for the first time at Pittcon 2014, is equipped with an interferometer where interference takes place only when split light beams are combined again on the focal plane. There are two types of implementation of this technology, 2D type and one-shot type devices. The 2D type device is particularly suitable to take a spectroscopic image of as wide an area as a few 10 centimeters square like a human face.

We implemented the 2D type interferometer in as small device as a 50mm cube. This newly developed device is more than five times smaller than the previous one. Such a small device is suitable for several point-of-sales applications one of which is the whole face skin spectroscopy for the purpose of skin care.

Moisturizing cosmetics are used to help retain skin tension and elasticity. The amount of water contained in facial skin can be a good parameter to check how these agents work well and could help the customer choose the most appropriate moisturizing cosmetics.

When coupled with a compact 100 x 100 pixel infrared detector array, this device can divide the whole face into 100 x 100 pixels and infrared spectra are obtained for each of the pixels which could help estimate the facial skin moisture distribution.

This study was supported by a grant from the Japan Science and Technology Agency.

Abstract Text

Over the past several years, significant interest has been aimed towards determining the refractive index of living cells. By monitoring the refractive index important biological information can be assessed including cell activation, viability, accumulation and local interaction with biological stimuli. Current techniques to determine the refractive index of living cells are limited due to the non-uniformity of the cellular matrix and poor cellular adhesion. Surface Plasmon Resonance (SPR) has successfully been applied to refractive index monitoring of cellular cultures. SPR is advantageous for this type of detection because it is highly sensitive to small changes in the refractive index and provides a real-time response to changes in the cellular matrix. Previous investigations with SPR into the refractive index of living cells have been confined primarily to the visible and near infrared regimes. In these regimes, the penetration depth of the SP into the media is small, on the order of a few microns, whereas cellular height can vary from 2-12 μm . By extending SPR further into the mid-infrared, larger tunable penetration depths can be achieved which are compatible with the size of living cells. Herein we expand upon current MIR-SPR methodology, discuss the plasmonic resonances and characterize the bulk and surface sensitivities for gold in the MIR.

Abstract Text

In this article we report the maillard reaction, which was well researched by food, environmental, and organic chemistry field was induced inside human hair and analyzed micro changes by using focal plane array (FPA) detector attached to FT-IR. Arginine(A), glycerin(G), and xylose(X) which are common food ingredients were used to generate the maillard reaction. Each ingredient were dissolved in purified water and then heated at 150°C to induce maillard reaction. In this process label free study of monomer, which is the generated substance during maillard reaction kinetics, was proved. And the monomer structure was determined by using nuclear magnetic resonance (NMR) and FT-IR. The monomer formed within human hair was found by using FPA and it is the world first report.

Abstract Text

UV resonance Raman (UVR) spectroscopy has been applied to monitor the dependence of primary amide vibrations on hydration and conformation. Excitation within the $\pi \rightarrow \pi^*$ electronic transition of the primary amide group selectively enhances primary amide vibrations. We obtained UVR spectra of propanamide in solution and in the solid state in order to investigate the dependence of primary amide vibrations on hydration. The primary amide I, II, and III, and NH₂ rocking vibrations all display significant sensitivity to hydrogen bonding. We measured the Raman cross sections of the primary amide bands of propanamide in water and used these to determine the changes in cross section as a function of increasing mole fraction of water. The primary amide Raman band frequencies can also be related to the primary amide hydration. We will discuss these relationships and how they can be applied to molecules containing primary amides to determine the environment of the primary amide group. Additionally, we obtained visible Raman, IR, and pre-resonance Raman spectra of propanamide, butyramide, valeramide, L-glutamine, L-asparagine, and N-acetyl-L-glutamine in order to probe the dependence of primary amide vibrations on conformation. Preliminary results indicate that the primary amide NH₂ rocking vibration, which is enhanced in the pre-resonance Raman spectra, is sensitive to the O=CCC torsion angle. This vibration may be used to determine the O=CCC torsion angle distribution of side chains that contain a primary amide group, e.g. glutamine, in peptide and protein structural studies. Funding for this work was generously provided by the University of Pittsburgh and NIH 5 T32 GM 88119-3 (EMD).

Abstract Text

A recent study [1] has shown that ATR-FTIR, coupled with support vector machines, can discriminate low and high grade glioma (brain cancers) serum from serum collected from healthy patients. Highlighting the potential of IR spectroscopy for the screening of blood serum, which has the potential for significantly reducing current diagnosis times and greatly increasing the chance of successful treatment. However, the current instrumental setup only allows sequential data collection with each spectral acquisition of a blood serum spot taking approximately 10 minutes when taking into account drying times.

Recently, the first commercial laser based infrared micro-spectrometer has been developed by Daylight Solutions Inc. The Spero instrument incorporates a broadly tunable quantum cascade laser source producing hyperspectral images with a wide field of view, micron spatial resolution and high signal to noise over the 900-1800 cm^{-1} spectral range; hyperspectral images being recorded in 12 minutes over the full 900-1800 cm^{-1} spectral range. The Spero also has the unique ability of discrete sparse frequency imaging of samples, recording absorption information from a number of pre-selected wavelengths, further increasing the speed of spectral image acquisition times. We present the use of Spero for the rapid screening of cancerous blood serum, recording spectral images over the full achievable spectral range as well as discrete frequencies, chosen based on their saliency for distinguishing normal from cancerous blood serum. With sparse images recorded based on 12-14 discrete wavenumber frequencies being approximately 6 times faster than spectral images recorded over the full achievable range, sparse spectral images produced have the potential for the rapid diagnosis of blood serum. We also discuss recent methodological developments for high throughput serum analysis and diagnosis.

Abstract Text

Detecting and studying chemical changes on the surface of implanted medical devices during infection is challenging because the chemical sensor must provide a low background, surface-specific signal that can pass through tissue. We are developing sensor films that can be coated on implanted devices and interrogated through tissue with a combination of X-ray excitation and visible spectroscopy. When an X-ray beam irradiates the implant surface, light is generated by X-ray scintillators coated on the implant. This light first passes through a chemical sensor layer (e.g. pH indicator-loaded film that alters the spectrum according to pH), then passes through the tissue, and finally is detected by a spectrometer. A reference region on the implant is used to account for tissue-induced spectral distortion. pH images are acquired by moving the sample and collecting a spectrum at each location, with a spatial resolution limited by the X-ray beam width. Using this technique, we detected a pH drop during normal bacterial growth on the sensor surface, and a pH restoration during antibiotic treatment through with millimeter resolution through 6 mm ex vivo porcine tissue. We can also detect other spectrochemical changes such as dissolution of silver nanoparticles coated on an implant surface. Overall, this technique enables noninvasive, high-spatial resolution chemical imaging of implant surfaces through tissue to detect and study implant infection.

Abstract Text

FTIR spectrochemical images of Arctic sea ice diatoms have been obtained at a nominal 1.1 μm pixel edge spatial resolution, using upgraded optics installed in our thermal-source Agilent Cary 620 microscope (64x64 Focal Plane Array) attached to an Agilent Cary 670 spectrometer. The new optics provide the capability for diffraction-limited spatial resolution and thus enable bench-top FTIR spectromicrotomographic (SMT) imaging, previously demonstrated only with a multi-beam synchrotron-based system (Martin et al, Nat. Meth. 2013 10:861-864). As diatoms are a major primary producer in the Arctic spring, the volume of organic matter in organelles contained within their encapsulating silica frustules is relevant to the health of these organisms, and to the Arctic ecosystem at large. We have now used FTIR SMT to evaluate the composition of individual, intact diatoms, harvested from a landfast first-year ice site in Resolute Passage, NU, Canada (74 43.628'N; 95 33.330'W) and from Dease Straight, an important section of the Northwest Passage. Diatoms, selected individually under a dissecting microscope for species-specific examination, were captured on a MiTeGen polyamide microloop, to be mounted onto a goniometer and imaged. No further treatment of the specimen was required, as only native signals from unaltered diatoms are measured, and these are well resolved spectrally. Data import, computed tomography (CT) and voxelated display algorithms in MatLab[\circ] were adapted for back-projection of FTIR images. The distribution and abundance of compounds was reconstructed while maintaining a sub-cellular level of spatial resolution in three dimensions.

Abstract Text

The persistent need for biological and diagnostic tools has resulted in a growing demand for targeted affinity reagents. While antibodies remain the gold standard for affinity interactions, aptamers—short, single-stranded oligonucleotides that bind target molecules with high affinity and specificity—have emerged as a viable alternative. Aptamers derive their functionality from the various secondary conformations they adopt, including the G-quadruplex (G4) structure. The G4 structural motif is prevalent throughout the human genome, particularly within oncogene promoter regions, and may play an important regulatory role in gene transcription. Thus, guanine-rich promoter regions represent a source for potential aptamer sequences as well as possible targets for oncogene regulation. We have previously proposed a genome-inspired reverse selection pathway towards aptamer discovery based upon naturally occurring DNA sequences within human oncogene promoter regions. Here, we describe the application of our method to investigate several oncogenic promoters, including c-myc and c-myb, and their interactions with proteins extracted from the nuclei of human cancer and tumor cells. We report our findings concerning the captured proteins from initial screening by MALDI-TOF MS through sequence analysis via LC-MS/MS. In this way, new affinity interactions can be discovered, offering further insight into aptamer behavior as well as potentially elucidating biomarkers that may aid in cancer diagnosis and treatment.

Abstract Text

Vitamin D comprises a class of lipid-soluble secosteroids responsible for regulation of calcium stores in the human body. Deficiency can lead to osteomalacia, and has been implicated in cancer, cardiovascular disease, and diabetes. Immunoassays and LC-MS/MS are used to quantitate 25-hydroxy vitamin D₂ (25-OHD₂) and D₃ (25-OHD₃), the most common serum biomarkers. However, serum also contains a significant concentration of their less potent respective C₃ epimers, which can interfere with accurate quantitation. Although LC-MS/MS methods capable of chromatographically resolving these epimers have been developed, ion mobility spectrometry (IMS) offers an additional dimension of separation for the epimers.

We have evaluated two mobility strategies: drift tube IMS and field asymmetric IMS (FAIMS). Drift tube IMS separates compounds based on differences in mobility (collision cross section) through a drift tube. FAIMS separates compounds based on differences in their high and low field mobility. While 25-OHD₂ (m/z 412.6) and 25-OHD₃ (m/z 400.6) differ in molecular weight and can be separated using mass spectrometry, their respective C₃ epimers have the same molecular weight and fragmentation patterns, and thus cannot be differentiated. Preliminary experiments using an Agilent 6560 IMS quadrupole time-of-flight mass spectrometer (IMS-QTOF-MS) show that sodiated 25-OHD₂ and 25-OHD₃ can be separated, with collision cross sections of 206.8 and 202.0 Å², respectively. Studies are underway to determine optimal separation conditions for the C₃ epimer compounds. FAIMS is also capable of separating low molecular weight isomers, especially with the use of modifier gases. Studies are underway to optimize drift gas (e.g., nitrogen, carbon dioxide) and modifiers, such as solvent vapor, for separation of the C₃ epimers with IMS-MS/MS and FAIMS-MS/MS. These techniques offer an additional opportunity for separation of isomeric metabolites in complex matrices using LC-MS/MS.

Abstract Text

In the present study, Time of Flight Secondary Ion mass spectrometry (ToF-SIMS) was used to investigate the lipid localization in brain and intestine tissue sections from rats fed specially processed cereals and control rats fed ordinary feed. Intake of the processed cereals increase active antiseecretory factor in plasma, an endogenous protein with proven regulatory function on inflammation and fluid secretion. This endogenous increase counteracts the clinical intestinal symptoms in patients suffering from inflammatory bowel disease is also known to provide protection against raised intracranial pressure induced by experimental head trauma.

An IonToF 5 instrument equipped with a Bi cluster ion gun was used to analyze the tissue sections. Data from 15 brain and 15 intestine samples from control and activated AF rats were recorded using the stage scan macro raster with a lateral resolution of 5 μm . Data were subsequently exported to MatLab and then subjected to principal components analysis (PCA). The preliminary data clearly showed changes of certain lipids following activation of aAF from SPC cereal feeding. In the brain tissue samples, PCA score plots showed a good separation in lipid distribution between the control and the SPC-fed group. The loadings plot revealed that the groups separated mainly due to changes in cholesterol, vitamin E and c18:2, c16:0 fatty acid distribution as well as some short chain monocarboxylic fatty acid compositions. PCA score plots from intestine sections also showed a well-defined separation between the control and the aAF group. Here, the c18:2, c18:1, c16:0 as well as the distribution of several other short chain monocarboxylic fatty acids were changed between the two groups. Hence ToF-SIMS has provided important insight into the working mechanism of a factor known to activate aAF and provided clues for a subsequent targeted quantitative analysis of the lipid content in brain and intestine.

Abstract Text

Bacterial biofilms, such as those created by the gram-negative bacterium [*Pseudomonas aeruginosa*], have a rich, three-dimensional spatial and chemical architecture that allows a clonal consortium of single cell organisms to live as a cohesive unit. Biofilm colonies thrive in a variety of environments, including on the surface of fuel tanks, in the depths of our lungs, and at the junctions of human prosthetics. We combine polyatomic secondary ion mass spectrometry (SIMS), matrix assisted laser desorption ionization (MALDI), and electron microscopy (EM) to develop a multimodal analytical approach capable of exploring the complex heterogeneity contained within bacterial communities. Using a chemical inkjet printer, a micro-droplet array of MALDI matrix is applied directly to the surface of [*P. aeruginosa*] biofilms. The spots in this array are subsequently used for both MALDI analysis, which provides information on the distribution of high mass biomolecules, and as fiducial markers for sample navigation and image correlation. The area between the matrix spots is then subjected to bombardment with a non-destructive C_{60}^{+} ion beam, yielding molecular ion images at high spatial resolution. The film is finally imaged with EM, providing structural information corresponding to the chemical images acquired by SIMS and MALDI. Initial SIMS results show micron scale chemical heterogeneity including areas with high levels of specific cell-cell signaling molecules (e.g. quinolones HHQ, NHQ and C_9 -PQS), while MALDI reveals more homogenous distributions of several larger biomolecules at macroscopic scale. Funding provided by the National Institutes of Health, the Department of Energy and the Springborn Endowment.

Abstract Text

Human histone deacetylase 8(HDAC8) serves as an essential epigenetic regulatory enzyme in gene transcription. HDACs act as components within many multi-protein complexes, and bind to metal ions in vivo. Understanding how HDAC8 interacts with other proteins, and the effects of metal binding on its enzymatic activity, are long-standing challenges for structural and molecular biology. Ion mobility- mass spectrometry (IM-MS) is an information-rich assay for protein-protein complexes, as it enables structure assessments on complexes from small amounts of sample within heterogeneous mixtures. Herein, Poly-r(C)-binding protein 1(PCBP1), an iron chaperone, is studied as a potential binding partner for HDAC8 using IM-MS. Specifically, we investigate the interaction, stoichiometry, metal binding, and structure of the complex. HDAC8 has one metal (e.g. Zn) binding site, and PCBP1 has three iron binding sites. Previous work suggests that HDAC8 interacts with PCBP1, but does not ascribe specificity the complex. Our nESI-IM-MS data, however, indicates the two proteins bind specifically, forming a heterodimer at low protein concentrations in vitro to an extent that appears enhanced relative to any homodimers. The specificity of the HDAC8-PCBP1 heterodimer was tested further by introducing Carbonic Anhydrase II(CAII) as a negative control. No significant ion intensity was detected for CAII hetero-complexes in our IM-MS experiments, further confirming the specificity of the HDAC8-PCBP1 hetero-dimer. To further investigate the role of metals on the structure of the complex, samples containing either apo, zinc or iron(II) bound HDAC8 were incubated with apo, as well as iron(II) bound PCBP1 and screened for complex formation and structural effects by IM-MS. This presentation will contain our latest IM-MS results that track the binding efficiencies and structures of these newly-discovered, centrally-important protein complexes.

Abstract Text

Proton-transfer-reaction-time-of-flight-mass-spectrometry (PTR-ToF-MS) is a powerful tool for real-time analysis of VOC profiles in breath. Time resolutions as low as 200 msec and detection limits in the pptV-ppbV range enable breath-resolved measurements in mechanically ventilated and spontaneously breathing patients.

The high water content in breath samples however can have a distinct impact on the quantification. The objective of this study was therefor to systematically investigate the effects of humidity on the quantitative detection of breath VOCs and the adequacy of standard data processing algorithms applied in PTR-MS.

More than 20 VOCs (hydrocarbons, ketones, aldehydes and aromatics) were investigated in different trace concentrations (2, 5, 10, 25, 50 and 100ppbV) and different amounts of humidity (0, 1, 25, 50 and 100% rel. humidity). Further, normalization of data onto primary ion count and normalization onto primary ion count in combination with watercluster ion count was tested.

Measured intensities of VOCs varied up to 40% when water content was varied, while variation was less than 5% when water content was kept constant, independent of the total amount of water in the sample. Normalization onto primary ions reduced the variation for aldehydes (from 40 to 32% for heptanal e.g.), but increased it for aromatics (from 8 to 15% for toluene). These effects were even more pronounced when watercluster was included in the normalization process. Quantification of biomarkers thus can be compromised if matrix effects like humidity are neglected. Hence, adapted calibration mixtures are mandatory for the reliable quantification of humid samples in real-time PTR-ToF-MS measurements.

Abstract Text

Surfactants are used in protein sample preparation and analysis to improve protein solubility and stability. Sodium dodecyl sulfate (SDS) is a common anionic surfactant which is currently used for protein analysis by Matrix Assisted Laser Desorption Ionization (MALDI) - Mass Spectrometry (MS). The major drawbacks of SDS use in MALDI-MS protein analysis are deleterious spectral effects which are caused by sodium-protein adducts formation. The use of SDS affects the resolution and signal to noise ratio which results in inaccurate mass analysis. We have synthesized novel cationic ionic liquid surfactants (ILS) which can be used as additives in protein samples for MALDI-MS analysis. The spectral effects in protein analysis of both ILS and SDS were examined and compared at different concentrations (0%, 0.02%, 0.05%, 0.1%, 0.5%, 2%, and 5% (w/v)) using a MALDI-TOF mass spectrometer. Interestingly, the protein signal intensity was significantly improved in the presence of low concentrations of ILS as compared to 0% ILS. Above the concentration of 0.5% ILS, the signal intensity was reduced. Conversely, the protein signal was suppressed at low concentrations of SDS as compared to 0% SDS and the signal was highly degraded at 0.1% SDS. Recovery of signal intensity occurred above the concentration of 0.1% SDS. The results suggests that low concentrations of cationic ILS can be used as MALDI MS signal resolving agents for protein analysis where high concentrations of anionic SDS are currently required to obtain comparable spectral features.

The work is supported by the National Science Foundation under Grant number CHE-1307611.

Abstract Text

Discovery of biological markers at the earliest possible stage of cancer progression is a priority in all aspects of cancer-related research. Earlier detection methods and more accurate markers result in lower mortality rates and higher quality of life for patients. Recent studies have been published revealing an apparent difference between the volatile metabolome of melanoma and melanocyte cells, but only after pre-concentration and preparation steps. Identification of additional biomarkers, as well as development of a real-time method incorporating little or no sample preparation would revolutionize current melanoma-detection schemes.

Three mass-spectrometric setups were utilized: an Agilent 6220 TOF, a Thermo Scientific LTQ XL, and a Thermo Scientific Q Exactive. Multivariate data analysis was performed through MetaboAnalyst and SIEVE. Cells of a given type were pooled in H₂O, lysed in cold 80% MeOH/H₂O to precipitate proteins, and then centrifuged before drying the supernatant under nitrogen at 35 [degree]C. Dried samples were reconstituted with 0.1% FA in H₂O for LC/HRMS or 80% MeOH/H₂O for direct analysis (APCI/MS and DART/MS).

In preliminary studies, normal melanocyte and malignant melanoma human cell cultures were analyzed by LC/HESI/HRMS, APCI/MS, and DART/MS. Both PCA and PLS-DA were performed on the data, and first component separation was ubiquitous among all methods. This finding suggests a distinct difference between the volatile and semi-volatile metabolomes of melanoma cells vs normal melanocytes, in addition to allowing identification of potential biomarkers for melanoma. Ongoing experiments have been performed on swabs of live human skin at sites of normal skin and latent melanomas.

Abstract Text

Accurately detecting and de-convoluting overlapped chromatographic peaks generated by co-eluted metabolites in GC-MS is the key to high accuracy metabolite identification and quantification. We developed an algorithm for de-convoluting the overlapped chromatographic peaks at the mass spectrum level, including baseline correction, total ion current (TIC)-based peak detection, selected ion chromatogram (XIC)-based curve fitting, and chromatographic peak center and width-based clustering. The baseline correction removes background noise for accurate determination of true peak shape from the TIC and XIC, respectively. We used TIC-based peak detection to recognize candidate chromatographic peak ranges followed by Gaussian model-based curve fitting. In order to determine the number of compounds present in a range of overlapped chromatographic peaks, mass spectrum similarity scores between every two adjacent spectra were calculated. The number of co-eluting compounds was considered as the initial number of Gaussian functions. A mixed Gaussian model was then employed to fit each XIC by minimizing the curve fitting error. After the Gaussian model fitting, the XIC of each compound is represented by a set of coefficients, peak center and peak width. We further use pairs of peak center and peak width to distinguish the co-eluted compounds by retention time.

Our developed method was applied to analyze GC-MS data of mixtures of standard compounds. Compared with the software from the Agilent instrument, our method found more compound standards with high values of positive predictive value, true positive rate and their F1 score.

Abstract Text

USEPA, Office of Groundwater and Drinking Water, and CB&I Federal Services LLC have developed an improved method for estimating the lowest concentration at which 'reliable' measurements of analyte concentration can be made, known as the Lowest Concentration Minimum Reporting Level (LCMRL). The LCMRL procedure is a single laboratory, single analyst method. It is currently used by individual laboratories to establish their lowest achievable reporting limit for Drinking Water analysis.

The LCMRL is the lowest concentration for which future sample recovery is predicted to be between 50 and 150%, with high confidence (99%). The procedure simultaneously takes into account precision and bias. A designed experiment is carried out in which samples at each of several known concentrations are taken through the entire measurement process. Regression functions for the mean and variance of the measured concentration are estimated from this experimental data. The variance function is a constant + power function, which includes the well-known Horwitz Law for the variance of repeated analyses as a special case.

Given the estimated mean and variance functions, the distribution of repeated measurements at a specified concentration is taken to be Gaussian when negative measurements are possible (such as when background or 'dark current' corrections are required) or Gamma when they are not. Given this information, we can estimate conditional probabilities of any event that we are interested in, including the probability that the measured value is between 50% and 150% of the true value. The lowest concentration at which this coverage probability equals the desired confidence (99%) is the LCMRL.

Time: 09:10 AM

Room: 255

Co-Author(s)

Abstract Text

Anomaly and target detection methods tend to be treated as independent algorithms for analysis of hyperspectral images. The difference in the approaches is that target detection is a supervised pattern recognition technique while anomaly detection is an exploratory analysis method. Target detection algorithms such as generalized least squares (a.k.a. matched filter) typically employ known, well-characterized, library spectra for detection and classification. Unfortunately, due to measurement related differences between the library and the measured data (e.g., matrix effects) there may be mismatch between the library and the measured spectra resulting in a compromise in detection performance. Additionally, only the selected target is considered in the detection task. On the other hand, anomaly detection methods such as maximum signal factors (MSF) can be used with current measurements to explore anomalies where the observed anomaly is used as the measurement relevant target. Recent advances in MSF algorithms have improved detection performance, reduced memory and time requirements, and reduced the number of scores images that to be inspected during exploratory analysis. However, the detected anomaly must be compared to library spectra for classification. As a result, it should be seen that target detection and MSF form complimentary approaches to detection and classification resulting in measurement relevant target detection. Examples of the two approaches, applied separately and together, will be shown with hyperspectral images.

Abstract Text

The large amount of data generated by modern analytical instruments and the complexity of samples being analyzed is fueling interest in the use of chemometric techniques. However, with the inordinately large number of variables per sample present in some data sets (notably chromatography-mass spectrometry) some form of feature selection is mandated. This is due to the presence of a large number of irrelevant variables which will collectively degrade or completely obscure any useful signals in the data. We have previously developed and demonstrated a model quality assessment parameter for classification models termed Cluster Resolution (CR), which lends itself to guiding automated feature selection processes.

Generally, the CR metric is used in a hybrid backward elimination / forward selection algorithm for objective variable subset selection in supervised classification/pattern recognition models. In earlier works, CR-FS was applied to classification of complex samples with a high degree of success. Notwithstanding, the performance of this algorithm has not been compared with other feature selection techniques already available.

In this study, we benchmark CR-guided feature selection against other feature selection algorithms such as genetic algorithm, random forest, etc. The parameters for objective comparison include feature selection time; model quality i.e. specificity, sensitivity and accuracy; robustness of the FS process and the chemical significance of the features that survive the process.

Abstract Text

Modern automotive paints have a thin color coat which on a microscopic fragment is often too thin to obtain reliable chemical information. The small size of the fragment also makes it difficult to compare it with manufacturer's paint color standards. Since adhesion between paint layers is strong, both primer layers are often transferred during a collision if the clear coat and color coat layers are also transferred. As the clear coat and primer layers are often unique to the automotive assembly plant where these layers are applied, combining chemical information obtained from IR spectra of the two primer layers and from the clear coat layer has made it possible to rapidly and accurately identify the assembly plant of an automobile from its paint system. Applying data fusion techniques where IR spectra from multiple sources (e.g., the clear coat and primer paint layers) are combined and class membership information is extracted, search prefilters for the PDQ library have been developed to determine both the manufacturer and the model of a vehicle from an automotive paint sample. Even in challenging trials using a database of 1324 paint samples where the clear coat and undercoat paint layers evaluated were from GM, Ford, and Chrysler with a limited production year range (2000-2006), the respective assembly plant of an automobile was correctly identified using only information extracted from IR spectra of the clear coat and primer paint layers. Applying wavelets to preprocess the IR spectra, advantages associated with higher order data fusion techniques were achieved when a genetic algorithm was used to identify the informative wavelet coefficients. The development of search prefilters to cull library spectra to a specific assembly plant and a cross correlation library searching algorithm to identify spectra most similar to the unknown in the set of spectra identified by the search prefilters is the subject of this presentation.

Abstract Text

The ability to rapidly generate chemical-based image contrast from hyperspectral image data is a fundamental challenge due to the large quantity of data in these datasets. Currently-used spectral angle-based methods can be problematic because obtaining the same correlation scores for two distinct spectra becomes probable as the number of spectra increases or as the signal-to-noise ratio decreases. We have developed a fully-automated method called reduction of spectral angle symmetry (ROSAS), which is effective in differentiating spectral shapes in hyperspectral image data. ROSAS is a data reduction method that enables estimates of the original spectra to be recovered from the smaller-dimensioned sets of cosine scores. The effectiveness of the recovery algorithm can be calculated based on the magnitude of the resulting spectral vector. By utilizing principal component analysis with cosine correlation analysis, chemical-based image contrast is generated that results in the reduction of degeneracies caused by angular symmetries. ROSAS can be done rapidly, requires no training datasets or a priori information about the sample, and takes advantage of the full color-space of modern RGB displays. A full theoretical description of the method is given along with performance metrics. The description has been generalized to work with any number of wavelength dimensions and spectra. A concise protocol is put forth that will enable other researchers to utilize this method by following a short, simple list of steps.

Abstract Text

A novel application of linear discriminant analysis (LDA) is proposed for determination of optimal digital filters for data deconvolution. The theoretical framework underpinning the generation of LDA-filters is described. Results from the use of LDA-filters are presented for recovering impulse responses in photon-counting from a high speed photodetector (rise time of ~1 ns) and applied to remove ringing distortions from impedance mismatch in multi-photon fluorescence microscopy. Training of the digital filter was achieved by defining temporally coincident and non-coincident transients, and identifying the projection within a high-dimensional "filter-space" that best separated the two classes. Once trained, data analysis by digital filtering can be performed quickly. Assessment of the reliability of the approach was performed through comparisons of simulated voltage transients, in which the ground truth results were known a priori. The LDA filter was also found to recover deconvolved impulses for single photon counting from highly distorted ringing waveforms from an impedance mismatched photomultiplier tube. The LDA filter was successful in removing these ringing distortions from two-photon excited fluorescence micrographs and from data simulations was found to extend the dynamic range of photon counting by approximately three orders of magnitude through minimization of detector paralysis.

Abstract Text

How does one compute the mathematical certainty of wavelength standards used for calibrating instrumentation used for molecular spectroscopy measurements? This question becomes of major importance when the technique used for measurement requires collection of large databases for use in qualitative searches or quantitative multivariate analysis for multiple applications. Wavelength drift over time within a single instrument or wavelength differences between instruments creates errors and variation in the accuracy of measurements using databases collected with different wavelength registrations. The loss of integrity over the wavelength axis of data collected over time is a significant problem in large database creation and usage. So what are the techniques and mathematics used to compute uncertainty, and the optimum methods for maintaining wavelength accuracy within instrumentation over time, when considering measurement condition changes? This paper addresses a comparison of commercial instruments for wavelength precision and accuracy and what techniques are available for improving the agreement between first principles physics and metrology as compared to current common practices (1-2).

Abstract Text

In general PLOT columns are used for analyzing volatile compounds. Alumina has an ideal selectivity for light hydrocarbons, but it has a limitation for many other compounds. Also water in the sample or carrier gas, has a big impact on retention reproducibility.

Using Silica as an adsorbent, a much wider range of components can be analyzed.

Besides hydrocarbons, silica also elutes many other neutral compounds like halogenates, and sulfurs. Even slightly polar compounds like ketones or aldehyde elute from silica surface. Additionally, by using surface deactivation, one can make silica also in such a way, that water does not impact retention.

The challenge is to create silica surface that has enough retention and loadability to be used as a GC PLOT column. A new adsorbent material has been introduced called Silica BOND, which provides a high selectivity for hydrocarbons without adsorption of moisture. The new PLOT column also shows a high degree of inertness as it elutes also polar volatile compounds.

Besides this, a new immobilization process is developed making the column suitable for valve switching and high flow applications. Several applications of this new adsorbent will be presented and discussed.

Abstract Text

Thermochem Recovery Intl (TRI Inc) is developing integrated thermochemical biorefineries that have recently begun demonstrating conversion of municipal solid waste (MSW) to Fischer Tropsch fuels. By undertaking the challenge of converting MSW to a gas that must then be refined and used for synthesis, TRI has found it absolutely necessary to improve on traditional methods of refinery gas analysis.

MSW syngas contains an unpredictable and extremely large range of organic and inorganic species rarely seen in other gasification and refining developments. To allow further refining of this syngas, near real time analysis with ppb level sensitivity for numerous organic and inorganics sources of sulfur, nitrogen, and chlorine is a necessity. Traditional methods like GC-FID, GC-TCD, GC-SCD, and GC-MS are not functional due to dynamic gas compositions and/or lack of qualitative or quantitative capabilities. Maintaining suitable calibrations for the wide range of compounds and concentrations is also problematic.

After years of collaboration with Prism Analytical on various gas analyses, TRI is excited to report on a new technology that offers a paradigm changing analytical solution for this and other refining applications. GC-MAX™ provides near real time analysis of MSW syngas regardless of the potential interferences. From the analytical perspective MSW syngas is a very challenging gas stream to analyze both qualitatively and quantitatively. Despite this complexity, initial tests with the GC-MAX™ technology on model MSW syngas suggest that it can provide the analysis and speeds required for tight process control and optimization. The GC-MAX™ technology and the MSW syngas application will be discussed.

Abstract Text

Wood is one of the possible starting materials for producing biofuels. Unlike crop sources for biofuels (e.g. corn and sugar cane), wood can be harvested year round. In order to produce a biofuel from wood, it must first be broken down to its fermentable carbohydrates. This is often accomplished by acid hydrolysis. Fermentation then yields the biofuel (e.g. bioethanol). To maximize process efficiency it is necessary to determine the types and amounts of fermentable carbohydrates in the wood acid hydrolystate. We designed a high-performance anion-exchange chromatography with pulsed amperometric detection (HPAE-PAD) method to separate and quantify the neutral sugars fucose, arabinose, galactose, glucose, xylose, mannose, fructose, cellobiose, and maltose contents of wood acid hydrolysates. Rhamnose content can be determined with the same method by lowering the column temperature from 45 to 30 oC. To determine the galacturonic and glucuronic acid contents we designed a method using another HPAE column. These methods yield a nearly comprehensive assessment of the carbohydrates present in the wood acid hydrolysate. Another method, using a third HPAE column, was developed to determine the neutral sugars and uronic acids in a single method, albeit in a longer time than required for the other two methods combined. The utility of these methods was demonstrated by quantifying the carbohydrates in a Loblolly pine wood acid hydrolysate and a rinsate.

Abstract Text

High quality control of hydrogen gas, during production, transportation, storage, and utilization, is requested for commercialization of hydrogen and fuel cell technology. With the aim of assuring uniformity in the final quality of the hydrogen product, the International Organization for Standardization has been considering an international standard of technical specification, indicating the maximum content of certain non-hydrogen gases (ISO 14687-2). The technical issues being addressed in this standard, which has been published in December 2012, concern the detection of impurity species in hydrogen, at levels that are for some of them very low (ppb level). Especially, achieving the detection of active sulphur compounds at ppb-level, the major poisons of fuel cells systems, is highly challenging. Considering the ISO requirements, the Analytical Sciences Group at Air Liquide has developed a series of accurate and robust analytical methods using a single, multifunction instrument based on gas chromatography coupled to different detection systems. The instrument, which allows the detection of carbon monoxide, nitrogen, oxygen, argon, methane, carbon dioxide, but also non-methane hydrocarbons, sulphur compounds and formaldehyde, will be described.

Abstract Text

The Aviv Analytical 5975-SMB GC-MS with Cold EI provides significantly enhanced molecular ions for all hydrocarbons and thus enables their vastly improved analysis including their isomer distributions. In addition, isomers and structurally related fragments mass spectral peaks are exhibited which enable their NIST library identification. Furthermore, extended range of compounds are amenable for analysis with short column and high column flow rates, including low volatility large oil and wax compounds that cannot be analyzed by standard GC-MS. In addition, the 5975-SMB GC-MS enables much shorter analysis time and improved sensitivity that could be up to and over three orders of magnitude better on the molecular ions of large hydrocarbons than what can be achieved with standard GC-MS.²

The isomeric content and its distribution affect all the major physical and chemical properties of oils and fuels, including: combustion efficiency, octane number, flash point, viscosity, lubrication properties, solubility and solvation power, boiling points and melting points. However, since current GC-MS can not be properly used for isomer distribution analysis in view of weakness or absence of there molecular ions, this important subject is being ignored and represents an untapped opportunity. The presentation will demonstrate how the provision of enhanced molecular ions combined with extended range of compounds amenable for analysis and faster analysis dramatically improves GC-MS analysis of real petrochemical fluids and how it enables isomer distribution analysis for unique fuels and oils characterization.

Abstract Text

There is a considerable amount of research focused on the formation of bioethanol using nonfood biomass feedstocks (lignocellulose, hemicellulose and cellulose). Studies indicate that by 2015, bioethanol production will exceed the needs of E10 fuels, resulting in an oversupply of ethanol. Consequently, bioethanol appears to be the platform molecule for the production of value-added chemicals in the next decade. The ethanol-to-ethylene conversion using various zeolite catalysts is well documented. The role of the catalyst in ethanol stream reforming (ESR) continues to be of interest.

The catalytic conversion of ethanol appears to be an ideal process to use as a benchmark for system performance: ethanol is stable, and the ethylene selectivity is high using readily available zeolite catalysts. This work describes the findings of an evaluation of the Tandem Micro-Reactor GC/MS system based on the conversion of ethanol. The results of the following tests will be reported:

1. Monitor hydrocarbons formed as the temperature of the catalysis is heated at a fixed rate.
2. Monitor hydrocarbons formed at selected catalyst temperatures.
3. Determine the amount of sample converted to char using EGA-MS.
4. Monitor the surface activity of the catalyst using ethylene as a test probe.

Abstract Text

Long term interconnected organ-on-a-chip systems (OoC) present the opportunity to more accurately predict patient reactions to pharmaceuticals than traditional cell culture protocols. Integrating heart, lung, liver, and kidney OoCs, presents an opportunity to observe how drug metabolism in the liver as well as the resulting side reactions could affect other organs in the system. To determine the long term effects of particular stimuli, effluent from the system should circulate through each of the organs, just as blood continually circulates through the human body. For meaningful information to be determined from studies of this nature, the health of the organs needs to be monitored without sacrificing excessive amounts of fluid. Previous work has shown the detection of glucose, lactate, oxygen and acid levels using modified screen printed electrodes in a 26 μ L chamber; however, measurements on smaller volumes are necessary to avoid altering the system significantly. A new platinum electrode array has been fabricated using electron beam deposition and soft lithography, and modified through electrodeposition and ink-jet printing techniques. Upon modification, the sensor array was capable of measuring glucose, lactate, oxygen and pH as well as significant changes in solution conductivity. Electrochemical detection occurs in a multichannel PDMS housing defining an approximately 350nL sample chamber.

This work was funded by the Defense Advanced Research Projects Agency (DARPA W911NF-12-2-0036) and Vanderbilt Institute of Chemical Biology.

Abstract Text

Reactive oxygen species (ROS) play a vital role in the etiology of disease in vivo. Physiological levels of these species appear to be involved in myriad of physiological and pathological processes. Superoxide radical (SO), in particular, plays a significant role in ischemia-reperfusion injury in the brain. Real-time monitoring of superoxide dynamics in vivo would provide useful insight into the evolution of this free radical, but real time monitoring has not been achieved due to the lack of adequate methods. This presentation will discuss the use of electrochemical, Cyt C microbiosensor that can reliably measure the temporal evolution of superoxide continuously in a rat brain in vivo. We will also discuss the dynamics of superoxide evolution during the progress of ischemia-reperfusion (I-R) injury in a rat model of stroke. Additionally, we studied the role of ceria nanoparticles as a model antioxidant and explored their capacity to scavenge the superoxide and to use them as a potential therapeutic target during I-R injury. We will present the ability of our biosensor to examine, in situ in intact animals, the scavenging ability of Cerium oxide nanoparticles and their contribution in controlling SO levels during normoxic, ischemic and reperfusion periods in whole animals.

Abstract Text

Real-time monitoring of chemical changes in patients is currently an area of great interest, as it provides the possibility of real-time feedback of the patient's condition to the clinical team. However, there are two main barriers to accomplish this:

1. Real-world sensors or biosensors do not maintain constant sensitivity and offset during long-term monitoring.
2. The clinical team need chemical concentrations from biosensors to have the physiological understanding of the patient's condition.

Currently, most research monitoring devices give signal output of voltage, rather than concentration, hence they are not able to provide real-time clinical feedback to improve the treatment of patients, due to these two conflicts.

We have designed a novel miniaturised wireless microfluidic-based sensor auto-calibration system, with on-board high-precision data converter, high-speed micro-processor, and relevant user interface, which allows users to set up relevant calibration parameters seamlessly. After every calibration process, the processor will automatically calculate and store the calibration curve, and fill the most up-to-date sensitivity into the monitoring system. For each sensor channel, the system provides two different outputs: raw voltage signal, and processed real-time concentration. The controlling application software has been implemented on computers and mobile devices (e.g. smart phones and tablets).

The experimental data from different applications will be presented.

Abstract Text

Real-time in vivo measurements of neurotransmitters such as dopamine are critical for advancing research in biology, psychology and pharmacology. Fast scan cyclic voltammetry (FSCV) coupled with carbon-fiber microelectrodes is a proven technology for monitoring rapid chemical changes in the brain and associating these changes with behavior. Recent advances have enabled wireless system capable of making in vivo FSCV measurements, allowing animals more unrestricted motion and behavior. However, power consumption and data transfer requirements have significantly limited further development and application of these wireless systems. Traditionally, in vivo FSCV collects 10 CVs per second with 1000 data points per CV. In this work, the in vivo performance of FSCV was evaluated at reduced sampling rates and with reduced data points per CV. The research demonstrates that FSCV applied at as low as 1Hz with 100 data points per CV is still capable of detecting spontaneous dopamine fluctuations in freely moving animals. Moreover, the effects of cocaine on electrically-evoked dopamine kinetics and spontaneous dopamine dynamics in behaving animals was studied at reduced sampling rates. Utilizing the 1 Hz sampling rate at 100 data points reduces the quantity of data generated per second by two orders of magnitude compared to the traditional protocol, and is expected to decrease the power consumption by a similar value. This research will help guide development of wireless FSCV systems while retaining their performance for in vivo measurements.

This work was supported by the ASSIST Center (NSF NERC EEC-1160483) and NIH (NINDS NS076772).

Abstract Text

Novel methods of culturing including the use of bioreactors and organ on a chip environments and an increasingly diverse range of molecules of interest require new approaches to monitor the metabolic behavior of mammalian cell cultures. Platforms such as bioreactors can provide a more in vivo-like environment than traditional two dimensional platforms for cell cultures and as a result may dramatically affect the yield of biomolecules and the signaling molecule profile. Unfortunately, non-traditional approaches can complicate standard methods of metabolic monitoring such as optical spectroscopy. A screen-printed electrode array and accompanying fluidic control system has been developed for real-time monitoring metabolically significant molecules such as glucose, glutamate, lactate, and oxygen as well as observing changes in solution pH. Flexible methodologies have been developed to allow a variety of choices in the monitored analytes and applicability to diverse culturing platforms. Monitoring of up to four analytes simultaneously and in real time is demonstrated. The sensors are low-cost, have a lifetime of several weeks, and can be recycled for use in multiple experiments and for the detection of different analytes. The capabilities of this method have been demonstrated by the real-time monitoring of cellular responses to well-studied metabolic stimuli and validated by comparison to established methods for 2D cultures.

Abstract Text

Amperometric sensing is a sensitive, compact, and inexpensive approach to quantitative detection of nitric oxide (NO) in physiological systems. The current gold standard for direct gas-phase detection of NO is chemiluminescence, which is both sensitive and selective, but remains impractical in a clinical setting due to its cost and footprint. While many amperometric sensors exist for the detection of NO as a dissolved gas in aqueous environments, direct electrochemical gas-phase detection for biomedical applications remains largely unexplored. We have adapted a solid-polymer electrolyte membrane-electrode preparation in the development of an amperometric NO sensor capable of direct gas-phase detection. Nafion, a cation exchanger, can be impregnated with Pt ions, which are then chemically reduced to a porous Pt metal in the presence of a reducing agent such as sodium borohydride. The resulting Pt/Nafion membrane-electrode can then be fashioned into a sensor with high sensitivity, low limits of detection (as low as 3.7 ± 0.5 ppbv), fast response times (< 10 s), and low cost. Potential applications of this sensor include the NO sensing of exhaled human breath and NO released from novel NO-donor-based biomaterials.

Abstract Text

Because controlling the corrosion rate of magnesium metal will be crucial to the success of biomedical implants containing pure magnesium or magnesium alloys, many ways have been sought to improve in vitro tests to analyze corrosion rates, and also to identify new methods of preparing or post-processing magnesium. In this work, for an in vitro assay, we explored the use of a commercially available conductivity sensor alongside a commercially available assay for magnesium ions to characterize magnesium corrosion under cell culture conditions that duplicate many physiologically appropriate parameters. With this assay system, we studied the corrosion of two previously untested magnesium single crystal samples that differed in surface treatments that could alter corrosion rates.

Abstract Text

Real-time monitoring of patient's biochemical changes requires well characterised biosensors that are fast responding, with analytical performance that is quantified during the period of use in for example the operating room or intensive therapy unit. Additionally, there is a great need for miniaturisation of such devices in order to reduce analyse consumption and critically reduce the instrument footprint in such congested hospital areas. Real-time measurement of the biochemical changes is most easily achieved using microdialysis as the sampling probes are FDA approved, but such probes typically produce dialysate for on-line analysis at 10-30 nl/sec. We have perused the development of microfluidic 'circuits' using LabSmith component that can give us precise fluid delivery, excellent temporal control of multiple liquid streams. Custom electronic controlled by 'Apps' provide a complete solution for new biosensor development and use. New sensors can be optimized, calibrated automatically and on-board signal processing allows a direct concentration output. Examples will be shown for a range of new sensors including novel carbon based electrodes.

Abstract Text

We report a unique colorimetric sensor array based on a single ionic liquid (IL) for accurate detection and identification of closely related organic solvents and mixtures. This unique array was fabricated by ion-pairing bromothymol blue (BTB) anion with trihexyl(tetradecyl)phosphonium ($[P_{66614}]$) cation. Based on the concentration dependent response of this IL, four concentrations of $[P_{66614}]_2[BTB]$ were used as individual sensors to fabricate this sensor array. Eight alcohols and seven binary mixtures of ethanol and methanol were examined to provide a stringent test for the proposed sensor array. Reproducible UV-visible absorption peak ratios were obtained for each sensor. These peak ratios were used to develop predictive models for alcohols and mixtures identification. We demonstrate that this array can identify eight alcohols and mixtures with 96.4% to 100% accuracy. Overall, this array is very promising for facile, inexpensive, rapid discrimination of structurally very similar solvents and solvent mixtures.

Time: 09:10 AM

Room: 266

Co-Author(s)

Abstract Text

In this study, a simple, label-free, sensitive and selective DNAzyme-based QCM-D sensor for rapid detection of toxic metals was developed. A quartz crystal microbalance with dissipation monitoring (QCM-D) biosensor was used for highly sensitive and specific detection of toxic metal ions. Oligonucleotide-functionalized gold nanoparticles were used for both frequency and dissipation amplification to enhance the detection sensitivity. Metal-specific DNAzymes were immobilized onto the QCM-D sensor surface and allowed to hybridize with substrate-functionalized AuNPs. The DNAzyme catalyzed substrate cleavage in the presence of metal ions, causing the cleaved substrate-functionalized AuNPs to be removed from the sensor surface. Metal ions were determined by monitoring the change in frequency and dissipation signals. Detection limits in the nanomolar range for both frequency and dissipation measurements were obtained. The sensor showed excellent selectivity toward the targeted metal ions in the presence of other metal ions. The proposed sensor system described here represents a new class of metal ion sensor, and its simple detection strategy makes it possible for pollution-free detection and could find applications in the on-line water quality monitoring.

Abstract Text

Harmful algal bloom (HAB) events have become more prevalent in the last few decades, with each event leading to the potential release of biotoxins in our waterways. To prevent detrimental damage to the environment and human health, bloom monitoring via analytical methods is essential. Typically this is done by direct cell counting using light microscopy with species identification based on cellular morphology. This method is extremely time consuming and is subject to false identification as some toxic and non-toxic species share similar morphologies. More recently, it has been shown that there is a variable rRNA region in HAB species that can be targeted with complimentary, specific oligonucleotide capture probes.

Here, we demonstrate the covalent attachment of amine modified oligonucleotides to aminated surfaces using a thiocyanate crosslinker. Thiolated oligonucleotide attachment to vinyl surfaces using thiol-ene click chemistry methods has also been shown. In both methods, fluorescently labelled oligonucleotide target sequences have been used to identify and optimise oligonucleotide attachment via a model system. This chemistry is being integrated with nanoparticle surfaces to determine if an increase in oligonucleotide capture probe density per unit area is able to increase overall detection sensitivity. The alternative surfaces will be compared and discussed with future work looking to apply the modified surfaces to cultured and natural lysed cell samples.

Abstract Text

Mycotoxins are toxic secondary metabolites produced by fungi, which can exist in food as a result of fungal infection of crops. Their strong resistance to decomposition and digestion cause mycotoxins to remain in the food chain. The analysis of mycotoxins in food and animal feed has been a challenge mainly due to the complexity of food matrices and desired low detection limits. In recent years, significant advances in the analytical techniques were applied to the detection of mycotoxins. There has been an increasing need for a method to detect multiple mycotoxins with a single sample preparation and analysis method.

Previously, research concentrated on an LC-MS/MS method for multi-mycotoxin analysis as mass spectrometry provides appropriate selectivity and sensitivity for detection. This study investigated the selectivity for over 15 common mycotoxins on a variety of solid-core and fully porous sub 2 μ m HPLC columns with different stationary phase chemistries. The results of these analyses were evaluated for optimum resolution and selectivity, and the conclusions will be presented.

Abstract Text

Spectroscopic techniques such as ultraviolet-visible (UV-Vis) and near-infrared (NIR) spectroscopy are common analytical tools used in many areas including environmental monitoring, food safety and quality, pharmaceuticals, bio-imaging etc. Fortunately, spectroscopic instruments are now available in handheld/portable form and do not require specialized laboratory facilities to operate. These portable devices are easy to use with minimum user training, and once the spectral signatures are developed and validated, suspected products can be tested within a few seconds. With all these advantages and the availability of cloud-like platforms, portable spectroscopic instruments can easily be used in many places. Furthermore, due to the availability of very low-cost HD-webcams and 3D printing, do-it-yourself (DIY) spectrometers become much more accurate, reliable and accessible.

In this study, we investigated the capabilities and limitations of portable, extremely affordable, webcam-based UV-Vis DIY spectrometer in the food safety and quality applications. More specifically, we focused on edible oil adulteration detection and added sugar detection in fruit juices. Our preliminary results showed that despite its simple design and low-cost, this webcam-based UV-Vis DIY spectrometer is a very promising tool which can be used by consumers to fight against food fraud. Furthermore, our results indicate that similar approach can be used to detect not only other types of food fraud and adulteration (milk, fruit juices, honey etc.) but also to identify oil contamination in water and soil. However, it is crucial to collect/maintain a nice library of spectral data and efficient and scalable algorithm in order to be able to achieve acceptable accuracy.

Abstract Text

Although the European Food Safety Agency has not yet established the migration level of many chemicals in foodstuffs, several classes of contaminants are commonly found in food packaging prepared from recovered paper fibers. Rapid and reliable analytical methods are needed for identifying and quantifying target contaminants in recycled paper and board in order to prevent food contamination. In the present work, a method suited to in-process quality control of recycled board for food contact applications is presented developed using benzophenones, phthalates and diisopropyl naphthalene isomers as contamination markers of recycled paper and board materials. The methods involve a sample pre-treatment by Accelerated Solvent Extraction, evaporation and SPE purification, followed by analysis with GC-MS.

Results will be shown of the analyses of commercial recycled board to validate method's applicability. Due to its characteristics of rapidity (less than 1 hour per sample), good sensitivity and partial automation, the proposed method may help food packaging manufacturers to keep contamination levels of recycled paper and board under control. Furthermore, a comparison of the performances achieved for the proposed method using Ion Trap MS and GC-Single Quadrupole MS will be presented.

Abstract Text

Aminoglycosides are a well-known class of antibiotics that are routinely monitored in animal-derived foods. Many countries have instituted regulatory limits for aminoglycosides. There is growing concern of the impact that these microbial resistant compounds have on human health and development. A sensitive and robust analytical method is required in order to enforce the regulations and ensure the safety and quality of the food supply.

This study compared the USDA sample preparation method for aminoglycosides in porcine tissue with a new method utilizing molecularly imprinted polymer (MIP) solid phase extraction (SPE). Older methods for sample preparation of aminoglycosides have used cation exchange SPE. The recent technology of molecularly imprinted polymer SPE can provide improved selectivity toward analytes and better removal of non-target matrix components. The MIP SPE procedure has the potential to offer improved cleanup as well as reduced sample preparation time.

Both cation exchange SPE and MIP SPE procedures were applied to the porcine tissue sample spiked with ten aminoglycosides. The samples were analyzed by LC-MS/MS using matrix-matched calibration curves. The results of this comparison will be presented and the overall method performance of two different sample preparation methods will be discussed.

Abstract Text

The application of electrospun nanofibrous substrates for surface-assisted laser desorption/ionization (SALDI) mass spectrometry was evaluated. SALDI substrates can yield high quality mass spectra without the use of a matrix, which can often hinder analysis through signal interference or formation of "sweet spots". Electrospinning is a fast and simple technique that can easily generate these substrates by applying an electric potential between a polymer solution and collector plate. These nanofibrous substrates can have a range of diameters and morphologies, and typically have very high surface area to volume ratios. This makes them ideal candidates for SALDI analyses. Polymeric nanofibers with different functionalities were prepared from commercially available, low-cost polymers: polyacrylonitrile (PAN), poly(vinyl alcohol), (PVA), and an epoxide-based photoresist (SU-8). These electrospun polymers were used as substrates in the analysis of peptide and protein standards, covering a wide range of molecular weights. Improved ionization efficiency and signal to noise (S/N) ratios was observed, particularly for high molecular weights compounds outside of the normal range for SALDI (>150,000 Da). The SALDI results also show enhanced shot-to-shot reproducibility compared to matrix-assisted laser desorption/ionization (MALDI). Further improvements in signal-to-noise ratios are obtained using matrix-enhanced surface-assisted laser desorption/ionization (ME-SALDI) compared to either MALDI or SALDI methods.

Abstract Text

We have recently developed a method for laser ablation of materials at micrometer size scales using the conducting tip of an atomic force microscope (AFM) to direct the ablation to a small size. Initial studies were performed with a 355 nm nanosecond pulsed Nd:YAG laser, which was able to ablate peptides and proteins with minimal fragmentation from micrometer or smaller spots. In this study, we have expanded the wavelengths tested from the UV to the visible and infrared wavelengths. The Nd:YAG laser provides output at wavelengths of 532 nm in the visible and 1064 nm in the near IR in addition to the 355 and 266 nm UV wavelengths. A wavelength tunable mid-IR optical parametric oscillator operating in the 3 μm wavelength region has also been tested for tip-enhanced ablation. In this work, an AFM is used to position a 30 nm radius gold-coated silicon tip at a distance of approximately 10 nm from the sample surface for material removal. The laser is mildly focused onto the target and the fluence is set to just below the far-field threshold to irradiate the AFM tip for material removal with a smaller spot size than a laser focused with a conventional lens system. The AFM is used to image ablation craters and place the tip at the area being analyzed. The captured material is deposited on a MALDI target or electrosprayed for mass spectrometry analysis. The effect of wavelength on spot size, transfer efficiency, and fragmentation will be reported.

Abstract Text

Nanoelectrospray ionization (nanoESI) is a soft ionization technique for mass spectrometry that is widely applied to determine the molecular weight of biological macromolecules. Presently, common ESI emitters possess orifice diameters of 50-100 μm , and nanoESI emitters have diameters as low as 1-2 μm . Work presented here demonstrates the ability to perform nanoESI from capillaries pulled to orifice diameters less than 100 nanometers and discusses the fundamentals of nanoESI from these small emitters. Smaller nanospray orifice dimensions are shown to increase charge/droplet ratios, and thereby improve ionization efficiencies, and dramatic shifts in average charge state have been observed with these small orifice emitters. Here, important characteristics, such as flow rate, spray current and analyte influence, relevant to ESI-MS are examined for nanopipette emitters. Our results demonstrate that use of nanopipettes as nanospray ionization emitters is a promising new approach for ultra-trace biological mass spectrometry.

Abstract Text

Measurement of glucosidase activity is of significance to diagnosis of certain diseases such as Gaucher disease. We report here a method to determine glucosidase (GD) activity using matrix-assisted laser desorption/ionization (MALDI)-time-of-flight (TOF) mass spectrometry in combination with novel surface chemistry. A new carbohydrate probe has been synthesized for capture of the reduced species and the probe is fixed to a fluorinated surface to generate a microarray. To measure the activity of alpha-GD, maltose has been used as a substrate. After reaction and washing with water, the noncovalent array was characterized by MALDI-TOF/MS. By measuring the ratio of intensities from peaks of the substrates and the products, we can accurately determine the level of enzyme activity. Using this method, we have also determined the half maximal inhibitory concentration (IC50) of acarbose and epigallocatechin gallate, and the values agree well with the reported IC50. Our approach is advantageous as compared to conventional colorimetric method that suffers from matrix interference in samples by removing matrices using the polyfluorinated surface.

Abstract Text

We describe pressure-driven manipulation of nanoliter volumes of fluids with nanopipettes for fluid aspiration and dispensing. The fundamental behavior of fluids confined in the narrow channels of the nanopipette shank was studied to optimize sampling volume and probe geometry. Matrix Assisted Laser Desorption/Ionization mass spectrometry was utilized to characterize nanoliter volumes (<10 nL) of analyte sampled from [*i*]Drosophila melanogaster[/*i*] first instar larvae and single [*i*]Allium cepa[/*i*] cells with nanopipettes of diameter ~600 nm. Nanopipettes are thus shown to be a versatile tool that might find further application in studies of sample heterogeneity and population analysis for a wide range of samples.

Abstract Text

Lipids are important inherent components in cell membranes, which play significant roles in cell function. Imaging mass spectrometry methods including secondary ion mass spectrometry (SIMS) and matrix-assisted laser desorption ionization (MALDI) are promising techniques to identify and map different lipids in tissues and cells. SIMS and MALDI can provide complimentary information. SIMS provides detection of small molecules at high spatial resolution while MALDI is capable of ionizing larger molecules of the sample albeit at reduced spatial resolution. Combining the data obtained from the two MS approaches can maximize the information available in biological analyses. Although these MS methods have associated abilities there are some limitations with each technique. In MALDI imaging, we replaced deposition of the organic matrix with a spray-on procedure for Au nanoparticle deposition to enhance the spatial resolution possibilities. This allows lipid molecular ion species and the relevant mass fragments to be imaged with enhanced spatial resolution. Additionally, we have combined this with backside laser illumination providing a high focused laser beam (~1 micron) and further enhancing spatial resolution. In SIMS imaging, we have used gas cluster ion beams (GCIBs) that have been developed for analyzing and imaging organic compounds such as lipids and metabolites of biological samples in the molecular ion mass range. Here, we show that improvements of these MS techniques for imaging of different types of lipids creates a potentially overlapping cross point that can deliver complementary data for molecular lipid imaging in biological tissue sections.

Abstract Text

CRAFTI (cross sectional areas by Fourier transform ion cyclotron resonance) is a novel technique for measuring molecular size that is based on measuring dephasing rates for the transient signal in FTICR-MS (Yang et al., Anal. Chem. 2012, 84, 4851). This study compares collision cross sections measured using CRAFTI with results from other experimental (ion mobility spectrometry, IMS and traveling wave ion mobility spectrometry, TWIMS) and computational methods.

Cross sections for 20 singly-protonated amino acid ions obtained using CRAFTI on a 4.7 T Bruker Daltonics APEX 47e FTICR were found to correlate well with the IMS measurements; the correlation between CRAFTI and IMS is roughly as good as the correlation between IMS measurements from different laboratories. CRAFTI measurements also correlate well with molecular surface areas calculated from low-energy structures predicted from molecular mechanics conformational searches, either by using CPK molecular model surface areas or by using MOBCAL trajectory method calculations (Shvartsburg et al. J. Phys. Chem. A 1997, 101, 1684). Further, CRAFTI cross sections exhibited the same structural trends as the other methods. For example, amino acids with aliphatic side chains have larger than average cross sections, those containing sulfur are smaller than average, and those that can internally hydrogen bond fold more compactly than those with less hydrogen bonding capability. CRAFTI thus shows great potential as an effective technique for experimentally measuring molecular conformations.

Abstract Text

Since the early 1990s, hydrophilic interaction (HILIC) has been the most widely applied retention mode in liquid chromatography in the pharmaceutical, biological, and food industries fields for the analyses of polar and/or ionizable compounds. It is commonly accepted that the retention of these compounds is controlled by both the adsorption onto the adsorbent and by the partitioning mechanism into the diffuse water-rich layer that is formed when the HILIC material is in contact with acetonitrile-rich eluents.

An unsolved enigma in HILIC is to assess the relative contributions of adsorption and partitioning retention mechanism to the overall, observed retention factor. The mere measurement of the sole retention factor is not sufficient because it only provides the sum of these two separate contributions. Therefore, the challenge is to propose and validate an original approach that can unambiguously decouple the adsorption from the partition process of small, polar and ionizable compounds in HILIC.

In this presentation, we discuss a method that consists in measuring both the retention factor and the intra-particle diffusivity. This latter property is crucial in HILIC because adsorbed molecules (zero mobility) and those concentrated in the diffuse water-rich layer (finite mobility) participate differently to the overall intra-particle diffusivity. This method is based on the validation of an original model of effective diffusion in porous particles in which the rigid adsorbed water, the diffuse water-rich layer, and the bulk eluent are considered as three different phases in equilibrium. This approach is applied to the determination of the HILIC retention mechanism of cytosine, nortriptyline, and nicotinic acid on a 3.5 [micro]m Bridge Ethyl Hybrid (BEH) and silica-diol adsorbents in contact with a series of ternary mobile phases ACN/water (10 mM acetate buffer pH=5)/third eluent (water, EtOH, THF, ACN, or n-hexane), 95/5/5, v/v/v.

Co-Author(s)

Abstract Text

Centrifugal Chromatography instrumentation is used in the natural products, pharmaceutical, biological, and in academia as a means of fractionating complex mixtures of organic components. Fast centrifugal partitioning chromatography [FCPC] offers several advantages versus traditional methods such as HPLC in that no solid packing material is required, which in itself can cross contaminate fractions. The FCPC is a discrete stage-wise device that uses the specific partitioning coefficients of the individual components for isolation of the product fractions. Due to the large quantity of extraction stages in the rotating column, components with similar molecular structures can be easily isolated. Recent improvements in the stage cell design, such as diamond shaped profiles versus traditional Z-cell profiles improve diffusion and reduce mobile phase holdup within the cells. Twin cell designs have been developed that improve resolution and degree of fractionation. FCPC technology is commonly used in isolation of botanicals such as Cannabis, Tobacco, Opiate Derivatives, and Nutraceuticals. Capacities range from the milligram scale for analytical scale quantities, up to preparative scale quantities in the gram scale, and production scale capacities are available for kilogram scale fraction collection. Developments have been made in the sample collection system software. Manual systems are available and they can be used in conjunction with a PLC. Commonly used solvent systems include the Arizona range, HeMWat, aqueous biphasics, and both polar and non-polar solvent pairs.

Abstract Text

Intermolecular interaction between solute molecules (2-phenoxypropionic acid) and functional ligands (β -bromo-cyclodextrin) on the stationary phase surface in a chiral HPLC system was studied by means of the moment analysis method. At first, pulse response and peak parking experiments were carried out for measuring some parameters concerning the column geometry, the adsorption equilibrium, and the mass transfer kinetics. Then, the values of the first absolute moment (M_1) and the second central moment (M_2') of elution peaks were analyzed by the moment equations, which had been developed on the assumption that the reaction kinetics between the solute molecules and the functional ligands was represented by the Langmuir type rate equation. Consequently, the flow rate dependence of HETP calculated from M_1 and M_2' was analyzed on the basis of the values of the parameters described above to derive the kinetic information about the intermolecular interaction, i.e., the association rate constant and the dissociation rate constant. In addition, the values of the association equilibrium constant were also obtained from M_1 as the related equilibrium parameter. It was demonstrated that the combination of chromatographic experiments and the moment analysis was one of effective strategies for the quantitative study on intermolecular interactions.

Abstract Text

In the manufacturing of Antibody Drug Conjugates (ADCs), small molecule linkers are used for connecting the cytotoxic agents to antibodies. The quality of the linkers is tightly monitored by a panel of analytical tests. The impurities present in these materials can be residual solvents, elemental impurities, moisture, degradation products, reaction byproducts and, if the molecule contains chiral centers, chiral impurities. Most common impurity assays on a release panel are GC- and HPLC-based assays that do not separate chiral isomers. Chiral purity is often controlled by the synthetic route itself and not directly assessed at the release. With recent advances in chiral stationary phases and increased availability and diversity of commercial chiral columns, development of chiral HPLC assays without derivatization has become more accessible. The development and evaluation of chiral methods for three linkers frequently used in ADCs will be presented. The different challenges faced during the assessment of racemic mixtures versus pure isomer product will be discussed. Linker 1 and 2 are examples of racemic mixture while linker 3 is a single isomer.

Abstract Text

Carbon dots (C-dots) have attracted interest over the past few years because of their distinctive properties such as high photostability, chemical inertness, low cytotoxicity, and excellent biocompatibility when compared to metal-based quantum dots. These unique nanoparticles are being explored for a wide range of applications including bioimaging, optoelectronic devices, and metal-ions sensing, among others. C-dots are usually separated by low-resolution methods such as dialysis, centrifugation, and filtration. It has been shown that after these procedures they can still be a complex mixture. Individual components of this mixture can have different size, charges, and photoluminescence properties. In this work, we separated the C-dots mixture by means of size exclusion chromatography to obtain fundamental insight on its complexity. Some of the chromatographic peaks were collected for further characterization using Fourier transform infrared spectroscopy and transmission electron microscopy. This presentation will focus on the chromatographic behavior of C-dots samples on SEC columns under various chromatographic conditions.

Abstract Text

Hydrophilic Interaction Liquid Chromatography (HILIC) is one of the fastest growing chromatography modes for separating polar and hydrophilic molecules. Most of the molecules of biological interest bear hydrophilic functional groups. The need to develop hydrolytically stable HILIC with novel selectivity for biological molecules cannot be overemphasized. Most of the HPLC stationary phases employ silica as a support because of its high efficiency and ease of chemical modification. However, attaching hydrophilic ligands on the silica for HILIC purposes comes with a challenge – such phases are hydrolytically unstable. Hydrolytic cleavage of the attached functional group and silica solubility in aqueous phases are the Achilles' heel in the column manufacturing process.

Our efforts are directed towards developing hydrolytically stable HILIC phases. This talk will discuss the trends and approaches in increasing the hydrolytic stability of HILIC phases using simple synthetic routes and novel silane designs. Using multipoint attachment technology for cyclofructan based columns, novel dipodal silanes functionalized with zwitterions, and employing base stable high efficiency silica, one can synthesize a series of hydrolytically stable HILIC with desired unique selectivity.

Abstract Text

We have applied a two-step procedure for the identification of the C₂₆H₁₆ polycyclic aromatic hydrocarbons, PAHs, present in a sample of coal tar. First, we have used normal-phase liquid chromatography for the fractionation of the coal tar products to isolate the fractions with the C₂₆H₁₆ PAHs, and second, we have applied a combination of liquid chromatography with ultraviolet-visible spectroscopy (LC/UV-Vis) and gas chromatography with mass spectrometry (GC/MS) with the purpose of establishing the unequivocal identity of the C₂₆H₁₆ PAHs. As an essential part of the procedure, we have developed suitable chromatographic methodologies that allow the separation of 17 C₂₆H₁₆ PAHs by LC/UV-Vis and GC/MS. These methodologies included the investigation of the elution behavior and the selectivity of two commercially available LC columns and two commercially available GC columns. In addition to the UV-Vis spectral information from reference standards and from literature references, the positions of the UV-Vis spectral bands of unknown PAHs have been theoretically predicted by means of the Annellation Theory.

Abstract Text

The Chemical Weapons Convention prohibits the development, production, acquisition, stockpiling, retention, transfer or use of chemical weapons by Member States. Verification of compliance or investigations into allegations of use requires accurate detection of chemical warfare agents (CWAs) and their degradation products. Detection of CWAs such as organophosphorus nerve agents in the environment relies mainly upon the analysis of soil. We now present a method for the detection of the nerve agent VX and its hydrolysis products by analysis of ethanol extracts of contaminated white mustard plants (*Sinapis alba*) which retained the compounds of interest for up to 45 days, providing a simpler sampling strategy, and protection against environmental loss of the nerve agent.

Sinapis alba was grown in VX, MPA and EMPA spiked (250 µg ml⁻¹) clay, loam or sandy soil. The different soils moderated the rate of initial uptake of VX but not the longer term uptake: the duration the VX was detectable (to sub 1 ng of VX per plant) in the plant was the same regardless of the soil type. In addition, the plants metabolised the VX to EMPA and MPA and interestingly the MPA found in the plants increased when they were grown in VX-spiked clay. VX, EMPA and MPA were detected in the plants for up to 45 days. The data suggest that the EMPA found in the plants grown in soil contaminated with VX originated from metabolism of VX demonstrating a possible use for bioremediation of contaminated land.

The method described for detecting nerve agent residues in the environment will help the OPCW and CWC Member States confirm their presence in future. The use of localized samples and a simple extraction procedure will increase the probability of discovering nerve agent use. The ability of plants to absorb nerve agents suggests that green manures might be useful for remediating nerve agent-polluted sites.

Abstract Text

Matrix Assisted Laser Desorption Ionization Mass Spectrometry (MALDI-MS) is an analytical technique used most often for thermally unstable large molecules, like proteins and polymers. The matrix is used to transfer laser energy and aid in desorbing and ionizing the sample of interest. Unfortunately, as low mass species', the matrices often interfere with spectra in the low mass range. Their peaks are larger than and in the same area as sample peaks leading to the need to find alternative assisting mediums.

The aim of this project is to use nanoparticles to assist in the desorption and ionization of low mass forensically relevant samples, not normally analysed via LDI-MS. This research is significant due to the fact that the MALDI, as an instrument, has various advantageous qualities including soft ionization and sensitivity, as well as rapid analysis via Mass Spectrometry. This could result in samples being analysed and identified with relatively minimal sample preparation.

Samples were analysed either in solution or from laden fibres of paper adhered to tapes of varying conductivity. They were then treated with a small amount of either silicon or gold nanoparticles. The MALDI was set to low mass range (less than 400 Daltons) in positive reflectron mode.

This project identifies the potential of a technique traditionally used for the analysis of biological and high mass samples, opening it up to uses in the forensic field. This is done by making use of new and popular innovative materials, nanoparticles.

Funding for this project is provided by Flinders University.

Abstract Text

Selected Ion Flow Tube Mass Spectrometry (SIFT-MS) (Smith & Spanel, 2005) is a real-time analytical technique that offers potential for rapid screening of volatile organic compounds (VOCs) to ultra-trace levels in air (Prince et al., 2010). Quantitation limits in the low part-per-trillion range (by volume; pptv) are achieved without sample preparation or preconcentration and results compare well with those obtained at an accredited laboratory using the United States' Environmental Protection Agency (US EPA) TO-15 Compendium Method (Langford et al., 2014).

This paper presents the results obtained during development of a rapid analytical method that targets the compounds in the US EPA TO-14A Compendium Method. A Syft Technologies Voice200Ultra SIFT-MS instrument was used in this study. The quantitation limits specified by the TO-14A method are achieved within a few seconds for each analyte. SIFT-MS also offers significantly enhanced dynamic and linearity ranges compared to the canister-GC/MS method.

Direct mass spectrometry techniques, such as SIFT-MS, cannot resolve all isomers as required by the TO-14A method. However, this study has demonstrated that SIFT-MS provides a rapid screening tool that saves busy laboratories significant money through pre-screening of incoming samples prior to regulatory analysis. These results also form the basis of deployment of SIFT-MS instrumentation as real-time analyzers for TO-14A method compounds, such as in ambient or fence-line monitoring scenarios.

Abstract Text

Cold vapor generation (CVG) is an alternative approach for determination cadmium (Cd) by atomic and mass spectrometry techniques. Extensive research has been done so far, but the performances of the analytical methods reported for Cd vapor generation has been far from being optimum in comparison to those of other hydride and vapor forming elements, such as arsenic, selenium and mercury. In this work, Ti(III) and Ti(IV) were utilized as a catalytic additive to develop highly efficient vapor generation methods for determination of Cd by CVG-ICPMS in complex samples. Acidified sample solutions were mixed online with KCN and Ti(III) or Ti(IV) solutions and then reacted with NaBH₄. Vapor generation conditions for Ti(III) and Ti(IV) were examined using HCl and HNO₃ within a range from 0 to 12% (v/v). Ti(III) provided optimum conditions in HCl-KCN medium, while highest efficiency was obtained in HNO₃-KCN medium with Ti(IV). On-line mixing sequences were varied using different manifold settings to elucidate the roles of Ti solutions. The results indicated that presence of Ti(III) or Ti(IV) was essential regardless of the mixing sequence. Sensitivity was improved about 50-fold. A detection limit of 3 ppt and 6 ppt were obtained for HCl-KCN-Ti(III) and HNO₃-KCN-Ti(IV) system, respectively. No significant interferences were noted from transition metals at 1.0 ppm levels. Among hydride forming elements, Bi, Sb, Sn and Pb induced suppression above 0.5 ppm levels. The procedures were verified by analysis different materials, including seawater, domestic sludge, liver and bone ash, for Cd by CVG-ICPMS.

Abstract Text

The ambient desorption/ionization (ADI) sources for mass spectrometry have been in continuous evolution over the past decade. ADI sources produce ions via a 'soft' mechanism, the ionization of the sample occurs in an open ambient environment which leads to more efficient sample handling (i.e. high tolerance of sample size/shape/physical state). Marcus and co-workers have developed a liquid sampling-atmospheric pressure glow discharge (LS-APGD) as a low power, small footprint, and cost efficient ionization source for mass spectrometry. A glow discharge microplasma is sustained between the surface of an electrolytic solution, introduced through a 0.28 mm (i.d.) capillary housed inside a 1 mm (i.d.) metal capillary, and a stainless steel counter electrode mounted ~2 mm away, while helium sheath gas flows between the two capillaries. Previously, the LS-APGD was utilized as an elemental ionization source for direct liquid sampling with LODs ranging from tens to hundreds $\mu\text{g L}^{-1}$. The LS-APGD can be easily modified into an ADI source, utilizing the microplasma to efficiently desorb/ionize the sample directly from a surface when it is placed ~2-3 mm below the plasma.

Presented here, the ADI-LS-APGD is mounted to the existing electrospray ionization (ESI) interface of a Thermo Scientific LCQ Fleet Ion Trap Mass Spectrometer. The parameters investigated for optimization include powering mode, liquid flow rate, He sheath gas flow rate, plasma discharge current, and the sampling geometry (incidence angle and take-off angle) and sampling distance. A well characterized small molecule, caffeine was used as the test analyte. 100 $\mu\text{g mL}^{-1}$ caffeine in 50:50 MeOH/ H_2O , was spotted on a glass slide, and oven dried. Intensity of the molecular peak ($m/z=195$), intensity of the major fragment ($m/z=138$), and signal-to-background ratio were factors for the optimization.

Abstract Text

On-line mass spectrometry (MS) was implemented and developed as a tool to monitor and quantify ethanol vapor productivity from multiple laboratory photobioreactors. Oxygen generation and carbon dioxide utilization profiles were measured for increased process understanding and optimization. A magnetic sector MS was found to provide enhanced stability and accuracy relative to a quadrupole mass spectrometer. A modified ion source with glass lined entrance was utilized to enhance ethanol response and reduce detector settling time. Ethanol mass balance values, comparing on-line vapor MS measurements to liquid gas chromatography samples, were within 7%. Measured ethanol vapor concentration correlated well with values predicted by an ethanol-water vapor-liquid equilibrium (VLE) model (Aspen Plus). The MS technique is relatively simple to interface to equipment, requires no direct sample contact, requires minimal maintenance, allows sampling of multiple components simultaneously, and provides fast measurement for increased sampling frequency from multiple reactors. Use of MS significantly reduced process development time for effective strain selection and ethanol productivity optimization.

Abstract Text

Combustion and pyrolysis of solid fuels are extremely complex chemical processes, that are by far not fully understood. The gas phase chemistry of solid fuel combustion in the fuel's voids and pores is difficult to address by conventional analytical methods. Recently photo ionisation mass spectrometry (PIMS) was established as a fast on-line analytical technique to analyse the chemical signature of highly dynamic combustion and pyrolysis processes in cigarettes during puffing. A new combination of PIMS and a capillary microprobe sampling system (μ -probe) was developed, allowing direct examination of the composition of organic vapours even in the centre of the cigarette's combustion zone. This μ -probe-PIMS approach was further developed to a spatial and temporal resolved mapping method. Repetitive smoking experiments using a smoke machine and reference cigarettes were done. Different sampling positions in the cigarette tip were multiply addressed by μ -probe PIMS. The time resolved PIMS sequences were later combined to spatially resolved, time-dependent "maps" for the different compounds. This new technique for dynamic mapping was used to measure quantitative distributions of nitrogen monoxide, benzene and oxygen in the burning tip of a cigarette during a 2 second lasting puff (with 0.2s time resolution). The different formation and destruction zones of the investigated compounds in the reaction region and their dynamic changes were observed during the puff, and space-resolved kinetic data was obtained. For example, the classical formation and destruction mechanisms of NO during the puff (fuel-NO formation and re-burn in hydrocarbon rich zones) could be observed in a space- and time-resolved manner. The μ -probe-PIMS mapping technology can be applied for comprehensive chemical studies on various combustion or pyrolysis systems as well as on e.g. model systems for catalytic processes and thus is of large interest for fundamental and applied research.

Abstract Text

A recent report from the Center for Disease Control and Prevention (CDC) has found evidence that current public swimming facilities may have inadequate methods for reducing human waste contamination. These methods include a variety of chemical treatments, filtration and required bacteria testing to ensure proper pool sanitation. One method employed to determine adequate sanitation is to measure E. coli concentrations. E. coli is a bacterium that is found in mammalian waste and surrounding runoffs into pools. Stercobilin is a mammalian metabolite found in both urine and feces. It has been demonstrated from previous studies that there is a positive correlation between E.Coli and stercobilin contamination in waste waters. Developing a method to quantify stercobilin concentration in public pools would allow for sensitive detection and a quicker result turnaround compared to current methods, thus allowing for facilities to quickly adjust water conditions. This presentation will focus on developing methods to extract a quantifiable amount of stercobilin utilizing solid phase extraction followed by analysis via Fourier Transform Ion Cyclotron Resonance (FT-ICR) mass spectrometry. Discussion will also take place on developing a viable internal standard used for quantification of stercobilin within pool samples by isotopically labeling methods.

Abstract Text

Autophagy is the main process for degradation of large cellular components and involves at least four different organelle types. Dysregulation of autophagy is a hallmark of cellular degeneration, including that observed in muscle degenerative disorders. Current monitoring of autophagy is limited to bulk measurements of autophagy markers such as LC3-II by western blot. These methods are inadequate to distinguish on what organelle type the bulk marker is found. A method based on individual organelle measurements would be ideal to distinguish marker levels on each organelle type. We previously reported analysis of individual autophagy organelles using GFP-LC3 as a marker. Unfortunately, this approach is inadequate for the analysis of autophagy organelles in tissue. This presentation will describe our efforts towards immunolabeling of autophagy organelles for analysis by capillary electrophoresis with laser induced fluorescent detection (CE-LIF).

C2C12 mouse myoblasts were chosen as proof of principle for antibody labeling. The post-nuclear fraction was labeled with DyLight-488 conjugated anti-LC3 antibody at concentrations ranging from 0-250nm. Samples were excited with an argon ion laser, fluorescence was spectrally resolved with a 560 dichroic long pass filter and selected with a 517.5-552.5 bandpass filter and detected by photomultiplier tube. Preliminary data from CE-LIF measurements shows that individual organelles appear as fluorescent events after 400s, indicative of their electrophoretic mobility. In addition, their fluorescent intensity is indicative of their LC3 levels. When no antibody was used, the fraction of false positives was 91.3%. On going experiments are the adaptation of this protocol to quantify LC3 levels in mouse skeletal muscle.

Abstract Text

Magnetic beads represent a powerful analytical tool in purification methods, both as native silica particles and with adducted high-affinity molecules. We recently showed that DNA-paramagnetic silica particle interaction could be directly observed with the naked eye when exposed to a rotating magnetic field. This approach allows for quantification of DNA mass, based on the extent of bead aggregation, with femtogram sensitivity. Here, we exploit the inhibition of aggregation for the detection of DNA or RNA in a sequence-specific manner following isothermal amplification. The fragments of target sequences generated by loop-mediated isothermal amplification (LAMP) are too short to induce aggregation of the paramagnetic silica particles, however, they are effective at inhibiting aggregation in the presence of trigger DNA. Coupling LAMP with magnetic bead aggregation inhibition allows for the specific optical detection of bacterial and viral pathogens. We show the detection of various pathogens down to two copies in a manner that is comparable to conventional methods, but without the requirement for expensive instrumentation. More precisely, we show the strain-specific detection of *Escherichia coli* O157, a notable food-borne pathogen, as well as Rift Valley Fever Virus, a weaponizable RNA virus of national security concern. Finally, we show the potential for simple, optical, label-free real-time amplification capable of quantifying starting copy number in a manner comparable to traditional qPCR.

Abstract Text

Quartz Crystal Microbalance (QCM) technology has proven to be an effective analytical tool for the real-time, dynamic, and quantitative analysis of mineral formation. One feature of the QCM that requires advancement for improved mineralization analysis is solution dynamics for controlled mineral precursor mixing. We present an analysis method that uses microfluidic laminar flow to achieve a liquid-liquid interface for controlled precursor reaction. This microfluidic device is integrated with QCM and optical microscopy to compare mass analysis with morphology of forming mineral. The new technique is much needed for the analysis of biomimetic mineralization templates, such as DNA aptamers. Characterization of the instrument, in conditions of no mass loading, viscoelastic mass loading, and rigid mineral mass loading has been completed, demonstrating a widely applicable instrument. Analysis of unique mineralization templates shows distinct differences in heterogeneous and homogenous biomimetic template activity.

Abstract Text

While bacteria exhibit amazing diversity, the vast majority of species have yet to be studied by researchers, as retrieving cells from exotic environments and identifying the nutrients required to sustain their growth has proven exceedingly challenging. However, research suggests that collecting and attempting to cultivate a large amount of cells of an individual species significantly improves the chances that they will eventually be domesticated and grown in the laboratory.

We, therefore, have designed and fabricated polymer microfluidic devices that can enable the cultivation of microorganisms in their natural environment by targeting the differences in size between species. Previously, we showed that bacterial species in heterogeneous samples could be isolated with these devices. In this study, we integrate nanoporous membrane filters onto the devices to enhance the exchange of nutrients between large chambers in the device and the local environment. As cells respond to chemotactic signals and attempt to colonize empty chambers in the device, they become trapped in size-specific constrictions. Eventually, the cells grow and divide across the constrictions and populate the chambers with individual species.

We show that individual species can be isolated from liquid cultures containing multiple diverse microorganisms by simply immersing the devices into the sample and waiting. The devices were filled with deionized water, and a polycarbonate membrane filter, with 50 nm pores, was sealed over the access holes of the collection chambers, leaving the constrictions as the only point of entry. Our results demonstrate that these devices can be used in-situ to isolate microbes from the environment and potentially increase the discovery rate of new species.

This project was supported by NSF Award 1125535 and 1353853.

Abstract Text

The absolute number of CD4+ T lymphocytes in per microliter of adult blood plays a critical role in human immunodeficiency virus (HIV) infection implications and antiretroviral treatment (ART) assessment. A routine monitoring of CD4+ T lymphocytes every 3-6 months is recommended for patients of HIV infections at all stages. The most widely applied techniques in CD4+ T lymphocytes counting, such as multi-purpose and single-purpose flow cytometry, are limited to use in resource poor settings due to their high cost and complex operation. The alternative non-cytofluorographic methods, however, have limitations of low throughput, high labor requirements and lack of accuracy. Isolation of CD4+ T lymphocytes is complicated by interfering monocytes. An accurate, easily-operated, and affordable method for CD4+ T lymphocytes isolation and enumeration is needed. We describe a microfluidic affinity separation that isolates CD4+ T lymphocytes from blood samples. Processed blood samples were injected to a straight channel microfluidic device; specific monoclonal antibody and shear stress were used to capture CD4+ T lymphocytes on the affinity surface while elute background cells. The fluorescent conjugated antibodies were used to stain and visualize corresponding cells. Captures were observed using inverted epifluorescence microscope with appropriate filters. Images were analyzed using ImageJ software. After separation, CD4+ T lymphocytes were isolated with high purity and efficiency. This method is inexpensive, rapid, and effective to isolate and enumerate CD4+ T lymphocytes from blood samples. It enables downstream analysis of CD4+ T lymphocytes.

Abstract Text

Macrophages are immune cells that are known to produce large amounts of nitric oxide (NO) when endotoxins are present. However, pro-inflammatory and anti-inflammatory phenotypes produce different amounts of NO and reactive nitrogen species (RNS). For instance, NO can react with superoxide to produce peroxynitrite, a highly reactive oxidant that has been linked to several neurodegenerative diseases. Previously, we reported a microchip electrophoresis with electrochemical detection method to detect NO in bulk cell lysates following stimulation with lipopolysaccharide. However, to study differences in RNS production due to cellular heterogeneity, a single cell analysis system is necessary. This work describes the progress in developing and optimizing a single cell analysis device to detect these species. First, macrophages were loaded with 6-carboxyfluorescein diacetate (6-CFDA). Once inside the cell, the diacetate group is removed, forming 6-CF, which is a fluorescent and electrochemically active molecule that can be detected from the single cell lysate by both laser induced fluorescence and electrochemical detection. Then ascorbic acid was added to the media and absorbed by the cells. Ascorbic acid is oxidized at a low potential and can be selectively detected using electrochemical detection. Then 6-CF and ascorbate were detected in macrophages cells using a combination of fluorescence and electrochemical detection to demonstrate the capability of the system. The ultimate goal is to use combined electrochemical and fluorescence detection to study the variations of RNS in macrophage cells due to different cellular phenotypes.

Abstract Text

Complete blood counts and chemistry panels are routine clinical diagnostic tests on whole blood where a variety of blood parameters indicative of a patient's health status are measured. Three important examples include: hematocrit percentage, total protein, and albumin concentrations. The importance of each ranges from a sign of internal bleeding, a first indicator of multiple myeloma, and an overall nutritional marker, respectively. The ability to obtain these quantitative clinical measurements from a small aliquot of blood in a rapid and cost-effective manner is critical to point-of-care applications. With the continued advancement of microfluidic technology, microdevices have become attractive solutions for clinical diagnostic measurements. In the presented work, polyester transparencies are laser-printed and cut in order to fabricate 5-layer microfluidic discs that analyze hematocrit, total protein, and albumin measurements from a few drops of blood. These devices are simple, disposable, cost-effective, and made from easily accessible materials and fabricated with standard lab/office equipment. Utilizing centrifugal microfluidics, rotation-driven fluid flow is facilitated through the microchannel architecture, allowing for whole blood separation, plasma metering, and mixing. Both colorimetric and image analysis using a cell phone camera and custom application have led to calibration curves with excellent R² values (0.999) and clinically relevant dynamic ranges. Preliminary studies have resulted in hematocrit values within 8% of clinically validated measurements, while total protein and albumin values are within 15%. Continued research is underway to increase the close correlation between the data obtained utilizing the presented devices and other conventional methods.

Abstract Text

Circulating tumor cells (CTCs) expressing invasive phenotypes down-regulate epithelial antigens such as EpCAM. As such, populations of CTCs may have a continuum of phenotypes. We have used a CTCs selection strategy that employs a panel of antigens to improve the clinical sensitivity of the CTC assay. In addition to EpCAM, we used FAP⁺ antibody to target CTCs. Cells expressing FAP⁺ are found in >90% of human epithelial cancers. A dual selection process was used that employs two microfluidic chips for CTC⁺FAP⁺ and CTC⁺EpCAM⁺ arranged in a serial fashion so each sub-population can be individually analyzed. The CTCs selection chips were made from a thermoplastic via hot embossing and provide high CTCs recoveries and purities >85%. Using a detection threshold at the 99% confidence level, clinical sensitivities of 100% for metastatic ovarian, colorectal, prostate, pancreatic, and 80% for breast cancer were achieved. Molecular analysis of both sub-populations of CTCs was performed. Gene profiling showed that CTC⁺EpCAM⁺ from pancreatic cancers demonstrated overexpression of CD133, CD24 and CD44 mRNA, which are markers indicative of a cancer stem cell characteristic. CTC⁺FAP⁺ showed high expression of CD133, CD24 and CXCR4, but no CD44. KRAS mutational analysis using a PCR/LDR assay detected mutations in codons 12 in 80% of CTC⁺FAP⁺ and CTC⁺EpCAM⁺ samples isolated from pancreatic and colorectal cancer patients. In few samples, CTC⁺EpCAM⁺ tested negative for KRAS mutations, but CTC⁺FAP⁺ from the same patient showed mutated gene. This is important finding useful in decision making process on EGFR-targeting therapy in cancer patients.

Abstract Text

The interaction between Polysorbate 80-coated Poly(butylcyanoacrylate) nanoparticles (PBCA NPs) loaded with doxorubicin and without doxorubicin with in vitro models of the blood brain barrier (BBB) was evaluated using Langmuir Blodgett monolayer techniques, atomic force microscopy and lactate dehydrogenase measures of cell membrane toxicity. Results indicate that PBCA NPs loaded with doxorubicin disrupt the composition of the liquid condensed (LC) and liquid expanded (LE) phases of the 1,2-dipalmitoyl-sn-glycero-3-phosphocholine (DPPC) lipid monolayer. The disruption is concentration dependent and increased for PBCA NPs with doxorubicin. Lactate dehydrogenase (LDH) assays using a primary astrocyte and brain capillary endothelial cell (BCEC) culture model of the BBB indicate that PBCA NPs containing doxorubicin exhibit higher levels of toxicity than those lacking doxorubicin. This approach provides valuable information to assess nanoparticle toxicity for drug delivery to the brain.

Abstract Text

Understanding molecular transport processes in nanoconfined environments is important for a lot of applications including separation, sensors, heterogeneous catalysis, and drug delivery. It was recently found that the axial motion of individual biomolecules/nanoparticles inside nanopores can be significantly slower than in bulk solution, suggesting that either chromatographic adsorption was present and/or the viscosity inside the nanopores was unusually high. In this study, we measured the 3D trajectories of individual nanoparticles diffusing in cylindrical alumina nanopores using an astigmatism-based 3D single molecule/particle tracking method that was recently developed in our group. C 18 solutions of a series of concentration and sucrose were used to modify surface properties and control viscosity, respectively. With the ability to track particle precisely within a range as large as 4 μm , we were able to observe different motions of nanoparticles for a relatively long period, including diffusion in single pore, multiple pores and across adjacent pores. We found that the trajectories, diffusion coefficients and mean-square displacement (MSD) plots varied with C 18 percentage and viscosity of media, potentially providing a method to distinguish the effects of adsorption and viscosity. These observations provide new insights into conventional liquid chromatography as well as size exclusion chromatography and membrane separations. An upright Nikon Eclipse 80i microscope is used for single particle fluorescence imaging and a cylindrical lens is introduced to obtain axial information. All data is analyzed by NIH ImageJ and Matlab.

Abstract Text

A beam-scanning microscope based on Lissajous trajectory imaging is described for achieving streaming 2D continuous ~1kHz imaging or 3D continuous video rate volume mapping. The microscope utilizes two fast-scan resonant mirrors to direct the optical beam on a circuitous trajectory through the field of view to generate a 2D image. By incorporating a resonant Z-scanning assembly, sample volume mapping can be achieved. The separation of the full Lissajous trajectory time-domain data into sub-trajectories (partial, undersampled trajectories) affords effective frame-rates much higher than the repeat time of the Lissajous trajectory. By using a model-based image reconstruction (MBIR) 3D in-painting algorithm to interpolate the missing data for the unsampled pixels, full images are recovered. The MBIR algorithm uses a maximum a posteriori estimation with a generalized Gaussian Markov random field prior model for image interpolation. Because images are acquired using photomultiplier tubes or photodiodes, parallelization for multi-channel imaging is straightforward.

Preliminary results (Figure 1) for 2D Lissajous trajectory imaging demonstrate experimental frame rates of 1.460 kHz for simultaneous acquisition of laser transmittance and polarization-dependent second harmonic generation (SHG). Multi-channel data acquisition cards allow for simultaneous acquisition from multiple detectors, for perfect image overlay. The high frame rates also successfully removed image blur due to sample motion. Preliminary results for 3D volume imaging show that, in combination with the MBIR in-painting algorithm, this instrument has the ability to generate video rate images with the potential to access 6 total dimensions of space, time, and polarization for SHG, spectral TPEF, and laser transmittance data.

Abstract Text

Biointerface has been attracting considerable attention in variety of areas including medical or bioanalytical applications. In extracellular recording, cell-electrode interfaces are important to have tight contact of cells on the electrodes since it strongly influences the signal intensity, and thus a tool for its investigation is highly required.

Here, we introduce new surface plasmon microscopy (SPM) allowing label-free and real-time investigation of a biointerface, especially measurement of cell-electrode cleft gap distance, which was difficult with conventional fluorescence or electron microscopy. The microscopy exploits surface plasmon polaritons, electromagnetic waves propagating along a metal-dielectric interface, and combines two different modes; one is for real-time large area observation of the cell-gold interface (lens-imaging-type, LISPM); the other is for in situ measurement of the gap distance with high spatial resolution up to the diffraction limit (scanning localized, SLSPM).

Human embryonic kidney (HEK) 293 cells cultured on poly-L-lysine coated gold substrates for 3-6 days in vitro were observed with the SPM. LISPM qualitatively visualized the cell adhesion on the surface (Fig. 1a) and SLSPM quantitatively determined average distance of 49.6 ± 15.9 nm (Fig. 1b), which is in good agreement with the previously measured value (37 nm) with transmission electron microscopy (TEM) (G. Wrobel, et al., J. R. Soc. Interface, 5 (2008) 213.). In conclusions, the developed SPM could be a powerful technique to pave the way for further understanding and optimizing the interface.

Abstract Text

Bioanalytical methodology has seen major advancements since the introduction of microfluidics. However, rapid and selective protein quantitation in continuous flow systems with a simple optical readout remains an unmet challenge. For example, to study hormone secretion from endocrine cells, microfluidic devices with on-chip, low dead-volume valves are particularly well suited. Although microfluidic systems with on-chip valves are ideal for secretion sampling from small numbers of cells, the development of compatible, simple-readout assays has lagged behind device development. Here, we have combined a customized nanoliter rotary mixer with our novel proximity immunoassays, which permit selective, direct-readout fluorescence quantitation of proteins in picoliter-to-nanoliter volumes. The device contains low dead-volume, push-up membrane valves for precise sample and proximity probe metering (9 nL each), peristaltic pumping, and rotary mixing. This integrated, sample-to-readout system allows continuous sampling, mixing times as short as 2.2 s, then detection of only 180 attomoles of thrombin and we expect similar results for the insulin.

Abstract Text

The crystalline form of pharmaceutical materials can profoundly impact the bioavailability and materials processing characteristics. Consequently, screening for new crystal forms has become a critical step preceding formulations design. Standard methods based on X-ray diffraction become challenging as the throughput increases and the volume of crystalline material per trial decreases. Polarization-dependent second harmonic generation (SHG) microscopy is suggested as a high-speed complement to current methods for initial assessments of crystal form. As a first step toward this application-space, instrumentation for rapid polarization modulation SHG microscopy is demonstrated, capable of completing full polarization acquisition at each pixel in a 315×315 image with up to video-rate frame rates. Alternative established methods of polarization modulation are based largely on mechanical rotation of polarization optics. These methods are relatively slow, introducing 1/f noise as well as artifacts from sample movement, bleaching and thermal effects, and are incompatible with high-throughput assays. In the present work, polarization modulation was performed by cycling through a series of 10 unique input polarizations at 8 MHz using an electro-optic modulator. Rapid polarization modulation was combined with fast beam scanning and synchronous digitization to enable nonlinear optical stokes ellipsometric (NOSE) microscopy at video rate. Each video rate frame provided a set of 10 polarization dependent images per detector, which were converted using linear fitting to a set of 5 parameters that are directly related to the Jones tensor of the sample and provide information on crystal form and orientation. Preliminary measurements designed to assess the advantages and limitations of NOSE microscopy for high-throughput detection of new crystal forms suggest promise for this approach.

Abstract Text

The first Raman LIBS (Laser Induced Breakdown Spectroscopy) combination system characterizes micro particles, and has many industrial and medical applications.

Firstly, the system determines particulate morphology and size. Particles within a size range of 2µm to several millimeters can be analyzed easily. After this step, the system locates an exact point on each particle where the micro Raman and/or LIBS will be applied to reveal its composition.

Raman spectra exhibits features specific to molecular structure, giving a 'fingerprint' for comparing and differentiating materials.

The LIBS technique utilizes a high energy pulse laser to ablate a microscopic amount of material and raise its temperature by tens of thousands of degrees. As the various elements return to their ground states, excited matter emits characteristic emission spectra that can be measured. The specialty of the instrument is its ablation area of 20µm in diameter, and its high quality spectroscopic system. This technique enables the system to reveal the chemical elements of a particle larger >20µm with a single shot.

These laser systems, coupled with advanced image analysis techniques provide maximal information about the micro-particle. Chemometric algorithms subsequently match the spectroscopic fingerprints of micro-particles with a spectra library.

Benefits:

- easy, fast and self-contained □high throughput particle ID of unknown or contamination materials
- parameters are software controlled in receipts □high repeatability and reproduce-ability
- identification with real samples □immediate ID of materials from customized libraries

Application of this new technology

We explain the instruments application in the pharmaceutical and automotive industries. See how any user can match the chemical fingerprints of contaminants, allowing their identification. Useful decisions regarding the damaging potential of the particles or their general avoidance can be made immediately.

Abstract Text

Dynamic Imaging Particle Analysis (DIPA) is increasingly being used as a method of characterizing different particulate types in heterogeneous samples. DIPA can measure many different particle properties simultaneously for each particle, which can be later used to construct digital “filters” to separate out each different particle type. Many different filtering methods are available, the simplest and most common being value filtering, like one would do in a spreadsheet. In value filtering, a range of a single measurement, or of multiple measurements, is defined and the particles that fit those criteria are counted. There are also statistical filters, which use particle statistics to search for particles which have similar statistics to a set of user-designated particles. This is more generally known as pattern recognition. Even within statistical filtering, there are many different algorithms available.

All of these types of digital filters produce results which may contain false positives and false negatives. The only way of measuring how well a filter performs is to actually compare the results to a “hand classified” result. By hand classified, we mean that each particle has been looked at and classified by a human being, as they would in manual microscopy. Obviously, this can be a very tedious process. A method has been developed to more rapidly put together such a comparison in order to quantify the effectiveness of different filters attempting to isolate the same type of particle. This presentation will outline both the method, and results of using the method on a specific sample of data. From this analysis, some general conclusions can be drawn which will be useful in narrowing down the most efficient methods for particle identification.

Abstract Text

For flour supplied to the baking industry, various properties are of particular concern including but not limited to endosperm purity, protein content, and particle size. Of these properties, flour purity in terms of endosperm content is of higher interest; however, traditional methods have been limited to measurement of the impurities by ignition of the organic material and weighing the mineral residue. Factors such as endosperm purity, protein content, and particle size need to be monitored closely by millers in order to meet specifications of the baking industry because they have a significant impact on the value of the final product for end use. Near infrared chemical imaging enables the identification of flour composition on a pixel-by-pixel basis and subsequent pixel counting yields a quantitative result. From select spectral characterizations, different factors such as protein content and endosperm purity can be measured directly. Furthermore, image analysis from the same experiment can be used to determine particle sizes within the heterogeneous mixture. Imaging data are presented to demonstrate the utility of quantitative chemical imaging in the milling field.

Abstract Text

Lebel and coworkers have recently shown that triazine derivatives are a class of small organic molecules capable of forming an amorphous phase without requiring a deep quenching from the melt or an ultrafast solvent evaporation. The outstanding glass-forming ability (GFA) of these molecular glasses is attributed to the poor packing efficiency of their self-assembled aggregates that are held by multiple hydrogen bonds. To deepen our understanding of the relationship between the H-bonds and the observed GFA, we aim to quantitatively monitor hydrogen bonding while these compounds undergo their glass transition (T_g), from their viscous state to their vitreous one.

In this presentation, we will show that variable temperature infrared spectroscopy is a tool of choice to probe the vitrification process of these glass-formers. Indeed, we succeed to correlate their molecular features to their bulk thermal properties by pairing the selectivity of this vibrational technique with chemometrics analysis, leading to the quantitative monitoring of hydrogen bonding during the glass transition. For instance, this approach reveals that, on average, around 60% of the molecules are still H-bonded even at 50 °C above the T_g of the molecular glasses, preventing their reorganization into an organized lattice. These results underline the significant role of hydrogen bonding in frustrating the crystallization upon cooling, providing new insights to further our knowledge of glass engineering.

Abstract Text

When choosing a near-infrared spectrometer (NIR) for industrial applications, the question of which technology is best should be considered. The choice often times comes down to dispersive scanning grating spectrometers (SGS) versus Fourier transform near-infrared spectrometers (FT-NIR). This discussion will review a comparison of the two techniques as they apply to the analysis of clear liquid samples, such as the hydrocarbon liquids found in petroleum and chemical industry applications. In addition, the comparison will be narrowed to include instruments that are coupled to the sample probe/cell through fused silica fiber optic cables. This will explain the basic differences between the various instrument types and how this relates to performance for an on-line analyzer system. A discussion of the true advantages that each technology holds will be provided.

Abstract Text

The safety of our food supply depends heavily on the quality and purity of ingredients used to produce food products. Adulteration of food and feed ingredients, whether economically motivated, contamination with other substances, or simply off-spec products impact product safety, quality and consumer perceptions of the product. Many companies invest considerable resources in high-end analytical instruments and persons to operate them in an effort to detect individual contaminants and adulterants. Smaller companies often do not have those resources available in-house due to the cost of instruments and the personnel to operate them.

FT-NIR has been employed by the pharmaceutical industry for raw material identification for many years. The same information can be easily extended to use FT-NIR as a non-targeted screening method for food and feed ingredients. Non-targeted screening is intended to identify ingredient shipments whose NIR spectra differ from what is normally received. When an ingredient batch has been determined to differ from previous shipments that have met established quality and safety criteria it can be excluded from the production queue. The suspect ingredient batch can then be examined using more targeted analytical methods. Statistical evaluation of NIR spectra can be used to determine variation in ingredients between individual lots of materials. These statistical methods can be used to determine if the NIR spectrum for a food ingredient is within the normal variance seen for that particular ingredient. In this paper the use of FT-NIR as a non-targeted screening method for food and feed ingredients will be presented. Two different software methods for determination of variation between individual lots of ingredients will be described including method development and validation considerations. Applications that can be successfully addressed will be discussed along with limitations of the technique.

Abstract Text

Wavelength standards for high resolution near infrared (NIR) spectroscopy are excellent. The same cannot be said for low to moderate resolution instruments. The development of NIST's SRM2035 and other rare earth standards have been a significant improvement in the last decade. However, problems and inconsistencies still exist in these standards. We will review the state-of-the-art and present data on the temperature dependence of the SRM2035 peaks. In addition we will investigate the utility of using atomic emission lines, specific standard laboratory solvents, and other rare earth glass materials for wavelength calibration and calibration transfers. A technique for using spectroscopy to measure the temperature of a rare earth filter and then correct the peak wavelengths in real time will be presented.

Abstract Text

In durum production, the objective is to produce a semolina product that is uniform in color and particle size and free from non endosperm material. The presence of the latter item is revealed via visual speck counting under a low power microscope. The recently developed quantitative near infrared imaging based on chemical distinction provides the approach to objectively rank the purity of various durum milling fractions. The objective is to enable operating millers to optimize their processing parameters at key unit process steps based on chemically determined objective numerical data.

Abstract Text

Head space Raman spectroscopy is a method well suited to the study of compounds in the vapor phase. We have used it to study the volatility of solvents, the release of gas dissolved in a liquid solvent, and the difference in molecular interactions in the vapor phase vs. the condensed phase (liquid or solid). An advantage of head space Raman measurements is that spectra of the condensed and vapor phases can be obtained from the same sample. The differences between the Raman spectra of the liquid and vapor phases can be quite striking; e.g., the effect of hydrogen bonding on the OH stretch of methanol vanishes in the vapor phase. We will present the results of our studies of phase dependent molecular interactions, gas release from solution, solvent volatility, and partitioning of mixed solvents.

Abstract Text

In order to produce consistent high quality plastic bottles it is essential to verify the crystallinity of blown bottle walls in order to ensure product consistency, strength and overall quality. Current methods such as X-ray diffraction, density measurement or calorimetry are often inaccurate, slow and require chemical consumables.

In this paper we present an alternative method, using FT-NIR, for the performance of rapid determination of bottle crystallinity that overcomes these limitations.

Abstract Text

Synthetic polymers manufactured by a condensation process such as polycarbonates may have a significant fraction of low molecular weight oligomers. This oligomer fraction can have an effect on the overall material properties such as melt flow rate, impact resistance and tensile strength. Short oligomers may also cause aesthetic issues during the injection molding process by creating deposits on the mold surface. Accurate characterization techniques are required to determine the types and amounts of oligomers generated during polymerization to aid in the development of appropriate process controls.

For condensation polymers, the oligomer fraction is typically measured using chromatographic techniques such as size exclusion chromatography and high-performance liquid chromatography (HPLC). Both of these techniques can provide for reproducible measurement of the total amount of oligomers present however identification of individual oligomers can be problematic. Matrix-assisted laser desorption/ionization (MALDI) mass spectrometry is now an established technique for identifying oligomers in many types of synthetic polymers. In this work, we investigate the correlation between the relative signal areas from both HPLC and MALDI analyses of oligomer fractions for a variety of polycarbonate and polyetherimide resins. The techniques are found to be quite complementary and provide for a more complete characterization than can be achieved using a single technique.

Abstract Text

Mammalian olfaction possesses a high capacity for the discrimination and quantification of gas phase compounds as well the ability to identify new compounds and mixtures. While there have been significant advances in machine vision through the invention of the coupled charge device (CCD) chip, its equivalent for sensing the chemical environment has yet to be achieved. One of the biggest challenges has been the integration of chemically diverse sensing materials (the equivalent of olfactory receptors) onto integrated circuits. Current approaches for generating chemically diverse sensors include conducting composites containing different polymers that function through variations in analyte partitioning and corresponding changes in resistance. While these systems have excellent performance, fabrication methods are not compatible with lithographic processing of integrated circuits and spatial deposition control during post chip fabrication is very limited.

The electrodeposition of conducting polymers has the potential of overcoming spatial limitations, however the number of polymers available are few resulting in limited chemical diversity. In this presentation an approach using co-electrodeposition of conducting polymers and chemically diverse co-monomers is explored as a means for enhancing diversity in conducting polymer composites that will be compatible with integrated circuits with sensing elements on the micron and sub-micron scale. In particular results from the electrochemical copolymerization of pyrrole and styrene derivatives (styrene, 4-m-styrene, 4-chloromethylstyrene and 4-t-butoxystyrene) will be described. The ability to tune the relative amounts of the co-monomers in the resulting polymer as a function of polymerization potential and its impact on sensing will be covered.

Abstract Text

There is a growing interest for two-dimensional chromatography (2D) including its application to polymers. This is motivated by the need to characterize more complex materials such as multicomponent blends and copolymers with tailored microstructure. This is especially important in order to establish the relationship between structure and property, to gain a better understanding of the reaction pathways, and also for protecting intellectual property. 2D consists of coupling a first dimension where separation is carried out based on one material property (e.g. composition) with a second dimension where separation is based on a second material property (e.g. molecular weight). In this presentation, recent advances in 2D chromatography will be reported such as the use of UHP-SEC in the second dimension and coupling with infrared spectroscopy detection. Several examples of application of two-dimensional chromatography will be reviewed that will illustrate the benefits of using this technique in an industrial R&D environment.

Abstract Text

The volume phase transitions (VPT) of hydrogels are often utilized for chemical sensing applications. Our group has developed two dimensional photonic crystal (2D-PC) hydrogels to monitor VPT in response to stimuli by attaching a 2D photonic crystal array of ~500 nm polystyrene particles to the hydrogel surface. The particle spacing of the attached 2D photonic crystal array varies with the hydrogel volume. This volume can be measured by using a laser pointer to excite the Debye ring diffraction from the attached 2D array.

Decreasing the hydrogel thickness and/or the crosslink density increases the sensitivity of the sensor, but mechanically weakens it making it difficult to study. We developed a sacrificial polyvinyl alcohol (PVA) substrate to transiently ruggedize the 2D-PC sensors. To demonstrate the utility of the sacrificial substrate, we fabricated pH sensors that contain acrylic acid, acrylamide, and low concentrations of bisacrylamide crosslinker. These sensing gels were then attached to a PVA hydrogel substrate formed through a freeze-thaw process. The resulting bi-layer system is easily handled and shows long term stability. The PVA substrate was dissolved by transient heating to 70°C. The released pH sensing gels show dramatic swelling as the pH increases. Sacrificial substrates will enable the use of super-responsive 2D-PC sensors.

Abstract Text

Various novel colored poly(urea-urethanes) have been prepared by using a variety of benzothiazole derivatives, 3-amino phenol and hexamethylene diisocyanate. The resultant colored poly(urea-urethanes) were characterized by elemental analysis, IR, thermogravimetry. All the poly(urea-urethanes) were applied on polyester fabrics. These dyes were found to give a wide range of colored shades with very good depth and levelness on polyester fabric. The dyed fabric showed good fastness to light and very good to excellent fastness to washing.

Abstract Text

Tetracyclines are commonly used antimicrobial agents for agricultural livestock. Increased use of antibiotics in animal feed to enhance the growth of livestock has historically shown negative impacts on human health. Issues related to antibiotic resistance following consumption of contaminated animal muscle and milk have been fully documented within global populations. Regulating the agricultural use of tetracyclines is quickly becoming a global concern heading for more strict regulation and frequent testing. It is important to guarantee that beef, chicken, and milk are safe to eat within the Maximum Residue Limits (MRL) allowable by the Codex Alimentarius Commission, the responsible body for establishing international food standards for public safety and fair food trade.

With regulation changes, many laboratories will see increases in the number of samples and methods to test. Many food safety methods used for testing of agricultural contaminants in foods do not utilize current automation technology or improved chemistries to streamline the typical laboratory workflow that would greatly reduce the impact of increased testing and remove potential bottlenecks. Improving established methods to reduce the risk of backlog and human error is essential for timely reporting of results with confidence in the data. To help address the current global focus on the extensive and increasing agricultural use of tetracyclines, new methods using simple automation and new chemistries and technology will be utilized to accurately identify and consistently detect tetracyclines at the MRL of 100 µg/l in cattle milk, and 200 µg/kg in both cattle muscle and chicken muscle.

Abstract Text

Solid phase microextraction (SPME) is a solventless, fast, easy and relatively inexpensive sample preparation technique that integrates sampling, extraction and preconcentration into one step. It has widespread applicability in various fields that include environmental, food, drugs, in-vivo analyses etc. Commercial coatings may be expensive, show relatively short lives, extract limited numbers of compounds, and have relatively low thermal and mechanical stability, and/or solvent incompatibility. The aim of this study is to develop an SPME device that is thinner, robust, long lasting, has higher mechanical strength, greater thermal and solvent stability, and is devoid of the other drawbacks of commercial coatings. Silica-based nanoporous coatings were prepared via sputtering of high purity silicon onto a fiber substrate, which resulted in porous structures. The thicknesses of these fiber coatings were around 1 [micro]m. To increase the density of -OH groups on the surfaces, the coatings were treated in piranha solution and then reacted with n-octadecyldimethylmonomethoxysilane to render the surfaces hydrophobic. Using silanol/silane chemistry, we can introduce other functional groups for desired selectivity. Sputtering provides good control over coating thickness and high reproducibility. We compare our fibers against commercial PDMS 7 [micro]m fiber for the extraction of saturated alkanes, primary alcohols, and various real life samples. Preliminary results show that despite having a thinner coating, our fibers have comparable performance, and in some cases, especially for higher molecular weight compounds, show better results than the commercial fiber.

Abstract Text

Following the procedure presented by Grimm et al. (2000), catfish was heated in a modified microwave oven while being purged with N_2 . Water and flavor chemicals condensed in a cold trap and were analyzed by Solid Phase Microextraction/Gas Chromatography/Mass Spectrometry. Figure 1 shows the oven and customized glassware (Widget Scientific, Inc., Baton Rouge, LA, USA). A standard kitchen-type 1000 watt microwave oven was modified by drilling 2 holes and attaching lengths of conductive pipe to act as chokes. Chokes prevent microwave leakage, which can be verified by a microwave detector.

Three parameters influence the transfer efficiency of volatile flavor chemicals to the condensate: N_2 flow, microwave power and heating time. These parameters are interdependent. Response Surface Methodology (RSM) based on a central composite design (CCD) is a statistical technique which efficiently determines the optimum combination of these interdependent parameters. Preliminary experiments were performed to determine reasonable ranges and 5 levels of each parameter were analyzed in 15 combinations. Each combination of parameters was applied to a 20 g portion of catfish which had been spiked with 5 ppb of 3 chemicals: Methylisoborneol (MIB), Geosmin (GSM) and Decahydronaphthol (DHN). MIB and GSM are the most common off-flavors occurring in catfish. DHN is used as an internal standard. After analysis by GC/MS, peak areas were totaled. The CCD was analyzed by RSM. When the analysis of variance for the model is significant and the lack of fit was not significant, the model is valid.

Commercially available microwave ovens come in a range of power levels. Different glassware configurations can be used and many different food matrices can be analyzed. For each combination of variables, RSM must be repeated in order to determine the optimum combination of parameters.

We repeated this procedure using a condenser between the purge vessel and receiving cylinder and using vegetable oil spiked with the same analytes. The prediction profiler was used to determine each parameter value yielding the highest recovery. RSM is a powerful and efficient method for determining the optimum levels of interdependent parameters.

Abstract Text

Mycotoxin testing of raw agricultural products and food stuffs is an essential part of most country's food safety programs, ensuring the levels present are within the permissible limits per country or by the Commission Regulation (EC) No 1881/2006. Aflatoxins are the most widely tested mycotoxins, presenting challenges to identify this mycotoxin quickly and accurately as global food trade continues to rise.

AOAC methods for aflatoxin B1, B2, G1, G2 testing utilize post-column derivatization that requires iodine and a reaction coil. Researchers have shown post-column derivatization is successful using a post-column photochemical reactor enhancement detection system (PHRED). In both situations, specialty equipment is required. In addition, the fluorescence wavelength chosen for analysis varies among published research on aflatoxins HPLC analysis without discussion on sensitivity, linearity, repeatability of standards, as well as recovery and reproducibility of a variety of problematic sample matrices across a range of fluorescence wavelengths. A unique and innovative methodology has proven that pre-column derivatization is an effective means for generating acceptable linearity of aflatoxin B1, B2, G1, G2. Optimizing thermal conditions, in combination with the most sensitive fluorescence emission wavelength, generates reproducible and linear results over the course of several days of testing. The ability to generate accurate data with standards and problematic sample matrices is obtainable using commonly available laboratory equipment to allow for simplified but reliable routine testing of aflatoxin B1, B2, G1, G2 that conforms to the EU performance criteria with the highest sensitivity and without specialized hardware or procedures.

Abstract Text

Quantitative identification of engineered nanomaterials (ENMs) is complex, as these materials often exist at low particle number, very low mass concentration and are highly dynamic. ENMs may be found in environmental, biological, or engineered solutions as dissolved ions. In the simplest analytical cases (e.g. filtration then total metal analysis by ICP-MS), only total element concentrations are measured, usually at higher than environmentally relevant concentrations, and thus no “nano-specific” qualities are determined. In other cases, particle measurements are obscured by dilute particle number in complex matrices (e.g. difficult to “find” by TEM or Nano Tracking Analysis) or only broad particle distributions are possible (e.g. when measured by DLS, UV/VIS, etc.). Ideally, all comprehensive ENM studies should implement multiple characterization techniques, but often only a fragment of data is obtained because of these analytical difficulties and using multiple techniques can be time consuming, require much expertise, and expensive to obtain instrumentation. However, single particle (SP)-ICP-MS may replace many standard analytical analyses; either as a fast screening technique to determine the presence, size and concentration of nanomaterials in varied solutions and/or be implemented to collect precise data to monitor changes of ENMs and associated dissolved metal in time resolved environmental studies, all at dilute (ng/L) concentrations. A few varied studies are highlighted here, which use SP-ICP-MS to monitor dissolution of Ag ENM in environmental samples and release of NMs from textiles after washing. Increased development in terms of both data processing software and instrumental hardware have come about in recent years, which will facilitate SP-ICP-MS being implemented more easily in many laboratories. Discussed in this context, SP-ICP-MS can provide as much or more information in a faster and easier than several current analytical techniques combined.

Abstract Text

Evaluating the environmental and human health implications of nanomaterials requires an understanding of their fate, transport and transformation during their lifecycle, including their interaction with biological and other organic pollutants. Thermogravimetric analysis (TGA) and TGA coupled with infrared spectroscopy-GC-MS are used investigate nanoparticle interaction with biomaterials and their environmental transformations coated nanomaterials. The study also included investigating how hazardous organic compounds adsorbed to engineered nanoparticles. The techniques has shown to be promising in studying the partitioning of hydrophobic contaminants between nano-particles and water which is an important parameter for modeling the fate and transport of these contaminants in aquatic environment. The octanol-water partition coefficient is the ratio of the concentration of a chemical in octanol and in water at equilibrium. Octanol is an organic solvent that is used as a surrogate for natural organic matter, and partitioning of contaminants between the two phases helped to determine the fate of contaminants in the environment, such as to predict the extent of bioaccumulation of contaminants aquatic biomes animals. This study focuses on the aging of coated nanomaterials and the influence of nano-particles on the partitioning pollutants between water and organic phases. Sorbtion of hydrophobic organic pollutants to nano-particles increased the concentration of contaminants in the aqueous phase as compared to the "true" partitioning due to the octanol-water partitioning. The effects of nano-materials on the mobility of pollutants that are commonly found at many sites has been studied. These compounds including 2 and 3-ring PAHs: naphthalene, anthracene, and phenanthrene have relatively low water solubility and differing mobility in the soil.

Abstract Text

The presence of volatile organic compounds in carbon nanomaterial products such as single wall carbon nanotubes, multi wall carbon nanotubes, graphene, and modified single wall carbon nanotubes can affect its performance. Proper sampling and haracterization/quantitation of volatile components in highly adsorbent solids requires multiple analytical techniques. Volatile organic compounds are usually identified by measuring the mass spectra of the gaseous component evolved from the heated solid samples. This presentation illustrates the use of an integrated Thermogravimetric Analysis (TGA) coupled with Infra-Red (IR) coupled with Gas Chromatography Mass Spectrometry (GC-MS) using PerkinElmer TL-9000 transfer line for the complete and comprehensive characterization of residual organic compounds in carbon nanomaterials. TGA-IR is used to determine the temperature range over which the release of volatile components occurs. TGA-GC-MS analysis is used to identify each component separately by the use of a capillary column. Quantitative information can additionally be obtained by the sample mass loss in thermogravimetric analysis (TGA) and the peak area in the GC-MS.

Combining these different techniques into an integrated easy to use system provide users with comprehensive characterization of organic based nanomaterial.

Abstract Text

The interactions of nanoparticles (NPs) with the cells have gained increasing attention since NPs have been widely applied to biomedical fields including imaging, diagnostics, cancer therapy, targeted drug and gene-delivery. It was reported that NPs can change the fluidity of cell membrane. However, to our best knowledge, there has been no direct evidence provided regarding to whether and how flip-flop is involved in NP-cell membrane interaction which may due to the lack of surface/interface-sensitive techniques to study the interfaces between NPs and cell membrane. In our group, sum frequency generation (SFG) vibrational spectroscopy with a intrinsic surface/interface sensitivity was employed to study the interaction of model mammalian cell membrane (dDSPC/DSPC lipid bilayer) with Au NPs of four different sizes using three different dose metrics based on mass, NP number and surface area. The results show that the flip-flop rates trend to increase with the increasing size of Au NPs based on same particle number and surface area while they are independent of the size of Au NPs with the same mass. We rationalized the experimental results with a concept of "effective surface area" that is the real contact surface area between Au NPs and model cell membrane and can be estimated based on proposed mathematical model. This study is considered as the very first but crucial step toward the full understanding of the mechanism how NPs interact with model cell membrane.

Abstract Text

Biodegradable and biocompatible poly[(R)-3-hydroxybutyrate-co-(R)-3-hydroxyhexanoate] (PHBHx) electrospun nanofibers were fabricated by collecting the fibers on the sharp edge of a rotary disk at an angular speed of 3500rpm. Traditional methods, including wide angle X-ray diffraction (WAXD) and transmission Fourier transform infrared spectroscopy (FTIR), were used to examine the crystal structure and chain conformation of a bundle of fibers. The results revealed the existence of a new strain-induced metastable α -crystalline form in the macroscopically aligned PHBHx nanofibers, with the chains extended and adopting a planar zig-zag conformation.

In this study, we utilized AFM-IR, a new technique combining Atomic Force Microscopy (AFM) and Infrared Spectroscopy (IR), to look at both the structural and morphological details of a single electrospun nanofiber with a diameter of no less than 200nm. The results indicate that the structure of individual fibers is largely dependent on their sizes, and thinner fibers tend to contain more α -crystalline form. Comparing the AFM-IR spectra with the spectrum obtained from conventional FTIR, one can speculate that the FTIR spectrum is the average of the spectra of a bundle of rotary disk aligned fibers with different diameters. In addition, the mapping of individual nanofibers with 50nm spatial resolution revealed an interesting "core-shell" structure of the fibers where for each fiber, the peripheral area contains much more α -structure. Hence, AFM-IR is a powerful tool to investigate the chemical and crystalline structure of a single electrospun nanofiber.

Abstract Text

Self-assembly of anisotropic gold nanorods (GNRs) is attractive since it provides an additional way to tailor the optical properties of localized surface plasmon resonance (LSPR). To achieve an ordered GNR array with highly uniform and precise confinement, a template-guided convective assembly on predefined areas has been developed. However, a systemic study on the critical factors such as nanorod concentration, aspect ratio, surface charge and surface property of substrate is needed to fully control the quality of the assembly. Furthermore, tuning the interparticle distance, the number of assembled layers and assembly areas are critical to optimize the collective LSPR property in pursuit of maximal optical property in biomedical application. Here, we designed a hydrophilic-hydrophobic surface treatment of template substrate by depositing a thin layer of perfluorodecyltrichlorosilane (FDTS) on lithographically patterned glass. The wettability contrast of surfaces serves as a virtual barrier wall to confine the nanorod assembly in designated pattern. It was found that lower surface charge and higher dimensional identity render the vertical gold nanorod assembly more organized and uniformed. Nanorod concentration was critical for a full coverage of a given area in a monolayer fashion. As the size of the hydrophilic areas increased, a multiple layer fashion was preferred. In addition, the interparticle distance was precisely tuned by varying the ionic strength of solution, resulting in various local electric field enhancements by plasmonic coupling, which was validated by COMSOL simulation results. The orderly GNR array provides a new insight into the enhanced optical transduction of surface plasmon in a chip format.

Abstract Text

A Group of uniform materials based on organic salts (GUMBOS) include organic salts which exhibit the unique and tunable properties of ionic liquids in the solid phase. Nanoparticles derived from these organic salts, i.e., nanoGUMBOS, have been successfully used in a variety of applications including biological and analytical applications. Size-dependent optical properties of nanoGUMBOS is the key to widening these applications in optoelectronic devices. In this work, novel strategies for size-control of nanoGUMBOS are investigated and size effects on optical properties are assessed. This research focuses on two main aspects: the first is optimization of the synthetic procedures and the second is the measurement of nanoGUMBOS optical properties. Herein, nanoGUMBOS were derived from organic semiconductors and syntheses of these compounds were assisted using ultrasound in the presence or absence of soft templates. Characterization techniques such as transmission electron microscopy, UV-Vis and fluorescence spectroscopy were used to analyze the efficiency of the investigated strategies. Absolute quantum yields were also measured for these nanomaterials using an integrating sphere. Our results show that the size and aggregation level of nanoGUMBOS, and ultimately the optical properties can be tuned using different synthesis procedures. Our data implies also that the type of anion in the GUMBOS structure has a major effect on quantum yield values. As a result of this investigation, the efficient use of these nanomaterials in organic light emitting devices is examined in this context.

Abstract Text

Electron transfers (ETs) between small (< 2 nm), highly monodisperse, mixed-valent Au monolayer-protected clusters (MPCs) containing one or more ferrocene ($\text{Fc}^{\text{sup}+1/0\text{sup}}$) redox species in dry, solid-state films will be discussed. We previously observed that electron exchanges in films of highly monodisperse Au_{144} and Au_{25} MPCs is charge-state and core-size dependent at both high and low temperatures. At reduced temperatures (down to 77 K), the thermally activated ET process dissipates, revealing non-Arrhenius behavior, as ET rates become independent of temperature. The present experiments show that the addition of mixed-valent ferrocenated thiolates in the organothiolate ligand shells of Au_{225} , Au_{144} , and Au_{25} impedes electron exchanges between MPCs at and below room temperature. As with the non-ferrocenated Au MPCs, the thermally-activated ET process is diminished at lower temperatures, and the ET rates become temperature-independent. Obliging ET to occur through the $\text{Fc}^{\text{sup}+1/0\text{sup}}$ redox couple seems to help drive the ET behavior into the tunneling regime, suggesting that the $\text{Fc}^{\text{sup}+1/0\text{sup}}$ sites act as kinetic potholes (traps) in the serial electron hopping process. The activation energy barriers are little changed by the presence of ferrocenated ligands and are primarily determined by the cluster core size.

Abstract Text

Dr Boris Belousov reported an oscillation reaction of the redox change of Ce³⁺ and Ce⁴⁺, and Dr. Anatol Zhabotinsky improved the reaction sequence which had been investigated as Belousov-Zhabotinsky (BZ) reaction. To date, BZ reaction has been investigated as self-oscillating system toward a key feature of space-time self-assembly of nonequilibrium systems. The first complete mechanism for BZ reaction is known as the Field-Koros-Noyes (FKN) mechanism.¹ Porphyrin plays an important role in biomolecular system such as hemoglobin and chlorophyll derivatives. We have developed a self-oscillating gel actuator in the wake of BZ reaction catalyzed by ferroin for the first time,² which causes autonomous mechanical oscillation without an external control in a completely closed solution. Because ruthenium tris (2, 2'-bipyridine) ruthenium only has been used as the conventional self-oscillating gel systems. In this light, BZ reaction system driven by water soluble porphyrin derivatives was designed to clarify self-oscillating redox potential of porphyrin derivatives. This presentation is concerned with the self-oscillating reaction driven by water-soluble metallo-porphyrin derivatives for the first time. This system is of interest as a potential circadian rhythm mechanism and as a possible space-time self-assembly can be promoted by chemical reduction and oxidation system.

Abstract Text

Nitrogen is a principle element referred to when discussing nutrient pollution and, along with phosphorus, is largely responsible for the occurrence of algal blooms. The EPA approved method for Total Nitrogen, Total Kjeldahl Nitrogen (TKN) plus nitrate/nitrite, is cumbersome, time consuming, hazardous, and not very effective at determining total nitrogen in ambient water. Alternative methods are needed. This presentation evaluates two methods, a wet chemical oxidation that determines nitrogen colorimetrically and a high temperature oxidation method that determines nitrogen by chemiluminescence. Comparison data will be presented.

Abstract Text

Ultra-thin silica shells (UTSS) are an effective way to improve the stability and compatibility of nanoparticles without significantly attenuating their intrinsic optical properties. This is of particular importance to plasmonic particles used in sensing or surface related studies such as localized surface plasmon resonance (LSPR) or surface enhanced Raman spectroscopy (SERS). For silver nanoparticles an UTSS can both hinder oxidation of the Ag in both air and water as well as establish a scaffold for functionalization through well-established silane chemistry.

UTSS on metallic nanoparticles such as gold or silver generally involve first using a silane coupling agent to render the surface vitreophilic followed by precipitation of silica by the Stober method or addition of sodium silicate species. Here we present a method to obtain silver nanoparticles with a silica shell of a thickness between 1-20 nm on silver nanoparticles ranging in size from 20-300 nm. It is obtained during the growth of the nanoparticles themselves by addition of a silica source to the well-established method of silver nanoparticle synthesis by hydrogen reduction of silver(I) oxide in water that both catalyzes the reaction as well as generates the shell. This allows for fairly monodisperse spherical silver nanoparticles to be obtained in concentrations of approximately 4.8×10^{12} AgNP per litre (for 100 nm AgNP with 1 nm silica shell). This silica shell greatly improves the particle stability allowing for further concentration of the particles in water up to solutions containing 50% Ag by weight. In addition we demonstrated the ability of these particles to be easily integrated into substrates for both SERS and LSPR applications.

Abstract Text

Representation of measurement capabilities is essential for the integration of manufacturing applications as well as management of instrument reliability. This study presents methodologies and results for an MCA study of trace impurities (CO, CO₂, N₂, H₂, CH₄, Ar, O₂ and H₂O) in Helium. Linearity of concentration and instrument response, static repeatability, accuracy, standard deviation, method detection limit (MDL), Gage Repeatability and Reproducibility (R& R) and stability are investigated. The majority of the testing performed within this study was conducted on VICI Trace Gas Analyzer (TGA) and Servomex O₂ & Moisture dual analyzer at a Matheson facility. Finally, the instruments proved to be accurate, precise and reliable at a level sufficient to conduct the analysis of trace impurities in Helium.

Abstract Text

We describe a fast, efficient and mild approach to prepare chemically reduced graphene oxide (rGO) at room temperature. Divalent europium triflate {Eu(OTf)₂} has been utilized as reducing agent for graphene oxide (GO). We have also characterized the solution-processable rGO by using various spectroscopic (FT-IR, UV-visible absorption and Raman), microscopic (TEM and AFM) and powder X-ray diffraction (XRD) techniques. A detailed kinetic analysis was performed which provides that, the bimolecular rate constants for the reduction of GO are $13.7 \pm 0.7 \text{ M}^{-1}\text{s}^{-1}$ and $5.3 \pm 0.1 \text{ M}^{-1}\text{s}^{-1}$ in tetrahydrofuran (THF)-water and acetonitrile (ACN)-water mixtures, respectively. The reduction rate constants are two orders of magnitude higher compared to the values obtained in the case of commonly used reducing agents such as hydrazine hydrate, sodium borohydride and glucose-ammonia mixture. The mechanistic details of the reaction were unfolded by determining the rate orders for various components in the reaction. The present work introduces a feasible reduction process for preparing graphene at ambient conditions, which is important for bulk production. More importantly, the study explores the possibilities of utilizing the unique chemistry of divalent lanthanide complexes for chemical modifications of GO.

Abstract Text

Carvacrol (5-isopropyl-2-methylphenol) and Thymol (2-isopropyl-5-methylphenol) the predominant monoterpenic phenol which occurs in many essential oils of the family Labiatae used through the ages as a source of flavor in food. Thymoquinone (2-isopropyl-5-methyl-1,4-benzoquinone) is an active ingredient isolated from *Nigella sativa* and has been investigated for its antioxidant, anti-inflammatory and anticancer activities. Moreover, thymoquinone could act as a free radical and superoxide radical scavenger, as well as preserving the activity of various anti-oxidant enzymes. Free radicals and other reactive oxygen and nitrogen species (ROS and RNS) are generated by all aerobic cells and are known to participate in a wide variety of biological and biochemical processes. H₂O₂ is a major ROS in living organisms, and its homeostasis can have diverse physiological and pathological consequences. In addition, H₂O₂ and Fe (II) can produce reactive •OH radicals by the Fenton reaction. Oxidants are connected to aging and severe human diseases such as cancer, cardiovascular disorders and related neurodegenerative diseases. In the present study, antioxidant effects of carvacrol, thymol and thymoquinone were investigated against the Fenton reaction. H₂O₂ and Fe (II) were added to each antioxidant solution. Oxidation of each antioxidant was monitored at time period by UV-visible spectrophotometer until the stabilization of reaction. Oxidative products and intact antioxidants were determined by HPLC-DAD. While Thymoquinone oxidizes to quinones, carvacrol and thymol also produces another antioxidant compound of thymoquinone.

Abstract Text

Oxygen concentration analysis relies on the conversion of sample oxygen to carbon monoxide following the temperature-dependent Boudouard equilibrium, which favors the formation of carbon monoxide over carbon dioxide with increasing temperature during pyrolysis. In the past, the available furnace technologies did not allow temperatures exceeding 1200 °C during pyrolysis. This was a limitation for highly precise oxygen concentration measurements, because full conversion of sample oxygen to carbon monoxide requires furnace temperatures in excess of 1400 °C. Using novel furnace technology based on a glassy carbon reaction tube inside a silicon carbide furnace, it is now possible to perform pyrolysis at a temperature of 1450 °C. Full conversion of sample oxygen to carbon monoxide, which is a prerequisite for highly precise and matrix-independent oxygen concentration analyses, is therefore possible. This improvement leads to oxygen concentration analyses with unprecedented precision (standard deviation <0.1 % absolute) and convenience. We present the applicability of the novel pyrolysis technique based on selected organic as well as inorganic samples.

Abstract Text

It is often necessary to measure total organic carbon (TOC) <1 ng/mL in high purity water systems. This is especially true of the semiconductor industry where a statistical departure from baseline results in an abrupt system shutdown. Part per trillion TOC is most often measured by conductivity of dissolved CO₂ produced upon complete oxidation of organics present. These systems are commonly batch type analyzers prone to interferences from various other conducting species produced during oxidation. We present a continuous method for measuring TOC without digestion. All compounds absorb in the deep UV which we measure using the 214 nm line from a zinc lamp and a fiber optic coupled CCD spectrometer. Cavity enhanced absorption spectroscopy is used to improve the sensitivity of the device by increasing the effective pathlength. The absorption cell was constructed of extruded polytetrafluoroethylene, a diffuse reflector highly reflective even in the UV. The physical pathlength was 25 cm, but an effective pathlength of up to 280 cm was achieved. The system was evaluated using Potassium hydrogen phthalate (KHP) and glucose. Limits of detections for KHP and glucose were 0.484 nM and 64 nM respectively, or 46.5 ng C/L and 4.6 mg C/L. These values represent likely upper and lower bounds of sensitivity with real samples falling somewhere in between. Such a device may prove useful in identifying potential sources of contamination when used in conjunction with other TOC analyzers.

This research was supported through a grant from the National Science Foundation; NSF CHE1246368.

Abstract Text

The soil samples from different fields of rural area surrounding Kheda, Gujarat (India) was collected. Some Physico-Chemical analysis such as Temp, pH & Conductivity was studied. Some fertility analysis such as Nitrogen(N), Phosphorus(P), Potash(K) was studied. The soil samples were collected from different fields located at KHEDA in colorless polyethylene bag with necessary precaution. The soil samples were carried out in May-2010. The analysis of samples were carried out during May-2010 To Aug-2010. The major soil problems in India cause various kinds of soil degradation are soil erosion loss of fertility, salinity and alkalinity, acidity water logging and deterioration of soil structures. The survey numbers of the fields were collected from the Dist. Agricultural Office, Kheda, Gujarat (India).

Abstract Text

Chitin is the second abundant biopolymer after cellulose in nature. Chitosan is derived from deacetylation treatment of chitin in alkaline media. Its physicochemical and biological properties make it worthy in regard to many areas like medicine, cosmetic food, agriculture and biotechnology. However, its usage is limited, because chitosan does not dissolve in water and in common organic solvents. To improve the solubility of chitosan and extending its usability many derivatives of chitosan have been synthesized and carboxymethyl chitosan (OCMCS) is an important derivative.

In the present study, for solubility problem of chitosan in aqueous media was overcome, a new water-soluble O-carboxymethyl chitosan Schiff base (OCMCS-3a) and its Pd(II) complex was synthesized. Firstly, 3a (mono-imin) was synthesized via condensation reaction between 2,4-pentadion with 3-aminobenzoic acid in alcohol (1:1). The CS-3a was obtained as a result of reaction of free oxo groups of mono-imin (3a) and with amino groups on the chitosan. Then, water-soluble forms of CS-3a were obtained through oxidation of hydroxide groups on the chitosan to the carboxymethyl groups with monochloroacetic acid (OCMCS-3a) [1]. Pd(II) complex of OCMCS-3a was synthesized in water. Characterization of OCMCS and its Pd(II) complex was conducted using FTIR, ¹H-NMR, ¹³C-NMR, UV-Vis, TG/DTG, ICP, XRD, and SEM techniques.

Abstract Text

Hydrogen cyanide (HCN) is a highly toxic, water soluble molecule that is readily absorbed by aquatic organisms through contact with skin and mucous membranes (e.g. gills) and transported into the bloodstream. Section 304 (a) of the Clean Water Act requires the U.S. Environmental Protection Agency to publish and periodically update ambient water quality criteria (AWQC). The criteria establish maximum threshold concentrations of contaminants for freshwater and marine environments based on empirical toxicity data. Concentrations of free HCN in surface waters can range from 0.005 to several mg HCN/L. U.S. EPA acute and chronic AWQC for free cyanide in freshwater are 22 μ CN/L and 5.2 μ CN/L respectively. Rainbow trout (*Oncorhynchus mykiss*) were found to be the most acutely sensitive freshwater species to cyanide.

In May of 2012 the U.S. EPA approved ASTM Method D 7237-10 for analysis of free cyanide in environmental and NPDES wastewater samples. ASTM D 7237-10 is a flow injection analysis method which employs the gas diffusion amperometry technique to avoid analytical interferences encountered with earlier methods.

This poster will present performance data on ASTM D 7237-10 and application of the method to measure free cyanide and cyanide bound in metal-cyanide complexes that dissociate into free cyanide ions at the pH of an aquatic environment (pH 6 to 8).

Abstract Text

Traditional reaction's optimization is often cumbersome and time consuming. Significant efforts by manufacturers of automated systems have been directed at increasing the speed, efficiency, and consistency in performing chemical reactions. To date, the numbers of integrated systems that combine all the relevant steps of reactions preparations are few. The main feature of the SiliCycle® MiniBlock® is to offer a unique approach to support reaction's optimization and workup of diverse compounds without compromising reagent types or conditions used.

The SiliCycle MiniBlock has fritted reaction vessels, and combined with its patented built-in valve; solid-liquid phase reactions are made easy and elegant: tedious solid washing steps can be performed by simply opening/closing the valve in order to remove or add solvents. Vortex mixing ensures thorough agitation during the reactions.

Results for a number of fundamental reactions, including scavenging of residual impurities, coupling reactions, will be presented in this poster to demonstrate the versatility and the usefulness of the SiliCycle MiniBlock.

Abstract Text

Gold nanoshells consisting of a dielectric core with a gold outer layer are known to have absorption and light scattering properties that extend into the NIR region of the electromagnetic spectrum. This spectral feature enables gold nanoshelled particles to be used in biological and optical applications. Silica and polystyrene nanoparticles are commonly used as core materials with gold nanoshells. However, these materials have rigid physical properties which can limit their potential applications. Here, we use an approach involving nanomaterials with tunable properties. This new class of nanomaterials is derived from a group of uniform material based on organic salts (GUMBOS).

We have prepared thiol-functionalized GUMBOS, and prepared nanoGUMBOS by reprecipitation. Gold nanoshells are prepared by attaching Tetrakis(hydroxymethyl)phosphonium chloride (THPC)-gold seeds to thiol-functionalized nanoGUMBOS. The gold shells grow by mixing gold seeded nanoGUMBOS with gold hydroxide solution. Shell thickness is tuned by changing the ratio of gold hydroxide solution to gold-seeded nanoGUMBOS. Shifted UV-Vis absorbance spectra are observed according to the varied shell thickness.

This class of materials is versatile in that GUMBOS can be composed of an array of ionic combinations. More optical and biological properties will be studied with varied nanoGUMBOS cores.

Abstract Text

As an important biological indicator of cancer status and progression, biomarkers represent powerful tools for cancer study. Cancer biomarkers are molecules secreted by tumor or a specific response of the patient body to the presence of cancer and could be used for cancer diagnosis and prognosis. Among them, non-invasive cancer biomarkers are promising due to the easy collection process. They all originate from tumoral tissue to blood, urine and other body fluids and many isolation and detection techniques have been established targeting these cancer biomarkers. Despite the intense interest in biomarker development for cancer management, few biomarker assays have been approved by FDA. Introduction of aptamer may offer a novel platform for cancer biomarker research, due to its unique properties and ability to work with many analysis technologies. The goal of this project is to develop new aptamer-based cancer diagnosis methods for microvesicle, a promising non-invasive cancer biomarkers.

The Main aim of this project is development of cancer microvesicle aptamer and its application in cancer diagnosis. Cancer microvesicles exist in several bioactive fluids and perform as one non-invasive biomarker. Characterization and aptamer development have been done. The specific binding between aptamer and microvesicle have been demonstrated. Furthermore, by introducing microvesicle aptamer to microfluidics and other methods, target microvesicle separation and other application in cancer diagnosis have been studied.

This projects will demonstrate the feasibility of aptamer-based assays as effective platform to distinguish and isolate non-invasive cancer biomarker. In addition, these studies will eventually diverse and versatile applications in cancer diagnosis.

Abstract Text

Vanadium dioxide (VO₂) is a unique transition metal oxide that undergoes a first-order phase transition at approximately 340K from the insulating monoclinic phase (M) to the conducting rutile phase (R). This metal-to-insulator transition (MIT) results in a change in the resistivity and optical absorption of the material, which has made it useful in several electronic and electro-optic applications. Common synthetic techniques such as pulsed laser deposition (PLD), chemical vapor deposition (CVD), and magnetron sputtering allow for the synthesis of high quality films of VO₂ for these applications. Recently, however, hydrothermal methods have been used for the synthesis of relatively large quantities of VO₂(M) from inexpensive starting materials without the need for expensive instrumentation. While these hydrothermally synthesized VO₂(M) particles have thus far been unsuitable for electronic and electro-optic applications, their applicability in other areas, such as catalysis and sensing, is still being evaluated.

In this work, the amount of vanadium precursor present during a hydrothermal treatment was varied to produce several different morphologies of VO₂(M) including plates, snowflake asterisks, and truncated asterisks. Films of the particles were drop cast onto glass slides and four-point Van der Pauw resistivity measurements were used to determine the phase transition behavior of the particle films. We report, for the first time, resistivity data on drop cast films of VO₂(M) with resistivity changes of up to two orders of magnitude. Additionally, BET gas adsorption theory was used to determine the surface area of the particles in order to evaluate their potential as catalytic materials.

Abstract Text

Manual, colorimetric chemistries have been a mainstay in the lab for many decades. Many chemistries require complex sample preparation steps, prior to the analysis. The combination of budgetary constraints and increased sample loads is making automated of chemistries not only a nice to have, but an absolute must.

Since 2007, the USEPA has begun to allow automation of sample preparation steps as part of CWA (Clean Water Act) methods. Flow Injection Analysis (FIA) is one automated technique that allows automation of sample preparation steps, in addition to the automation of the colorimetric chemistry.

The manual determination of surfactants, (MBAS) includes an extremely complex, time-consuming and error prone extraction method which also involves extended exposures to chloroform for the analyst. Two Lachat methods will be shown, that automate both the extraction and the colorimetric determination. These methods also maintains the chloroform in a closed system to minimize exposure to the operator.

The methods utilize an in-line, dual extraction, whereby interferences are reduced by either a second extraction in an alkaline solution of methylene blue or a second wash with phosphate buffer (equivalent to SM 5540-C/ASTM D2330-02). These methods use a single membrane for phase separation, have rapid start-up and shut down times, and significantly reduce the amount of chloroform needed for each sample. 24 samples/standards per hour can be analyzed using these methods.

Abstract Text

Stable and monodispersed silver (~2-50nm) and gold nanoparticles (~40 nm in size) were produced through a one-pot synthetic approach utilizing the reduction of silver nitrate and gold (iii) iodide respectively in the presence of polyamic acid (PAA) as a reductant and stabilizer¹⁻⁵. The advantages of PAA as stabilizer are not only the enhancement of long-term stability, adjustment of the solubility and amphiphilicity of nanoparticles, but also the functionalization of nanoparticles with its amide and carboxylic moieties to achieve higher and tunable surface-density of shell/brush as well as to promote compatibility and procesability. Stabilization using the PAA is by physisorption⁶ and metal nanoparticles are sterically and/or electrostatically stabilized against aggregation by the oxidized polymer⁷. TEM, HRTEM, EDS, SAED and UV-VIS were used to characterize the nanoparticles. The effect of temperature on the formation of silver nanoparticles was also studied.

Abstract Text

Current explosives trace detectors (ETD) require human operations for swab-sampling of contaminants from surface of baggage. The throughput of commercial explosives trace detection portals, lower than 500 people per hour, is not high enough for investigations at ticket gates of train stations and airports, where more than 1000 people per hour pass through.

To analyze less-volatile explosives such as TNT, PETN, and RDX, we developed a novel particle sampler using a cyclone-type particle concentrator, which can collect and concentrate the explosive particles attached on the surface effectively and rapidly [1]. The explosives particles collected by the sampler are then vaporized by a heating unit that is located below the concentrator, introduced into a mass spectrometer.

We tested a prototype using NIST SRM2905, trace particulate explosive simulants. The ng-level of the particle explosive simulants, which included ng-level of TNT, were adhered to IC-cards ticket and we observed TNT signal within 1-2 seconds after the emission of the air jet from the nozzle to IC-cards ticket. We measured the false-positive rate with over 850 volunteer passengers at a train station in Japan to evaluate the false-positive rate. ROC (Receiver Operating Characteristic) curves were created from the field test data for both single-marker and multiple-marker analysis. The field test data showed that the multiple-marker analysis was more selective than single-marker analysis, which achieved a low false-positive rate of about 0.1%.

This work was supported by "R&D Program for Implementation of Anti-Crime and Anti-Terrorism Technologies for a Safe and Secure Society", Strategic Funds for the Promotion of Science and Technology of the Ministry of Education, Culture, Sports, Science and Technology, Japan.

Abstract Text

The goal of this research is to extend previous work on a spatial heterodyne Raman spectrometer, SHRS, by investigating the issues that affect the sensitivity of SHRS for standoff detection of minimally or non-absorbing solutions. In the SHRS, the high optical throughput of the interferometer offers high sensitivity, however this may not be realized in standoff applications where the etendue is limited by the telescope used for light collection. Unlike the case of a tightly focused laser beam, the throughput advantages of the SHRS may be realized for larger laser spots on the sample, where the SHRS can provide higher light throughput because of its wide field of view. Large laser spots on the sample may be useful for minimizing laser-induced damage or for quickly characterizing a large sample, with a secondary benefit of minimizing the effect of laser pointing stability on a remotely-located sample. In this paper, we will present standoff SHRS Raman spectra for a series of solution samples including nitrates, perchlorates, sulfates, and explosive, such as TNT and RDX. The effect of system parameters such as laser spot size, optical filtering, and coupling optics on sensitivity and signal-to-noise for samples that show both simple and complex Raman spectra will be discussed, as well as samples that fluoresce. Throughput trade-offs when using a telescope for standoff Raman measurements will also be discussed.

Abstract Text

Sensitive infrastructures such as e.g. airports have to be monitored to prevent fire disasters or protected against potential attacks using hazardous compounds such as chemical warfare agents (CWA) and toxic industrial chemicals (TIC). Several accident e.g. at the Düsseldorf airport in 1996 with 17 killed people and a damage of 500Mio€ show the great potential of destruction. On the other hand airports a subject to terrorist attacks e.g. at the Moscow airport in 2011 with 35 killed people. It is advantageous to have a supervision system that can monitor both cases.

In this paper we will present a stationary detection system based on ion mobility spectrometer (IMS) in combination with other orthogonal sensors like photo ionization detector (PID), electrochemical cells (EC) and metal oxide sensors (MOS). In the new developed IMS we are using a non radioactive ion source. With that a lot of national and international regulation regarding radioactive sources can be neglected. The various chemical gas sensing principles operated simultaneously provide a broad detection range with very short response times. The combination enhances the selectivity of the system in order to achieve low false alarm rates. Cross sensitivity is reduced by using the increased information content in the detectors response. The stationary detection system is designed for 24/7/356 operation.

Beside open fires and unknown sources, fires cause by defect electrical systems on the third place for causing disastrous fires. It is desirable to detect fires before main outbreak in a very early stage, already as smoldering fire.

In this paper we will present measurement showing the ability of the stationary detection system to detect fire already in a very early stage of smoldering fire. We will present and discuss the advantages of a hybrid sensor array for multipurpose detection tasks and the versatile application for safety and security monitoring usage.

Abstract Text

Polycyclic Aromatic Hydrocarbons (PAHs) are a large group of organic compounds found naturally in the environment. PAHs are monitored by the US Environmental Protection Agency due to their carcinogenic characteristics. In recent global events, PAHs have come to the attention for contamination in sea food samples due to the oil spills. In the oceanic environment, PAHs are bio-available via the food chain and contaminated sediments which could have the potential to bioaccumulate in the marine organism we eat.

QuEChERS is a Quick-Easy-Cheap-Effective-Rugged-Safe extraction method that has been developed for the determination of pesticide residues in agricultural commodities. Since its installment in 2003, QuEChERS has been adapted for use with many additional matrices and compound classes such as sea food and PAHs.

The aim of this project is to validate the extraction performance of the AutoMate-Q40 by monitoring Polycyclic Aromatic Hydrocarbons (PAH) extracted from sea food. The target compounds were determined by gas chromatography mass spectrometry (GC-MS).

Abstract Title **A Simple and Rapid Extraction Method of Rhodamine B Detection in Raw Samples Using SERS**

Primary Author Huaizhi Kang
Xiamen University

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Zhongqun Tian

Abstract Text

Rhodamine B has been abused in food industry in coloring and brightening numerous food products due to its bright color, high dyeing efficiency and low cost. In response, many analytical and physical chemical methods have been developed such as GC-Mass, HPLC, Uv-vis to detect Rhodamine B in food samples. However, most of them are lab-based methods and time and labor consuming. SERS-based method has been developed in recent years and is an attractive method due to its high sensitivity, intrinsic selectivity and nondestructive data acquisition and without accompanying with extraction method restricts its applications. Here we introduce a SERS-based detection method (SHINERS) using 55nm AuNPs as Raman signaling amplifying substrate and a novel liquid-liquid extraction route to detect Rhodamine B from raw fruit. The whole detection process can be completed within 10 min through a few simple steps and is able to achieve a detection limit down to 0.2ppm Rhodamine B concentration. More significantly, the result demonstrates no noticeable false positive and false negative with satisfied consistency, which extends the SERS detection method to in situ examination of suspicious food products. We have determined Rhodamine B with a simple extraction method and most common engineering AuNPs, which can be developed into a successful commercial method.

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Andrew Cowell, Fatma Ayouni, Herve Lechat, Marion Bonnefille, Valerie Vabre

Abstract Text

Entering the composition of many processed foods as a base ingredient, the wheat must be of high and constant quality. The presence of microbiologically tainted wheat can indeed contaminate large batches of other raw material in storage or even prevail into the finished product if not removed from the process. The evaluation of wheat contamination is commonly carried out by visual assessment and human smelling at reception of raw materials. This study proposes to evaluate wheat and detect possible off-flavors with HERACLES electronic nose, based on ultra fast chromatography. Eight samples of wheat were analysed, four of good quality and four considered as tainted. The comparison of chromatograms obtained with HERACLES e-nose shows significant differences in terms of VOCs concentration between good and bad batches of wheat. Several volatile compounds (mainly alcohols and geosmin) have been detected at much higher concentration in tainted wheat than in good samples. Upon building an odor map based on the global aroma profile, the discrimination between good and bad wheats is clear. Also this Principal Components Analysis confirms that the differentiation is mainly linked with alcohols concentration. These compounds are thus responsible for the off-flavors. The electronic nose can thus be successfully used to rapidly assess and monitor the sensory quality of wheat.

Abstract Title **Migration of Di-2-ethylhexyl Maleate and Fumarate from Pressure-Sensitive Adhesive Labels to Food Simulants**

Primary Author William Limm
FDA

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Timothy H. Begley

Abstract Text

Pressure sensitive labels are often pasted onto stretchable plastic food wraps containing meat, dairy products, and other food commodities. They can also be applied directly onto many produce items such as fruits and vegetables. In spite of such diverse usage, the US FDA possesses little or no relevant migration data on components of pressure sensitive adhesives. The majority of modern pressure sensitive adhesives are prepared from the following compounds: vinyl acetate, ethylene, di-2-ethylhexyl maleate (DEHM) and/or fumarate (DEHF), 2-ethylhexyl acrylate and carboxylic acid. In this work, GC-MSD has been used for the determination of the migration of DEHM and DEHF from adhesive labels to two solvents, 50% ethanol and isooctane, which are can be used as food simulants for lower and high fat foods.

The initial migration studies were performed at 40°C for 10 days and indicate that the highest combined amounts of DEHM and DEHF migrating from adhesive labels through a typical low-density polyethylene (LDPE) wrap is 18 ng/cm² for 50% ethanol and 69 ng/cm² for isooctane. Without the LDPE wrap, the highest amounts of DEHM and DEHF into 50% ethanol and isooctane are 50 and 8,000 ng/cm², respectively.

Because 50% ethanol is generally considered to be an acceptable food simulant for meat products, this migration data would provide fair estimates for the migration of DEHM and DEHF into meat products through an LDPE film. Since fruits and vegetables generally have low fat concentrations, data from the 50% ethanol migration study should conservatively estimate migration. This establishes that the expected combined migration of DEHM and DEHF is not expected exceed 50 ng/cm² in meat, dairy, and produce through a LDPE film. In addition, due to low consumption factors for products using these adhesive labels, consumer exposure from adhesive components from pressure sensitive labels is expected to be below the threshold of regulation.

Abstract Title **An Indirect Method for Pea Protein Quantification in Milk Formula by Real-Time Polymerase Chain Reaction**

Primary Author Son Q. Pham
Abbott

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Chunyan Zhang

Abstract Text

While pea protein is a good source of vegetarian protein for nutritional products, it could trigger allergic reaction for some consumers. The analytical requirement to quantitate pea protein from trace amount to nutritional relevant amount remains a challenging problem. Conventional methods like Kjeldahl or Dumas measuring total Nitrogen without any specificity to different protein sources or sensitivity for trace allergen analysis. Other technologies like ELISA and HPLC also face the problems associated with complex matrix and protein denaturation from the process. We propose a novel approach for pea protein quantification by indirectly measuring genetic material deoxyribonucleic acid (DNA) present in the protein commodity and correlating the DNA quantity to protein quantity. Real-time polymerase chain reaction (qPCR) coupled with fluorescent probe for DNA quantification offers high selectivity of pea species from the primer design, high sensitivity from the qPCR technology, and broad quantification range. In our lab, we developed the method for quantitating pea protein in finished product of formulated milk powder, with linear range from 16.2 ppm to 16200 ppm with a regression coefficient (R²) of 0.9987. The whole workflow from sample purification to detection was optimized to achieve PCR efficiency of 103% and less than 4 hours total run time. This newly developed method could be utilized to quantitate pea protein from trace level to a nutritional normal level in a complex formulated milk product.

Abstract Text

The identification of pesticide residues in foodstuffs by low resolution GC or LC-MS, commonly used in the monitoring of pesticides in this products, is frequently affected by high false positive (FP) and false negative (FN) rates due to instrumental limitations and the inadequacy of identification criteria [1]. This situation is a consequence of the difficulty to estimate the identification quality. This work presents a strategy for the selection of characteristic GC-MS signals of the analyte, the definition of adequate statistical criterion for the identification parameters and the reliable quantification of the uncertainty associated with analyte identity. The identification of compounds is based in the retention time and two ratios of the abundance of characteristic fragments of their mass spectra. Adequate probabilistic models were developed to handle the correlation between the abundance of fragments and of the non-normality of their ratio. The uncertainty of the identification is determined using Bayesian metrics [2] due to their ability to combine, in one parameter, the information from FP and FN. The FN was estimated by probabilistic models of the signal of the analyte and the FP by modelling the variability of signals of matrices free from pesticides. This tool was successfully used to estimate the reduction of the probability of identifications being correct as analyte concentration decreases and sample matrix complexity increases.

Abstract Text

Biogenic amines are biologically active nitrogenous compounds of low molecular weight and are formed through decarboxylation reactions of amino acids. The presence of biogenic amines in food is a strong indicator of food spoilage, which can lead to food poisoning when consumed. Previous work utilized the activated sulfonate or carboxylic ester of various dyes coupled to hydroxybenzotriazole (HOBt). This activated dye-HOBt bond was susceptible to cleavage from water (i.e. hydrolysis). Recent advancements in reagent design have produced a dye-coupled HOBt that is resistant to hydrolysis.

The goal of this research is to utilize this product in a colorimetric assay for the detection of aqueous biogenic amines. Specific targets are those biogenic amines commonly found in spoiled food products such as histamine, cadaverine, and putrescine. For this research, isopropylamine (a primary amine) is utilized as a less hazardous analog for the target analytes. It has already been shown that methyl red (MR) is visible to the naked eye in concentrations as low as 500 nM, and that the new HOBt-coupled dye (HOBt-MR) resists hydrolysis for over 48 hours.

In this presentation, optimization of reaction conditions for the HOBt-catalyzed detection of amines will be discussed in detail. Specifically, the optimized conditions for temperature, time, ethanol content and buffer strength are presented. Future work includes the development of a new colorimetric assay for the quantification of total amines in fish flesh. This assay would allow more accurate determination of spoilage and exhibit no interference from water.

Abstract Text

Off-flavor compounds are described as water-borne, organic chemicals that are deposited into surface water sources causing undesirable tastes and odors. These compounds have been recognized as a worldwide concern since the late 19th century, particularly affecting surface water sources such as streams, rivers, lakes, wetlands, and oceans. Additionally, attention has been increasing toward the effects off-flavors have in aquaculture. The following compounds, isopropyl methoxypyrazine (IPMP), isobutyl methoxypyrazine (IBMP), methylisoborneol (MIB), and geosmin, potentially produced in aquaculture systems cause musty and earthy odors in fish resulting in decreased quality of the crop. The overall goal for this research is to develop and validate an analytical method for the quantitation of specific off-flavor compounds at lower limits of detection than previously studied. Traditionally, vigorous, time-consuming, and expensive pre-concentration steps were required to detect the compounds. This study has implemented a unique pressure-balance headspace sampling system coupled to a gas chromatography mass spectrometer. The headspace technique eliminates the need for organic solvents, reduces sample carryover, and incorporates trapping capabilities for maximum extraction. Resulting data has simultaneously separated and detected all four analytes of interest in less than 7 minutes. Also, further method optimization of trapping parameters was configured to achieve limits of detection below 1 ppt. The proper identification for the analytes of interest will allow future profiling of the compounds amongst aquaculture systems for possible correlation to a definitive source.

Abstract Text

Many important decisions are based on results from instrumental methods of analysis such as the price of goods, the compliance of products with legal requirements or the outcome of research based on chemical analysis. A measurement procedure can only play its role properly if the reported information is objective and has the required quality. The reporting of measurement with uncertainty makes information objective since it defines an interval that should encompass the expected value of the measured quantity with a known probability. Different strategies for the evaluation of the measurement uncertainty can be used. The “bottom-up” approach involves dissecting the measurement procedure in individual uncertainty components responsible either for random or systematic effects, the quantification of these components and the determination of the combined effect of the various components. This approach is difficult to apply due to the complexity of involved models.

This work consists in the development of tutorials for the validation of quantifications performed by instrumental methods of analysis based on least-squares regressions. These tutorials include: 1) the definition of the Limit of Detection and calibration range, 2) the definition of the procedure for calibrators preparation, 3) the evaluation of the applicability of the regression model for describing the calibration curve and 4) the assessment of the measurement uncertainty using the “bottom-up” approach. The various stages are completed in a sequence of user-friendly MS-Excel spreadsheets. These tools were developed to be used by less experienced analysts and to ensure the production of sound metrological information.

Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Cevdet Demir

Abstract Text

Fruits and plants contain a wide range of antioxidant compounds in tissues which are responsible for their antioxidant capacity. These antioxidants include vitamins, carotenoids, phenolic acids and flavonoids which could play an important role since they behave as free radical scavengers, singlet and triplet oxygen quenchers and metal-chelators [1]. Several methods have been reported for determination of antioxidant capacity in plants and foods. Antioxidant capacity methods differ in terms of their assay principle and experimental conditions. Because of multiple reaction characteristics and mechanisms, a single assay will not accurately reflect all antioxidant in a mixed or complex system [2].

The CHROMAC method was used for determination antioxidant capacities of individual and combined phenolic compounds. The CHROMAC is a novel spectrophotometric total antioxidant capacity assay based on the reaction of excessive Cr(VI) and phenolic compounds and formation of coloured complex with remaining Cr(VI) and diphenylcarbazide [3]. The effects of pH, Cr(VI) and diphenylcarbazide concentration on the CHROMAC method were investigated. The reaction mechanism was controlled with the presence of chromium species of Cr(III), Cr(V),Cr(IV) and diphenylcarbazone in the reaction medium. The oxidation percentage of phenolic compounds by Cr(VI) were determined by chromatographic method. The antioxidant capacity determined by CHROMAC method was compared with chromatographic method.

The additivity of different classes of phenolic compounds was above 90% which implies that CHROMAC method is not influenced by other phenolics and interfering compounds. The TEAC values of different phenolic compounds were calculated with CHROMAC method.

Abstract Text

Tobacco is a crop that is associated with a large variety of molds, insects, and viruses from seedbed to storage in warehouses after manufacturing. Growers and manufacturers will use various chemical agents attempting to control these problems known as plant protective products (PPPs). There is a wide range of pesticides used on tobacco crops as plant protective products. The issue with pesticides used on tobacco leaf is related to the leaf after harvest and processing into is manufacturing forms. Pyrolysis pesticide residue is thus inhaled by the smoker and as an environmental tobacco smoke which may be one source of pesticides in the body. Due to the use of more polar pesticides, LC-MSMS technique has been implemented by laboratories. Improvements in the QuEChERS method allow for a quick and efficient sample preparation approach for the analysis pf pesticides from tobacco with LC-MSMS analysis.

Abstract Text

Bisphenol A (BPA) is used in the manufacture of many plastics and epoxy resins that are used to make milk containers and liners to seal metal food containers. Over time some of the free BPA will be leaching out from the plastics and resins to the food it contacts. Because of BPA's potential to act as an endocrine disrupter at low concentrations in humans, regulations have been enacted regarding BPA concentrations in food and beverages sold for human consumption, and associated methods for the detection and quantification of BPA in food and beverages have been developed.

This work presents a method for detection of low levels of BPA in milk and canned broths. Quantifying low levels of BPA in complex sample matrices, such as food samples, can present sample preparation challenges. Molecularly Imprinted Polymer (MIP) Solid Phase Extraction (SPE) is highly selective and considered the top choice for sample cleanup of a single compound or a class of structurally related compounds from difficult matrices. This method uses a BPA MIP SPE to extract and pre-concentrate BPA. Analysis was performed using LC with fluorescence detection. Recovery of BPA from milk at 1 ng/mL was over 80%, and from chicken broth spiked at 60 ng/mL was over 70% with good reproducibility. An unfortified beef broth was also analyzed and found to contain BPA at level greater than 60 ng/mL. We will discuss these results and address some practical issues related to the analyses.

Abstract Text

Iodine is an essential element required for the synthesis of the thyroid hormones thyroxine (T4) and triiodothyronine (T3). These hormones play an important role in regulating cellular activity, growth, and brain development. For humans, dietary deficiencies and excessive iodine intake have been shown to lead to a number of developmental abnormalities, mental retardation, and goiter. A recommended dietary allowance (RDA) of 150 [micro]g/day and a tolerable upper intake level (UL) of 1,100 [micro]g/day for iodine has been established for adults in the U.S. For dogs, a RDA of 29.6 [micro]g/kg body weight has been established for iodine. However, no UL is currently available for dogs. Additionally, the thyroid hormones T4 and T3 are orally active and the consumption of gullet contaminated foods can cause thyrotoxicosis, a type of hyperthyroidism. Several incidences of thyrotoxicosis in humans in the U.S. lead to a ban on the use of gullet trimmings in foods like hamburger or sausage.

In this work a method was developed for the detection of iodide, iodate, thyroxine, and triiodothyronine in dog jerky treats by liquid chromatography coupled to inductively coupled plasma mass spectrometry (LC-ICP-MS). This method was used for the speciation of iodine in multiple dog jerky treats available for sale in the U.S. Total iodine analysis using a separate method was performed and a mass balance comparison was made with the sum of the species obtained from this work. Additionally, several dog jerky treats were fortified at multiple fortification levels for all of the analytes in this method.

Abstract Title **Rapid Detection of Adulteration of Food and Health Products Using Mid- and Near-Infrared Spectroscopy**

Primary Author Ian Robertson
PerkinElmer Limited

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Ben Perston, Justin Lang

Abstract Text

A significant number of cases of food adulteration have been in the global news recently. The economic adulteration of high value food products with lower cost, lower quality materials has a significant negative effect on the food industry and consumer confidence. In some cases, such as the adulteration of powdered infant milk with melamine, the consequences can be fatal.

Mid- and near-infrared spectroscopies are powerful analytical tools for detecting adulteration of food ingredients at economically relevant levels. A single rapid measurement can confirm material identification and quantitative property prediction as well as screening for contamination by undesired materials. Mid-infrared analysis is performed using a diamond ATR sampling accessory. Near-infrared analysis is performed using a near-infrared reflectance accessory (NIRA). Both of these sampling techniques provide fast results and can be used with no sample preparation.

A number of examples of mid- and near-infrared detection of adulterants in solid and liquid food products will be presented, demonstrating targeted and non-targeted methods of analysis. Qualitative and quantitative data is presented for each application as well as results from a novel algorithm for adulterants, capable of estimating the amount of each adulterant present and its detection limit. Method development and simple end—user deployment will be described as well as highlighting the advantages and disadvantages of the different statistical approaches to the analysis.

Abstract Text

Pathogen contamination can lead to a variety of serious illnesses, and are often the reason behind recalls of consumer products. Current methods of bacterial detection are expensive and time consuming. As a result of the limitations of these methods, early detection of bacteria is difficult. Contaminated products may pass through the screening process undetected. In addition, these techniques are unable to determine whether or not any bacteria present are viable. If these techniques lead to the false conclusion that a food item is contaminated, an unnecessary recall of the item can ultimately have a negative impact on the economy, as well as leading to illnesses that may be severe. Electrochemistry use for the detection of bacteria has recently been implemented, and makes an ideal detection system due to the sensitivity, low cost, ability for miniaturization, and the rapidity of detection. Bacterial growth may also be monitored in real time, making electrochemistry an ideal method for early detection of pathogens. An autonomous electrochemical sensor was combined with a powerful multi-class Probabilistic Neural Network (PNN) system to classify four species of organisms (E. Coli #25922, E. Coli # 11775, S. Epidermis #12228, or C. Albicans #10231). This presentation will focus on the design, redox identification and classification of E.coli.

Abstract Title **Natural vs. Synthetic Wine Corks: The Great Cork Debate from a Mercury Content Perspective**

Primary Author Jason P. Gray
Nippon Instruments North America

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Alvin Chua, Koji Tanida, Tomoaki Watanabe

Abstract Text

Much debate has been made about which type of cork is better for your wine: Natural or Synthetic? While that debate may never end, after our research, there will be no question about which type of cork has the most mercury content.

Mercury may or may not play a deciding role in the taste of your aged wine or bourbon, or even if your treasured bottle of wine ends up smelling like wet cardboard due to cork taint. However, mercury is a known toxic pollutant to humans and other animals that attacks the central nervous system, resulting in serious health problems. Mercury is everywhere in our environment, occurring naturally in fossil fuels, such as coal, crude oil, & natural gas, and it's in our air, oceans, and freshwater sources greatly due to man's industrialization of Earth. With the wide-spread deposition of mercury in our environment, it should come as no surprise that natural cork used for bottling of wine and other liquors may contain significant levels of mercury.

In this presentation, mercury concentrations in a variety of natural and synthetic corks measured using the Model MA-3000 Mercury Analyzer from Nippon Instruments Corporation (NIC) will be discussed in detail.

Abstract Title **Evaluation of Inorganic Contaminants Present in Ceramic Houseware**

Primary Author Paulo Henrique M. Kiyataka
ITAL

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Bianca H. Oliveira, Sandra B. Jaime

Abstract Text

The purpose of this work was to assess specific migration (SM) of cadmium (Cd), lead (Pb) and chromium (Cr) in ceramic houseware into 4% acetic acid solution in accordance to ANVISA, the Brazilian Health Surveillance Agency. Twenty commercial samples of ceramic housewares, marketed in Campinas - São Paulo (Brazil), were studied. The samples were in contact with the 4% (m/v) acetic acid solution at 80 °C for 2 hours and the technique of Inductively Coupled Plasma - Optical Emission Spectrometry (ICP-OES) was applied for the quantification of the elements. The results showed that the samples analyzed presented values below the quantification limits of the method (LOQ) of Cd, Pb and Cr, corresponding to 1.80 [micro]g kg⁻¹, 18.6 [micro]g kg⁻¹ and 1.9 [micro]g kg⁻¹, respectively. Therefore was observed that the specific migration of Cd and Pb into 4% (m/v) acetic acid solution, abide by the limits established by National Agency of Sanitary Surveillance (ANVISA), corresponding to 0.30 mg kg⁻¹ and 4.0 mg kg⁻¹, respectively. In Brazil does not have limit established for chromium.

Co-Author(s) Cornelius C. Brombach, Peter B. Stockwell, Warren T. Corns

Abstract Text

The adverse health risk of arsenic (As) and its widespread occurrence in the environment as well as in the food chain has raised great public concerns worldwide. Therefore, a routine screening of As concentrations in food materials has become more of an urgent task for food authorities in many countries. It is already well known that speciation, rather than just total As concentration is the key to fully understand the toxicity of As in food products.

HG-AFS offers several advantages for this task such as low cost, high sensitivity and fast analysis. Selective hydride generation atomic fluorescence spectrometry (SHG-AFS) has already been successfully applied to the analysis of inorganic and total arsenic in rice samples with method detection limits (MDL) of 1 and 3 ng g⁻¹, respectively. High performance liquid chromatography (HPLC) together with HG-AFS has also been used to provide the most precise speciation information in food material.

In this presentation, an automatic online SPE approach is demonstrated for arsenic speciation in food materials. The system is consisting of an autosampler, a 6-port injection valve and a HG-AFS analyser. Sample loop is made of an inline cartridge which contains strong anion exchange packing material. No HPLC was required. The loading of sample extracts, clean-up of the cartridge, elution and detection of the As species was done automatically using a software package developed in house. The performance of the system will be discussed in detail in the presentation.

Abstract Text

Triacylglycerides (TAGs), which form the bulk of vegetable and animal oils, are subject to polymerization reactions when heated. These reactions occur by thermal polymerization¹ or by oxidative polymerization reaction via radicals. These polymeric compounds create high-boiling point, higher viscosity,^{2,3} and insoluble materials, which can affect product quality and properites. For cooking, these polymerized triglycerides (PTGs) can result in increased oil absorption into cooked foods,⁴ and possibly unhealthful properties (reduced digestibility⁵).

The current method for the determination of these PTGs is by high performance liquid chromatography (HPLC) with size exclusion chromatography (SEC) and refractive index (RI) detection, which also requires a solid phase extraction (SPE) process to remove these polymers from the TAGs.⁶ A reverse phase, gradient HPLC method was developed, using a C18 column and the Thermo Scientific™ Dionex™ Corona™ Veo™ charged aerosol detector. This method has several advantages: no SPE is required, as the TAGs will not interfere with the analysis of the PTGs, the chromatography provides more information in the equivalent time, and the detector is highly sensitive and precise, thereby improving data quality.

Charged aerosol detection (CAD) is a mass sensitive technique for determining levels of any non-volatile and many semi-volatile analytes after separation by HPLC. The use of CAD for the analysis of lipids is well documented, as it will detect any non-volatile analyte with a uniform response factor, and allows use of gradient methods. Unlike methods using evaporative light scattering (ELS) detection, HPLC methods using CAD have limits of detection of between mid-picograms to low nanograms on column and have a wide dynamic range from nanogram to microgram levels, with high reproducibility.

Comparative data from the results of this analysis with values in the literature is presented.

Abstract Text

In response to the increased focus on lowering sugar consumption from foods and beverages, food/beverage manufacturers are now introducing the highly touted sugar substitute rebaudioside A (Reb A), in place of all or most of the sugar in certain foods and beverages. The primary interest in Reb A is the fact that it is a naturally derived sweetener considered to be at least 400 times sweeter than sugar and, therefore, can be added to products in considerably lower concentrations. The use of Reb A has been especially accelerated now that it is considered as [i]Generally Recognized as Safe[/i] (GRAS) by the U.S. FDA.[sup]1[/sup]

Reb A and stevioside, both steviol glycosides, are the primary extracts from the *Stevia rebaudiana* plant from South America, particularly Paraguay. As the use of stevia extracts as sweeteners has gained significant momentum, due to its limited availability, there is a growing concern of both adulteration and label claim accuracy in products reported to contain these extracts. With the above in mind, this application highlights the HPLC separation of Reb A, stevioside, Reb B and Reb C, as well as the analysis of these components in a selection of three energy/vitamin drinks. The chromatographic conditions were so chosen as to closely match the latest monograph covering steviol glycosides, including the four listed above, published by the Joint FAO/WHO Expert Commission on Food Additives (JECFA).[sup]2[/sup] This monograph, specifying the use of HPLC and a UV-based detector, is considered the internationally recognized method for analyzing steviol glycosides in food and beverage products.

1. U.S. FDA Agency Response Letter to GRAS; Notice # GRN 000253, 2008
2. Monograph on Steviol Glycosides, prepared at 73rd JECFA (2010) and published in FAO JECFA Monographs (2010) [sup]

Abstract Title **Data Fusion of LC/MS Results for Olive Oil Analysis**

Primary Author Catherine Stacey
PerkinElmer

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Robert J. Seward

Abstract Text

Verification of provenance is important for food authenticity. With high value foods, the country of origin has a dramatic effect on the price. Falsifying the provenance of foods is an attractive proposition to fraudsters. An example is olive oil, being marked incorrectly from desirable regions. Whilst various techniques such as trace metal analysis or isotopic ratios have been shown to separate different geographical classes, other factors such as crop variations and weather conditions have caused these separations to be inconclusive. The use of more than one technique to differentiate can be more convincing. This work uses TIBCO Spotfire® advanced analytics and visualization tools to separate the cultivars and origin of olive oils with a combination of different LC/MS results.

Samples of 35 different monovariatal and blended oils were analyzed using a PerkinElmer HPLC system, with reversed-phase gradients on a C18 column. Detection was with an accurate mass electrospray instrument, the PerkinElmer Axion TOF.

Levels of various classes of compounds in the oils were measured after different sample preparation methods. Triacylglycerides were analyzed from diluted oils in positive mode, the phenolics and free fatty acids from an aqueous extraction of the oils and analysis in both positive and negative modes. All datasets were processed with a unique algorithm to extract levels of compounds and results combined for statistical analysis. Data fusion allowed a better separation of samples into cultivars than any single analysis method. Some regional grouping of samples within a cultivar was also possible.

Abstract Text

Globally the popularity of nutraceutical products continues to increase, such natural product remedies are found in foods, roots and herbs. The legislative focus has resulted in a growth in method development to analyse active compounds in such products.

Korean ginseng, ginko biloba, red panax extracts and ginsenocide standards were analysed using ultra performance liquid chromatography (UPLC). A UPLC® HSS T3 (100mm x 2.1mm, 1.8[μm]) analytical column was utilized. The chromatographic conditions consisted of a 20 minute water (0.1% Formic Acid)/acetonitrile (0.1% Formic Acid) gradient at 0.6 ml/min, using a sample injection volume of 1μl. Negative ion electrospray with ion mobility data acquisition was performed using a Synapt G2-S mass spectrometer.

Non targeted UPLC ion mobility mass spectrometry has been used to generate collision cross sections (CCS), precursor ion accurate mass, accurate mass fragment ions and retention times to profile ginsenocide standards Rb1, (Rb2, Rc), (Rd, Re), (Rf,Rg1) and Rg2. This data was utilised to create a scientific library incorporating the expected CCS values. Three extracts, ginko biloba, red panax and korean ginseng were analysed and routinely screened against the created ginsenocide CCS library, to determine the presence/unequivocal identification of the ginsenocide isomers. When comparing the expected against the measured collision cross sections determined (for the all eight ginseocides profiled in the extracts), the CCS measurement errors were typically <0.5%.

This approach offers a unique selectivity in profiling complex mixtures. The results obtained clearly show the benefits of using the collision cross section measurements and the combined peak capacity of UPLC and ion mobility. Co-eluting analytes and isomers have been resolved as well as unequivocally identified in the three extracts profiled. The approach changes the scope of authentication profiling.

Abstract Text

Milk proteins concentrates and isolates are used as an ingredient in a wide variety of food applications, they are commonly found in infant formulas, enteral nutrition, bakery products, desserts, meat products, dairy based dry mixes (coffee whitener), dairy based drinks (UHT applications, coffee) sports nutrition and weight-loss beverages, protein bars, sauces, toppings, as well as processed cheese products.

The composition and protein level is a determining factor in choosing the best MPC (Milk Protein Concentrate). One of the most important analysis in food additives is the determination of Nitrogen and protein content applied for quality control and R&D purpose. So, for this the use of an accurate and automatic analytical techniques which allows the fast analysis with an excellent reproducibility is required. The FLASH 2000 Analyzer, based on the dynamic flash combustion of the sample, copes effortlessly with the wide array of laboratory requirements such as accuracy, day to day reproducibility and high sample throughput. This alternative to the classical Kjeldahl method, based on Dumas (combustion) method, has been developed and approved by different associations.

This paper presents data on Nitrogen/Protein determination in different milk protein concentrates and isolates, obtained with the analyzer to demonstrate the validity of the method without matrix effect analyzer.

Abstract Text

N-protein analysis based on the Dumas principle relies on quantitatively converting the sample of interest into the gas phase at elevated temperatures in the presence of elemental oxygen. Excess oxygen is commonly bound on metals such as copper or tungsten prior to chromatographic separation of the combustion gases followed by detection of N_2 correlating to protein content. The reaction of copper or tungsten to the according metal oxide throughout the course of several hundred analyses causes deficiency in oxygen binding as well as insufficient conversion of NO_x to N_2 . Thus, erroneous nitrogen / protein values results. In order to circumvent these effects a frequent exchange of so-called reducing metals is required. Here, we present a unique method to recover the metal oxide to the active metal species increasing the life time. Experimental results clearly depict an approx. fivefold increase in life time of the reducing metal while maintaining outstanding precision in nitrogen / protein values results.

Abstract Text

This presentation will describe our research efforts to evaluate the structure-retention, structure-fragmentation and other structure-property analytical relationships for a large series of substituted aminoketones related to the cathinone-type drugs.

Our research has focused on the development of regioisomer specific methods for the identification of ring substituted aminoketone compounds (cathinone derivatives). The work includes the chemical synthesis of all regioisomeric forms of selected aromatic ring substituted aminoketones; generation of analytical profiles for each compound; chromatographic studies to separate/resolve all regioisomeric aminoketones having overlapping analytical profiles, and design and validation of confirmation level methods to identify individual compounds.

Based on the structure of the unsubstituted cathinone molecule, designer modifications are possible in three distinct regions of the molecule: the aromatic ring, the alkyl side chain and the amino group. Example compounds from all three of these areas of designer modification have been reported as components of clandestine drug samples. Commercially available precursor aldehydes, alkyl halides and amines can be converted to a wide variety of cathinone-type compounds. Legal control of a specific molecule often provides the driving force for clandestine development of additional substituted cathinone designer molecules.

The synthesis, GC-MS, IR and related spectroscopic properties will be presented for several series of substituted cathinone derivatives.

Abstract Text

Current methods for the extraction and concentration of ignitable liquids from fire debris utilize passive headspace concentration with activated carbon strips (ACS). Typical extractions are conducted between 60-80°C for 12-16 hours based on ASTM guidelines followed by a time consuming GC/MS analysis. A New Rapid Approach: Dynamic Headspace Sampling - Sorbent-Coated Mesh - DART-Mass Spectrometry method has been developed. Gasoline from seven different vendors was analyzed directly by direct analysis in real time (DART-MS). An evaporation series of gasoline consisting of 0%, 25%, 50%, 75% and >90% was created for each of the seven brands of gasoline. Following the analysis of the neat samples, a modified dynamic headspace sampler using a novel, sorbent-coated mesh for the selective capture of target analytes from fire debris samples was evaluated. A rapid, 5-minute, heated extraction requiring minimal sample preparation for the detection of the isolated species from ignitable liquids was accomplished. DART-MS generated spectra rich in ions characteristic of both hydrocarbons and additives were detected within the mass range of 50-1,000amu. Chemometric Analysis was used to generate statistical models built utilizing analytical data generated from the different vendor brands of gasoline. The weighted spectral linear chemometric algorithm was successful in identifying and categorizing each gasoline sample with a 0% error rate after running a 10 fold, 5 run cross validation on the samples. Statistical analysis of the generated mass spectral profiles obtained by DART-MS resulted in discrimination of the analyzed samples in a fraction of the time in comparison to traditional methods. The speed and efficiency associated with both the sample preparation and the DART-MS analysis, in combination with statistical methods and model building approach, demonstrates an attractive analytical approach for the rapid analysis of ignitable liquids from fire debris samples.

Abstract Title **Analytical Studies on 1-n-pentyl-naphthoylindoles: Regioisomeric Compounds Related to the Synthetic Cannabinoids**

Primary Author C Randall Clark
Auburn University

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Amber Thaxton, Forrest Smith, Jack DeRuiter, Karim Abdel-Hay, Tarek Belal

Abstract Text

Many of the synthetic cannabinoid drugs of abuse are 1-alkyl-3-acyl indole derivatives. One of the more common drugs in this series is JWH-018, 1-n-pentyl-3-(1-naphthoyl)indole. This report compares the GC-MS, HPLC and FT-IR properties of all 6 regioisomeric 1-naphthoyl and all 6 regioisomeric 2-naphthoyl substituted-1-n-pentylindoles. These compounds have the 1- and 2-naphthoyl-group attached at each of the 6 possible ring substituent positions of the indole ring. The twelve compounds have the same elemental composition C₂₄H₂₅NO yielding identical nominal and exact masses. Additionally, the substituents attached to the indole ring, 1- and 2-naphthoyl- and 1-n-pentyl-groups, are identical for all twelve isomers. The electron ionization mass spectra show equivalent regioisomeric major fragments resulting from cleavage of the groups attached to the central indole nucleus. Fragmentation of the naphthoyl and/or pentyl groups yields the cations at m/z 234, 220, 214, 186 and 144. While the relative abundance of the ions varies among the regioisomeric substances a number of these compounds share very similar relative abundances for the major fragment ions. Deuterium labeling studies were used to prepare the d₁₁-n-pentyl-, d₅-indole- and d₇-naphthoyl-analogues of JWH-018 in order to confirm the EI-MS fragmentation processes for these compounds.

Chromatographic separations by capillary GC as well as HPLC provided excellent resolution of these compounds. The elution order appears related to the relative distance between the two indole substituted groups. Infrared absorption spectral data show the carbonyl absorption band for each of the naphthoylindoles and provide distinguishing and characteristic information to help to individualize each of the regioisomers in this set of compounds.

Abstract Text

The rapid detection of the isotopes of uranium is important for the prevention of nuclear proliferation. Although several techniques exist for this purpose, common techniques such as mass spectroscopy require substantial sample preparation or potentially expose the equipment, the operator of the equipment, or both to radiation. Moreover, these techniques may not be able to make an assessment quickly, or they may require substantial amounts of material or high levels of enrichment to work properly.

One technique that solves these detection problems is laser-induced breakdown spectroscopy (LIBS). It can be fast, needs only sub-micrograms of material for an analysis, requires no sample preparation, and can be man-portable. In addition, it could be operated in a standoff regime to ameliorate some of the effects of radiation on the operator and equipment with the proper instrument design. These advantages make LIBS suitable for site-surveying of uranium, which can be difficult with currently available methods.

Though LIBS can detect uranium, as well as its isotopes under certain conditions, it can benefit from enhancement techniques that allow for lower levels of detection of uranium overall and better precision for isotopic abundance. More routine LIBS-enhancement techniques like double-pulse LIBS (DP-LIBS) can improve the overall emission, and techniques like LIBS with laser-induced fluorescence (LIBS-LIF) can improve the relative isotopic-abundance accuracy. Other enhancement methods, such as Townsend-effect plasma spectroscopy (TEPS), resonant LIBS (R-LIBS), and resonant-enhanced LIBS (RELIBS), can potentially improve the detection limits or relative abundance precision even more, though their application to uranium has been limited or is non-existent. Consequently, these latter techniques are chosen for study here, and the results of these techniques on potential detection-limit or relative-abundance accuracy improvements are discussed in this work.

Abstract Text

Ultraviolet (UV)-visible microspectrophotometry has been used for decades as means for discriminating metameric fibers in forensic casework. Recent studies have shown that multivariate classification techniques are an effective tool for characterizing such fibers. The ability to transfer classification models between laboratories could save time and resources in forensic analyses. However, issues transferring models of this type from one laboratory to another can arise as a result of differences in sample preparation, environmental conditions, and instrumental signal response.

In this study, UV-visible absorbance spectra of 12 blue acrylic fibers were examined at five separate locations including three academic research laboratories and two forensic laboratories. The data received from these facilities were analytically assessed in three manners. Multivariate classification models were initially constructed on each individual laboratory's dataset to evaluate intra-laboratory variability between samples. In a second subset of the study, discriminant analysis was performed after merging all data collected in the study. Lastly, the transferability of classification models was assessed by predicting class membership of samples analyzed at a single laboratory using models built from the spectra collected at the four remaining locations.

Principal component analysis (PCA) followed by linear discriminant analysis (LDA), quadratic discriminant analysis (QDA), or support vector machine (SVM) classification were used to evaluate the agreement of results among the laboratories. An average classification accuracy of 93.2% was found after training the discriminant analysis models using data collected at four laboratories and using the information collected at the fifth laboratory as an external test set. For comparison, intra-laboratory studies carried out produced an average classification accuracy of 96.3%. The reduction in the discriminative abilities of the transferred models was likely due to the differences in spectral noise and peak intensities experienced between laboratories. On the whole, the errors generated by QDA were lower than those resulting from LDA and SVMDA.

Abstract Text

Introduction:

'Spice' is a herbal mixture mostly sprayed with various types of synthetic cannabinoids which act as agonists at cannabinoid receptors and cause neurological effects similar to cannabis. Abuse of these herbal products is a current social problem worldwide. In this study we describe direct mass spectrometry (MS) coupled with counter-flow introduction atmospheric pressure chemical ionization (CFI-APCI) for rapid screening of synthetic cannabinoids in herbal products.

Methods:

Experiments were performed using a Hitachi DS-1000 ion-trap mass spectrometer equipped with an APCI source, a metal block heater and a diaphragm pump. Small pieces of herbal products (less than 1 mg) were sandwiched between glass microfiber filters and subjected to direct analysis. Authentic standard solutions of the cannabinoids were dropped on the filter for analysis. Analytes in the samples were thermally desorbed with the heater at 320[degree]C, and introduced to a CFI-APCI source with ambient air by the pump. Ions generated by corona discharge were sent in the direction opposite to the air flow by an electric field, and introduced into the ion-trap mass spectrometer.

Results:

Authentic standard JWH-081, JWH-210, APICA and XLR-11 had the major ions corresponding to their protonated molecules at m/z 372, 370, 365 and 330, respectively, in the full-scan mass spectra (single MS mode). Collision-induced dissociation of protonated molecules gave characteristic product ion spectra (tandem MS mode). Lower limit of detection for 91 synthetic cannabinoids tested in this study was less 100 ng on filter (S/N ratio, >5 on MS/MS traces). Analysis of herbal products containing these compounds showed characteristic ions both in single and tandem MS modes, enough for identification of the compounds.

Conclusion:

The method requires neither sample pretreatment nor separation step, and would be applicable for rapid screening of synthetic cannabinoids in herbal products.

Abstract Text

Microorganisms have been shown to retain a chemical signature indicative of the laboratory medium used for culturing. However, the repeatability of medium-specific chemical signatures has not been demonstrated from samples of microorganisms produced in the same batch or in different batches by the same sporulation protocol. The objective is to compare the variation in Raman spectra of bacterial endospores repeatedly prepared by the same procedure to the variation between Raman spectra of spores prepared using different media. Initially, variation was assessed by a comparison of five sporulation media. Secondly, seven additional medium formulations (12 media formulations total) were measured to increase the number of sporulation media that can be identified. Using Raman spectroscopy and multivariate data analysis, initial results showed that the five media used to sporulate Bacillus cereus T-strain (BcT) were correctly identified for 100% of spores grown in a controlled manner by the same scientist. The results from BcT spores produced in 12 different sporulation media showed correct identification with 98% accuracy (with all but one sporulation medium in this data set identified with 100% accuracy). Differences were discerned between freshly prepared/freeze-dried spores and frozen spores; however, the differences did not impact the identification of the sporulation medium. Since the sporulation medium has a reproducible impact on the Raman spectrum of a BcT spore, this technique may be able to provide leads in an investigation of a criminal release of microorganisms. Thus, the significance of this work is the provision of a tool for microbial forensic analysis.

Abstract Text

The use of 5975-SMB GC-MS with Cold EI was explored with advanced forensic applications. This unique GC-MS is based on interfacing the GC and MS with supersonic molecular beams (SMB) along with electron ionization of vibrationally cold sample compounds in SMB in a fly-through ion source (hence the name Cold EI). The 5975-SMB provides much faster analysis, enables simplified sample handling and preparation for analysis, increases the range of compounds amenable for analysis and improves sample identification via the availability of enhanced molecular ions and TAMI software, which provides elemental formulae and is automatically linked with the NIST library.

GC-MS with Cold EI approaches the ideal forensic GC-MS system via improvement of all types of forensic applications including:

- A) The full range of organic explosives is amenable for analysis including the labile peroxide explosives TATP and HMTD with enhanced molecular ions and femtogram range LOD.
- B) Universal very fast GC-MS analysis method serves for illicit drugs (heroin, cocaine) analysis in under 3 minutes total analysis cycle time, using flow programming.
- C) High throughput forensic analyses with a new Open Probe fast GC-MS provide real time analysis (20s) with separation and library identification.
- D) Unknown sample identification is improved via the combination of enhanced molecular ions, extended range of compounds amenable for GC-MS analysis and the TAMI software.
- E) Improved arson investigations are obtained via Isomer distribution analysis of fuels and oils for their source characterization.
- F) Unique material characterization is obtained via sample specific "large" compounds and their molecular ions.

Abstract Text

Proton-Transfer-Reaction Mass Spectrometry (PTR-MS) is a very sensitive real-time trace gas detection technology and thus well established in many fields of application (environmental chemistry, food and flavor research, medical sciences, etc.). However, so far PTR-MS is predominantly used as a research tool in scientific environments and only to a minute extend for automated detection. Here we present a very recently developed method enabling not only routine detection, but also substance identification with a high level of confidence. We demonstrate the functional principle by analyzing a blend of new psychoactive substances (NPS) marketed under the lurid name "synthacaine" (i.e. synthetic cocaine) via the internet. At first, we obtain a mass spectrum of the unknown blend's headspace using H_3O^+ as reagent ions and tentatively assign the major mass peaks to protonated benzocaine (anesthetic; used to create the cocaine-like numbness effect) and methiopropamine (active ingredient; stimulant; structurally related to methamphetamine; compare figure below). However, as information about the exact mass is not sufficient for the unambiguous identification of a substance, we subsequently change the E/N (reduced electric field strength) in the PTR drift tube and compare the product ion branching ratios to those we obtained from pure compounds. Furthermore, we switch the reagent ions to NO^+ and again compare the branching ratios with those of the pure substances at two E/N values. The whole process takes less than 30 s, facilitates nearly unambiguous compound identification and can easily be automated.

ML and KB have been supported by the European Commission's 7th Framework Programme (GA 287382).

Abstract Text

The developed method for arson detection involves the concentration of the volatile fraction of fire debris in activated charcoal strips, the extraction of these compounds to a solvent, the characterization of the extract by gas chromatography-mass spectrometry (GC-MS) and the demanding interpretation of the instrumental signal [1].

The interpretation of the GC-MS signal can involve the time consuming evaluation of the chromatograph by comparing the mass spectra of relevant peaks with adequate libraries. These comparisons are usually assisted by target compound analysis and extracted ion profiling.

In order to simplify this process, chemometric techniques are proposed.

These tools are based on signals of several ILs that were burned in the presence or absence of substrates. Afterwards, three machine learning tools (MLT), decision trees, random forests, and self organizing maps were trained and optimized for the identification of unknown samples. The multivariate space was also interpreted using Principal Component Analysis and the maximum Euclidean distance to cluster centroids.

The tools were validated through the analysis of unknown samples. The reliability of the output of the tools was quantified by the examination uncertainty using Bayesian metrics [2], allowing to estimate increments in the identification quality when independent tools are combined to identify ILR in fire debris.

Abstract Title **Development of an LC-MS Method for the Simultaneous Determination of Metformin and Miglitol in Human Plasma: Application to Pharmacokinetic Studies**

Primary Author Mahesh V. Attimarad
King Faisal University

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Ahmed O. Alnajjar, Bander E. Al Dubaib, Sree N. Harsha

Abstract Text

Objective: The purpose of the present study was to establish a simple, fast, and sensitive method for the simultaneous estimation of metformin (MET) and miglitol (MIG) in human plasma using voglibose as an internal standard (IS).

Methodology: Chromatographic separation was accomplished using a Zorbax Eclipse C18 analytical column. The mobile phase consisting of 95% ammonium acetate (0.02 mM, pH 6.8) and 5% methanol was pumped isocratically at a flow rate of 0.5 mL/min. Selected ion-monitoring mode with molecular ions $[M + H]^+$ at m/z 130.1 for MET, m/z 208.1 for MIG, and m/z 268 for VOG (IS) was selected for analysis. The developed method has been validated by evaluating all of the parameters specified according to the US Food and Drug Administration's bioanalytical validation method guidelines.

Results: The calibration curve showed a good correlation coefficient during the linearity study in the range of 40 to 2000 ng/mL for MET and 50 to 4000 ng/mL for MIG. The accuracy of the proposed method for analysis of MET and MIG was 98.18% and 99.13%, respectively. Furthermore, both interday and intraday analysis showed less than 7% of the relative standard deviation. In addition, recovery of MET and MIG from plasma was found to be 94.7% and 93.1%, respectively. Subsequently the method was applied to determine the pharmacokinetic parameters such as T_{max} , C_{max} , AUC_{0-t} , $T_{1/2}$ and K_{el} for both the drugs in human plasma. **Conclusions:** The developed LC-MS method is the first of its kind and could be used for the simultaneous determination of MET and MIG in pharmacokinetic studies.

Abstract Text

Anionic substances analyzed by reverse phase mode generally require pretreatment of the sample by derivatization or addition of ion pair reagent to the eluent. In this study, a multimode column (RP + anion exchange or HILIC), with polyvinyl alcohol packing material modified with quaternary ammonium functional groups was used under conditions without derivatization or ion pair reagent for the LC/MS analysis of various anionic substances.

One example of this column applies to the analysis of haloacetic acids which are common undesirable disinfection byproducts (DBPs) generated during water purification. In the past, GC/MS was used as the standard method for haloacetic acid analysis; three haloacetic acids (monochloroacetic acid, dichloroacetic acid, and trichloroacetic acid) were simultaneously analyzed by LC/MS with the multimode column. The optimized eluent condition was 25 mM CH₃COONH₄ aq. (pH 9.2)/CH₃CN = 50/50. The flow rate was 0.2 mL/min, and the column temperature was 30 °C. ESI-MS with SIM and MRM mode was used for detection. The mixed standard solution (2 ng/mL of each) was analyzed. All peak shapes were sharp with baseline separation, and the calibration curves showed high linearity. Tap water was analyzed without interference of detection.

We will also introduce the applications of other substances (e.g. oxyhalides including perchloric acid, iodine ion, organic acids, allantoin, and phosphorylated saccharides). The multimode column is useful for the LC/MS analysis of various anionic substances using more simple conditions than previous methods.

Abstract Text

The brain contains a wide range of molecular types; the ability to quantify polar and nonpolar compounds from the same volume-limited sample is important in many studies. Here we study changes in a range of biologically relevant molecules depending on nutritional supplementation. We use hydrophilic interaction chromatography (HILIC) to separate diverse molecular classes. We hyphenate HILIC to a triple-quadrupole mass spectrometer (TQ-MS) to quantify hydrophilic (e.g. □ alanine) and hydrophobic (e.g. □tocopherol) analytes from 1-2 mg of wet weight biological samples. The EVOQ UHPLC-TQ MS system (Bruker Daltonics) was used and a series of MRM methods created to quantitate compounds of interest in the mouse brain. Because of a high solubility of most targeted analytes in ethanol and the compatibility of HILIC with three-stage ethanol-water-ethanol extraction, we used this approach to reduce the number of sample steps. High throughput of analysis was achieved with an average run duration ~6 min. Linear working curves over a wide range (10 ppb to 10 ppm) for compounds of interest including the neurotransmitters such as GABA and serotonin were obtained. Although poorly separable in these experiments from other forms of tocopherols (□□□) the identification and quantitation of □ tocopherol from the brain samples was possible due to its high abundance, different molecular mass, as well as distinguishing MRM transitions. Changes in the levels of a range of these compounds in the mouse brain will be discussed as a function of nutritional supplementation.

Abstract Text

Carboxymethyl cellulose (i.e. CMC or cellulose gum) is a fluid absorbent used in food packaging and food contact materials. CMC can also be used as a direct additive for foods and drugs in order to change texture and act as a binder. CMC and other carboxymethyl starches are synthesized by condensing glycolic acid with monochloroacetic acid. Diglycolic acid (DGA) is an impurity produced by this condensation which cannot be completely removed. Currently there are no analytical methods to accurately detect and quantify DGA in foods and food packaging materials. Because DGA has been shown to be a potential renal toxicant, the determination of DGA available either from food packaging or from direct addition to food is needed.

Previously published methods for DGA analysis used liquid chromatography with UV/Vis detection and employed nonvolatile buffers. LC-MS/MS requires the use of volatile buffers, but allows for a larger dynamic detection range of the analyte. Multiple columns and mobile phases were tested during method development in order to achieve retention of the small polar molecule of DGA on the column. In addition, experimental conditions were optimized to ensure that the method could accurately differentiate DGA from the co-eluting isomer, malic acid. This poster will discuss the development and validation of a LC-MS/MS method for detection of DGA in a food packaging material and in food grade CMC material intended for direct addition into foods.

Abstract Text

Online databases can be used for the purposes of structure identification. The Royal Society of Chemistry provides access to an online database containing tens of millions of compounds and this has been shown to be a very effective platform for the development of tools for structure identification. Since in many cases an unknown to an investigator is known in the chemical literature or reference database, these "known unknowns" are commonly available now on aggregated internet resources. The identification of these types of compounds in commercial, environmental, forensic, and natural product samples can be identified by searching against these large aggregated databases querying by either elemental composition or monoisotopic mass. Searching by elemental composition is the preferred approach as it is often difficult to determine a unique elemental composition for compounds with molecular weights greater than 600 Da. In these cases, searching by the monoisotopic mass is advantageous. In either case, the search results can be refined by appropriate filtering to identify the compounds. We will report on integrated filtering and search approaches on our aggregated compound database for the purpose of structure identification and review our progress in using the platform for natural product dereplication purposes.

Abstract Text

Two phenylephrine (PE) unknown impurities were detected by HPLC in a commercial Cold & Flu stability samples. Their identification was confirmed by LC/MS analysis following the synthesis and structure determination of the products from the predicted interaction between PE and vanillin (component of formulation). The retention time and MS of synthesized compounds match the unknown ones.

Abstract Text

The natural gas from unconventional gas resources such as shale formations has gained attention due to substantial shale resources in the US, advanced extraction technologies and cost effective production. Those shale formations, such as the Marcellus Shale, are stimulated by hydraulic fracturing to allow for natural gas recovery. Hydraulic fracturing involves the injection of large volumes of water along with sand and chemical additives into the formation. The process generates large volumes of produced water that are being evaluated for potential environmental and health concerns, mainly due to implications from disposal methods and potential surface spills that could affect groundwater aquifers. Our research focuses on investigating the organic compounds present in Marcellus Shale produced water. Solid phase extraction using a Sep-Pak C18 cartridge was employed to isolate organic compounds from produced water. The different organic compounds were further eluted by organic solvents of different polarity and analysis was performed using liquid chromatography/quadrupole time-of-flight mass spectrometry (LC/Q-TOF-MS) in positive electrospray ionization mode. This presentation will summarize the mass spectral results that indicate the presence of specific organic compounds in produced waters. Further characterization of these compounds by targeted MS/MS will also be discussed.

Abstract Title **Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS) Detection of 2-Monochloro-1,3-propanediol (2-MCPD) Esters and their Occurrence in Edible Oils**

Primary Author Nicole Shyong
US Food and Drug Administration

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Lowri DeJager, Shaun MacMahon

Abstract Text

Fatty acid esters of 2-monochloro-1,3-propanediol (2-MCPD) are toxicologically relevant contaminants formed during the industrial processing of edible oils. Currently, the only validated methods for the detection of 2-MCPD esters in edible oils are so-called "indirect" methods which require hydrolysis followed by chemical derivatization prior to analysis. These methods do not provide information about the structures of the intact esters as they occur in edible oils. Identification and quantitative information for individual 2-MCPD esters is required in order to perform an accurate risk assessment hence, the development of a quantitative method which detects intact 2-MCPD esters is needed.

The approach described herein involves rapid solid-phase extraction (SPE) cleanup of solid and liquid oils followed by LC-MS/MS detection using electrospray ionization for quantitation of intact 2-MCPD esters in edible oils. This rugged, sensitive and specific method allows for the direct determination of fatty acid esters of 2-MCPD. The method is then applied to edible oils samples to determine the occurrence of 2-MCPD esters in edible oils in the United States.

Abstract Text

Tea is the second most consumed beverage in the world behind water. Catechins are polyphenols with antioxidant properties found in high amounts in tea, especially green tea. Green tea beverages and dietary supplements containing green tea extracts are often marketed for health benefits. Current popular methods for quantification of catechins use liquid chromatography (LC) with ultraviolet or electrochemical detection. These methods typically have long analysis times of 20 to 60 min. A reverse phase gradient elution LC method was coupled to electrospray tandem mass spectrometry was used to quantitate catechins in green tea beverages and dietary supplements. A method was optimized with a 3.5 minute cycle time for rapid determination of eight common catechins. Methods with external standard and internal standard calibrations were evaluated for reproducibility. The figure shows an example of a typical chromatogram of catechins from a green tea beverage.

Abstract Text

This paper describes a simple high-throughput LC/MS method for the determination of glyphosate, AMPA, and glufosinate in milk. One milliliter of milk was shaken with three milliliters of water containing EDTA and acetic acid to precipitate protein for 10 min. After the centrifugation, the supernatant was passed thru an Oasis HLB SPE to retain suspended particulates and phospholipids. The sample extract was then injected directly to a mixed-mode HPLC column. The analytes were detected by a Sciex 5500 LC/MS/MS system in a negative mode. The internal standard was used to correct for matrix suppression. The average recovery for all analytes at 0.025, 0.1, 0.5, and 2 ppm (n= 7) are between 97-106% with relative standard deviation is less than 9%.

Abstract Title **LC-MS/MS Determination of Arachidonic and Linoleic Acid Product Profiles in Colon Cancer Cells**

Primary Author Stacy Brown
East Tennessee State University

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Martha Borketey, Sharon Campbell

Abstract Text

Arachidonic acid is acted upon by lipoxygenase enzymes, which add a hydroxyl group at 3 different positions on arachidonic acid (corresponding to the 3 different lipoxygenase enzymes, 5-lipoxygenase, 12-lipoxygenase, and 15-lipoxygenase). The products of arachidonic acid that we are interested in include 15-HETE, 5-HETE, and 12-HETE. Linoleic acid is acted upon by 15-lipoxygenase, which produces 13-HODE. Our method involves a liquid-liquid extraction using ethyl acetate of 15-HETE, 5-HETE, 12-HETE, and 13-HODE from cell debris, drying under nitrogen, and reconstitution in methanol. Cell media samples are subject to solid-phase extraction (SPE) using 85/15 hexane/ethanol elution, dried under nitrogen, and reconstituted in methanol prior to LC-MS/MS analysis. The LC-MS/MS experiments are performed using a Shimadzu IT-TOF instrument and involve a direct MS/MS method in negative electrospray (-ESI) mode, monitoring m/z 295 and 319. Chromatographic separation of the analytes is achieved using a gradient elution (A: 30% acetonitrile/70% 0.1% formic acid in water/B: 0.1% formic acid in acetonitrile) on a 250 x 4.6 mm Beckman Ultrasphere ODS column running at 0.500 ml/min flow rate. The dynamic range for the method is 0.5 – 4.5 micrograms/ml. The S-stereoisomers are the primary products when AA or LA are oxidized by human lipoxygenase enzymes, and are thus the targets of this assay. This method has been successfully applied to the study of 15-HETE, 5-HETE, 12-HETE, and 13-HODE in colon cancer cell lines HCT-116 following treatments of gamma tocopherol, gamma tocotrienol, and 95/5 gamma/alpha tocopherol.

Abstract Title **Effects of Biogenic Amines on the Stomatogastric Nervous System of Cancer Borealis**

Primary Author Bryan Crook
Santa Clara University

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Soni Anjali

Abstract Text

The identity and function of many neuromodulators have been found to be largely conserved across species, including both vertebrates and invertebrates. Using the model system of the crab *Cancer borealis*, we wish to better understand the roles neuromodulators play in regulating biological systems. In the crab, the pericardial organs have been shown to release a variety of neuromodulators into the circulatory system (hemolymph). We focus on the roles of biogenic amines, a class of modulators including dopamine and serotonin. These amines have been demonstrated to have important roles in regulating the functions of biological systems. We are investigating the effects amines have on the stomatogastric nervous system, a likely target for these amines, in a similar manner to our laboratory's past research on the hormonal role of GABA on stomach muscle contraction (Suljak et al., Biol. Bull. 2010, 218: 293-302). We have developed a microdialysis method to sample amines in vivo in real time, as well as multiple methods to detect and quantify amine concentrations, including liquid chromatography-tandem mass spectrometry. We have detected all amines of interest from standard aqueous and saline dilutions down to concentrations of 100 nM. We have confirmed the presence of two amines from in vivo dialysate samples and are in the process of confirming others. Results suggest the neuromodulators are present in in vivo dialysate samples, and quantifying baseline levels of each neuromodulator along with relating the dynamic nature of neuromodulator concentrations in response to different stimuli are our current focus.

Yelena Adelfinskaya

Abstract Text

The development of new agricultural chemicals requires the identification of a variety of trace level unknown environmental metabolites. Some of the most challenging problems in compound development are encountered in the area of metabolite identification from complex environmental matrices. These unknowns are generally present at ultra-trace (low pg) levels, precluding their identification with NMR. In most cases, their initial identification must be performed using high resolution/accurate mass LC/MS. We will describe our use of several new approaches for accomplishing this identification using UPLC/MS (AB Sciex 5600 QqTOF) as well as the use of Ultra High Resolution NanoLC-QqITOT instrumentation (Thermo Fusion) to separate and detect the unique isotopic fine structure of these isotopically-labelled metabolites.

Metabolites were generated soil, plant cell culture, and whole plant systems. These samples were analyzed using UHPLC separations on several LC/MS systems including: 1) a Sciex 5600 (QqTOF), and 2) a Thermo Fusion (QqITOT) 'tribrid' instrument configured for both nano-infusion and nanoLC separations. Radiolabeled metabolites were tracked using online (RAM) detection, and ESI ionization combined with accurate MS, and MS/MS data acquisition was performed on the 5600. When required, the fractionated LC effluent was collected and assayed using a TopCount radiochemical counter to localize fractions containing the peaks of interest. These fractions were then analyzed using either an Advion Nanomate or an Eksigent 2-D nanoLC operating in trap and elute mode. These were coupled to the Thermo QqITOT instrument operating MS, MS/MS, and MSn modes at resolutions up to 450,000 (FWHM). We will present several examples where we have obtained employing these methodologies on these instruments in the identification of xenobiotic metabolites.

Abstract Text

In today's world, there are many manufacturers offering sample preparation products and HPLC columns on the market. Choosing the most suitable sample preparation technique and the right HPLC column to develop a robust method is a big analytical challenge. As systems are becoming more and more sensitive, an efficient sample clean-up is crucial to remove interference which could alter results. This is why SiliCycle introduces SiliaPrep(X) 96 well development plate to help quickly screen which sorbent needs to be used.

Once a method is developed and validated, reproducibility is extremely important. Almost all HPLC columns on the market present a non-negligible variation from one lot to another, especially with specialty phases like ion exchangers. This is really problematic for the chromatographer as the development of robust method is extremely hard. With the new generation of SiliaChrom® HPLC columns, fluctuation is minimized and when a method is developed, you will be able to use it over and over. The tightly controlled proprietary grafting processes, combined to the unique and consistent packing processes, achieve uniform and stable bed for long lifetime and reproducibility. Recently, we introduced to new bonded phases to this series: SCX and pentafluorophenyl (PFP).

In this poster, the combination of the use of SiliaPrep(X) development plate with the new SiliaChrom phases will be presented along with a complete study on performance and stability.

Abstract Title **Column Performance: Comparison of the Superficially Porous Particle (SPP) to the Fully Porous Particle (FPP)**

Primary Author Sharon Lupo
Restek

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Carrie Sprout, Frances Carroll, Paul D. Connolly, Rickard J. Lake, Rob Freeman, Shun-Hsin Liang, Ty Kahler

Abstract Text

Superficially porous particles (commonly referred to as SPP or “core-shell” particles) have been proven to provide fast and efficient separations. These particles feature a solid, impermeable core enveloped by a thin, porous layer of silica that decreases the diffusion path and reduces peak dispersion. As a result, significant improvements in efficiency and sensitivity can be achieved over fully porous particles of similar dimension.

In this presentation the performance of 5 μm SPP particle columns will be compared to columns packed with traditional 5 μm and 3 μm fully porous particles (FPP). The relationship between pressure and efficiency will be explored. In addition, run time, signal to noise ratio, peak width, and resolution will be evaluated in several chromatographic experiments. Each experiment will be performed on the same instrument using identical method conditions for each particle.

Through these experiments we hope to demonstrate the following advantages of 5 μm SPP particle columns over columns packed with traditional 5 μm and 3 μm FPP particles. When used in the development of new assays, they allow the chromatographer to obtain fast run times and excellent method performance without changes in instrumentation. When substituted into existing methodologies which utilize 5 μm and 3 μm FPP columns, 5 μm SPP columns have the potential to dramatically decrease analysis times while improving efficiency and sensitivity.

Abstract Title **Optimization of a Platform Method for Characterization of Intact Proteins by RP-LC-MS Using a Standard Protein Mix**

Primary Author Kevin Ray
Sigma-Aldrich Corporation

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Benjamin Cutak, Jim Blasberg

Abstract Text

Analytical labs are increasingly tasked with performing characterization of recombinant proteins. In principle, RP-LC-MS of intact proteins can rapidly provide information about the purity, sequence fidelity, post-translation modifications, and conformation. In practice, generalized methodologies and system suitability metrics are lacking for such applications. In this study, we aimed to develop a platform workflow for intact protein analyses by RP-LC-MS using a standard protein mix and define quality metrics for routine use.

For this study, more than 25 intact proteins were screened to qualitatively assess their reversed phase and MS behaviors. Selection for the final protein cocktail was based on several criteria including: relative retention time to cover a range of hydrophobicity; molecular weight spanning an approximate range of 5,000 Da to 80,000 Da; the presence of post-translational modifications, such as sialyated glycans; ease of electrospray ionization; and the quality of deconvoluted mass spectra produced. All separations were performed using BIOshell A400 Protein C4 columns packed with 3.4 micron fused core particles with 400 angstrom pore size. These fused core particles are known to enable high efficiency separations of proteins by reducing analyte diffusion in and out of the particle while maintaining typical HPLC back pressures and short run times.

Methods were developed on 2.1mm and 200um ID columns using traditional and capillary flow rates, respectively, to accommodate a variety of available instruments and sample amounts. LC conditions including mobile phase, flow rate, and gradient profile were varied. ESI source conditions, such as temperatures and voltages, and deconvolution parameters were also optimized. The generalized RP-LC-MS platform can be applied to analyte proteins in an unbiased manner and the standard protein mix enables system suitability and processing parameters to be established for proteins of various sizes.

University at Buffalo

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Diana S. Aga, Troy D. Wood

Abstract Text

Vitellogenin (VTG) is an egg yolk precursor protein expressed in the females of nearly all egg laying species including fish. The expression of VTG in fish can be used as a molecular marker of exposure to estrogenic endocrine disrupting chemicals (EDCs). Enzyme-linked immunosorbent assay (ELISA) is the conventional method for measuring VTG in fish, which requires expensive ELISA kits to be purchased, and more importantly, the commercial ELISA kits are not available for all fish species. This work aims to develop a generic method to accurately measure the concentration of VTG, in more than one fish species using liquid chromatography coupled with mass spectrometry (LC/MS), which offers an accurate, cost effective and efficient way of quantifying VTG through measuring the peptides digested from VTG. A signature peptide was selected through running digested VTG standards for two fishes---fathead minnow and carp---on a 12 Tesla high resolution Fourier transform ion cyclotron resonance mass spectrometer. Fish serum samples were run through SDS-PAGE to obtain separated VTG from other proteins, then the VTG band went through in-gel digestion, and finally the VTG was quantified by measuring the signature peptide on LC/MS. The method was applied to fish serum samples from fish being exposed to different levels of EDCs. Fish samples exposed to EDCs was also analyzed by ELISA, and the results from two analyses were compared and discussed.

Abstract Text

Hydrogels have gained considerable attention as a controlled-release system for drugs. We have synthesized a transparent hydrogel with three-dimensional fibrous networks by the gelation of sodium deoxycholate in aqueous solution. Doxorubicin (DOX, a cancer drug) is loaded into the hydrogel with the swelling process. We find that the DOX loaded hydrogel can be injected into aqueous solution as hydrogel fibers through a syringe. The release rate of DOX from the injected hydrogel fibers can be tuned by altering the pH of aqueous solution.

Abstract Text

Particle size analysis of dry powders by laser diffraction offers many advantages. The technique is fast, reliable, and can be used for analyzing a wide range of particle sizes. One question that arises in these measurements is the value of the refractive index, RI, for a sample. As such, the implications of errors in this choice are an important part of understanding the uncertainty in a result. Understanding sources of and magnitude of uncertainty is important to improving measurement accuracy. For many particle systems the determined size distribution is a function of the RI used in calculating the size distribution. That is, if an incorrect value of RI is chosen, the obtained particle size distribution will be incorrect and that error is a function of the RI choice. In the historically more common analysis of samples in liquid dispersants, the RI effect is smaller than the case of dry powder analysis since the RI of air is effectively 1 and therefore smaller than values of common liquids (1.3 to 1.5). Here, the effect of RI choice on determined particle size is quantitatively analyzed for samples measured both as a dry powder and in a liquid suspension. Interestingly, even when the effect of RI is negligible, the Mie model gives better results than the Fraunhofer model. This data can be used to obtain a rough idea of the sensitivity of determined size distribution to the value of the RI used in the analysis.

Abstract Text

An ability to alter the properties of the microfluidic channel walls via introduction of nanostructures is of high-importance for lab-on-a-chip applications. Nanotexturing has been used to control material hydrophobicity, increase biomolecule-surface interactions, and control cell attachment and growth. Many of the nanotexturing techniques are expensive, labor intensive, and can only produce nanostructures at the bottom of the microfluidic channel. To address these limitations, our group has recently developed a novel technique for the fabrication of truly 3D nanostructured (3D-NS) surfaces poised within microstructures. 3D-NS micromolding masters were fabricated in impact modified (IM) PMMA using hot-embossing followed by O_2 plasma etching. Poly(dimethylsiloxane) (PDMS) transfer molds were then prepared via casting using 3D-NS masters as templates and were subsequently used for single step hot-embossing of both micro and nanostructures into variety of thermoplastic materials. NS surfaces were characterized using SEM, AFM, and contact angle measurements. It has been observed that the exposure of two phase material, such as IM-PMMA, to O_2 plasma produces NS surfaces with the average roughness in the range of 10 – 80 nm depending on the exposure time. Nanostructuring was equally effective on flat surfaces and on preformed microstructures due to isotropic character of the unbiased plasma. Flexible character of transfer molds prevented shearing off of nanostructures during de-molding step. 3D-NS microchannels were evaluated for variety of applications including isolation of circulating tumor cells (CTCs), isolation of nucleic acids, and cell cultivation.

Abstract Title **Long –Term Thermal Stability of Na-PHEMA Stationary Phase in HTLC**

Primary Author Sema Akay
Aksaray University

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Berkant Kayan, Mehmet Odabasi, Yu Yang

Abstract Text

High-temperature liquid chromatography (HTLC) is recognized today as a valuable technique in reversed phase high-performance liquid chromatography (RP-HPLC). Some aspects probably limit the use of high temperatures, including the lack of commercially available instruments equipped with ovens (1). Since high temperature liquid chromatography requires elevated temperature, an associated concern is whether the stationary phase is thermally stable (2). In order to develop more stable packing material for high-temperature liquid chromatography (HTLC), a new stationary phase, 1-naphthylamine attached poly (2-hydroxyethylmethacrylate-N-methacryloyl-(L)-histidine-methyl-ester) (NA-PHEMAH), was investigated in this work. The temperature used was 150 oC depending on the working conditions. The column was evaluated for 6000 – 18000 column volumes at each elevated temperature. Retention factors and plate numbers were calculated for each chromatogram at a given column volume to monitor any degradation of the stationary phase under high temperature conditions. The results demonstrate that the new NA-PHEMAH stationary phase is more suitable for high-temperature liquid chromatography separations with a good thermal stability.

Abstract Text

There has always been an interest in the rosin extracted from pine and other trees, due to its wide spread use from musical instruments to printing inks to fluxes. In last many years people have started to modify the rosin to enhance certain properties. This has resulted in many varieties of modified rosin also available for applications. In order to keep up with the changes, analytical techniques are also getting modified. Initially only FTIR was the method for knowing the type of rosin. Now FTIR is used as a qualitative tool, but other modern techniques like GC, MALDI are used for detailed exploration of rosins.

We present a method to compare various types of rosin using Gas Chromatography, and quantify them in mixtures. We have compared six types of rosin including natural rosin and modified rosins. Rosin being of natural origin are mixtures, and it is a challenge to analyse and quantify. The lowest limit of detection for rosin is 100ppm.

The instrument used is Agilent GC equipped with FID detector and DB-1 column 30mt x 0.32mmid. Using standard setting the method has been validated as per ICH guidelines. The correlation coefficient is calculated to be 0.998 with accuracy and precision between the acceptable limit of 90-110%. One step derivatization is used before analysis by GC. Using the above method many in-house samples as well as commercial samples have been analysed, and individual rosin acids have been quantified. The results have been very useful in research and development and have been applied for routine testing of rosin.

Abstract Text

USPD is a cost effective ultrasonic backscatter means to measure concentration and particle size distribution with resolution comparable to TEM that can be used in a batch mode or, by virtue of its single-transducer operation, inserted into existing equipment. With USPD, particles in suspension insonified by narrowband unidirectional ultrasound are accelerated into motion away from the transducer. Velocities measured by Doppler shifts in the backscatter collected by the same transducer for particles in the range 5 – 100 nm vary inversely with particle size. To calibrate the system, size distributions of identically prepared samples of polystyrene and colloidal silica (Ludox) particles determined by TEM have been correlated with backscatter USPD spectra. To compare these measurements, TEM-determined PSD's have been converted to "expected" backscattered USPD spectra by multiplication of the number in each TEM histogram bin by particle diameter to the sixth power based on the Rayleigh-scattering dependence of scattering on particle size. Calibration curves for polystyrene and silica (Ludox) particles so constructed are very similar, suggesting that calibrations for a variety of materials may be comparable. A historical limitation of USPD has been a requirement for relative high concentrations. Recent work to modify and upgrade system hardware and software, presented here, has reduced the system noise floor by a factor of about 300, allowing for the measurement of PSD on samples with concentrations less than one percent.

Abstract Text

The complexes of the type $[ML_2]$ and $[MLL'Cl]$ where $M=Cr(III), Mn(II), Co(II), Ni(II), Cu(II)$ and $VO(II)$, L =tridentate ligand (ONS) o-carboxyl-N-phenyl- β -amido thiophene and L' = heterocyclic N-base such as 2,2'-dipyridyl or 1,10-phenanthroline. All the complexes isolated in solid state, are stable in air and characterized by elemental analysis, metal content determination, FT-IR, 1H -NMR, electronic spectra, magnetic measurements, thermogravimetry analysis (TGA/DTG). The physicochemical data suggest a square pyramidal structure of $VO(II)$, pseudo octahedral to $Cu(II)$ and an octahedral for $Cr(III), Mn(II), Co(II),$ and $Ni(II)$ complexes. The ligand field parameter have been calculated and related to the electronic environment. The tridentate ligand (L), binary and ternary complexes were screened for their antimicrobial activities against various bacteria.

Abstract Text

Laser induced breakdown spectroscopy (LIBS) is widely used laser spectroscopic techniques in various fields, such as material science, forensic science, biological science, and the chemical and pharmaceutical industries. In most of LIBS work, the analysis is performed using radiative transitions from the atomic emissions. Recently, some work on Laser Induced Molecular Emission Spectroscopy (LIMES) has started. The LIMES analysis was performed using radiative transitions from the molecular band emissions. In this work, the comparative study of saturation effect in LIBS and LIMES is performed to obtain the optimum experimental condition to lessen the saturation problems. A binary mixture of strontium oxide and aluminum oxide of different concentrations in powder form was used as sample. LIBS and LIMES spectra were collected by varying various parameters, such as laser energy, gate delay, and gate width to optimize the LIBS and LIMES signals. The atomic emission from Sr and Al lines observed in LIBS spectra of different sample composition were used to characterize the laser induced plasma and correlate the effect of saturation.

Abstract Text

Organic light-emitting diodes (OLEDs) are semiconductor devices that use thin films of organic molecules as the emissive electroluminescent layer. Displays with OLEDs do not need backlighting such as liquid crystal displays (LCDs), hence save tremendous amount of energy. In this research, a simple synthetic protocol was applied to synthesize carbazole-derived GUMBOS (Group of Uniform Materials Based on Organic Salts) as potential candidates for emissive material in OLEDs. One group of synthesized compounds has a substituted carbazole as the cation and a bis(pentafluoroethylsulfonyl)imide (BETI) as the anion, which emits a single color of light. The other type also has a substituted carbazole as the cation and an anion which is also capable of electroluminescence such as Fluorescein. The latter group of compounds emits more than one color of light. Evaluation of their photostability and thermal stability showed these compounds are sufficiently resistant to photo-bleaching and thermal degradation, which are the most common problem associated with OLEDs. Calculations of the valence and conductance band gap (E_g), HOMO and LUMO energy levels, and quantum yields also indicated that they can be successfully applied as emissive layers of OLEDs.

Abstract Text

Terahertz time domain spectroscopy (THz-TDS) has the capacity to explore intermolecular interactions and lattice vibrations of solids, thereby providing a means to understand the structural properties of materials. In addition, THz-TDS has the potential to probe dielectric properties of materials at frequencies much higher than conventional MHz methods. Dielectric measurements are difficult at any frequency when sample dimensions are small, as is common for crystals and nano-particles.

We are interested in establishing the utility of dielectric measurements for small dimensional materials at THz frequencies. These measurements involve transmitting coherent THz radiation through a sample and determining the dielectric properties from changes in the phase angle of the transmitted radiation relative to air. Our primary interest is the accuracy of such dielectric measurements for binary samples where the material of interest is embedded within a polymer matrix with known dielectric properties. Landau, Lifshitz, and Looyenga have proposed a model (LLL-model) for such binary mixtures where the dielectric constant of the sample is the volume-weighted sum of the dielectric properties of the individual components.

This presentation will focus on accuracy of dielectric constant measurements for solid materials embedded in pellets prepared by compressing a mixture of the solid material in a polymer matrix of either high density polyethylene or Teflon. Materials tested include Mg(OH)₂, Al₂O₃, and ZnO, for which the dielectric constants are known at THz frequencies. Results for our THz TDS measurements coupled with the LLL-model demonstrate accurate dielectric constants for these materials.

Funding for this research was provided by the University of Iowa.

Abstract Text

Characterization of colloidal systems and investigation of their stability in their native state (i.e. without denaturation) is of prime importance for the formulator who wants to optimize the development of new products. A new technique has been developed, based on Multiple Light Scattering (MLS), to fulfill this purpose. It has been designed to measure and elucidate instability phenomena in liquid colloidal dispersions from 0 to 95% in volume fraction, with particles from 0.1 μ m to 1mm, 5 to 50 times quicker than the naked eye. It has also proven to be a useful technique to characterize the dispersion state of colloidal samples (for quality control purposes) and the mean diameter of the particles in the dispersion.

The Turbiscan[®] technology is fitted with a fully automated ageing station enabling to monitor the stability of various formulations at three different temperatures and to get automatic data processing, helping the formulator to save time and test more formulations. This ageing station can be used for high throughput screening tests, determination of expiry dates or quality control.

Abstract Text

A simple approach for the preparation of monodisperse porous polymer particles was proposed based on the inkjet technology. A piezoelectric drop-on-demand (DOD) inkjet injector with its nozzle submerged into an organic phase was used to generate monodisperse particles. With fine tuning of the waveform applied to the piezoelectric transducer on inkjet microchip, aqueous polymer solution (sodium poly-styrenesulfonate, NaPSS) was easily ejected from the injector into the organic phase (1-butanol). Subsequently, a polymer droplet was generated in the organic phase. Due to the extraction of water from the droplet to the organic phase, accompanied with self-assembling property of polymer molecule, the volume of the droplet shrank. Consequently, the micro-scale particles yielded with a smooth polymer shell and internal porous structure. With the presented system, the porous polymer particles with a narrow size distribution can be obtained by single step. The influencing factors for polymer droplet generation in organic solvent, including polymer property, organic solvent type, and inkjet waveform, were investigated. And the relationship between final particle diameter and initial emulsion droplet size were also studied. By changing the waveform on inkjet microchip, diameters of particles could be precisely controlled from 15 μm to 60 μm with RSD of 2.7%–4.8%. Additionally, various dimensional hollow polymer particles were produced by changing the polymer solution concentration. It predicted that the smaller particle could be obtained when a smaller size nozzle of inkjet was adopted. And the high-throughput production could easily achieved by fabricating multi-nozzle inkjet setup via adding the number of nozzles and cables. We believe that the inkjet-based approach described here would become a universal platform for production of monodisperse porous polymer particles.

Abstract Text

Silk fibroin (SF) is a typical natural biopolymer derived from cocoons of domestic silkworm, *Bombxy mori*. Silk protein is environmentally friendly, renewable, and non-toxic, and has unique material properties, such as tunable biodegradability and good thermal stability. In addition, it is a semicrystalline polymer with two phases, beta-sheet crystalline phase and non-crystalline structures including random coil, alpha-helix and beta-turn conformations, etc. However, regenerated SF materials with high beta-sheet crystallinity are often rigid and brittle and could not be used for soft tissues regeneration. Therefore, blending SF with other soft biomaterials needs to be developed, which can significantly improve the physical or chemical properties of regenerated SF materials. Poly(lactic acid) (PLA) is a synthetic biopolymer with good mechanical properties, biocompatibility and biodegradability etc. In this study, we blended SF with PLA systematically to produce SF/PLA composite films at different mixing ratio in chemical solvents. Differential scanning calorimetry (DSC) and Fourier transform infrared analysis (FTIR) techniques were used to investigate the molecular interactions between SF and PLA. And thermogravimetric (TG) analysis was used to evaluate the thermal decomposition temperature and the degradation rate of SF/PLA composites. This study provided comprehensive information about miscibility and stability properties of SF/PLA blend films. The SF/PLA composites can be further fabricated into various forms such as nanosphere, sponges, gels and fibers. Therefore, this study provided an important platform for the fabrication of different SF composites with various biomedical, green chemistry and engineering applications in the future.

Abstract Text

In the past few years, researchers have introduced photoacid generators (PAG) in ion-selective optodes. PAG are compounds that upon exposure to an electromagnetic radiation generate protons and are irreversible, thus making them not reusable. We utilize a similar concept by incorporating photoacids (PAH), which are compounds that upon irradiation generate protons and are able to thermally reassociate their protons. This reversibility function of PAH shows promise for use in ion-selective optodes. In previous work, we showed a new type of ion sensor containing a meta-stable merocyanine PAH polymer which provides the protons for ion-exchange but also replaces traditional pH sensitive dyes (chromoionophores) and anionic sites (ion-exchangers). Herein, we have synthesized two new PAH each with a different functional group, one electron withdrawing and one electron donating. We have studied their characteristics in terms of pK_a change before and after irradiation in organic solution, and response time in both organic solution and ion-sensing membranes. In our findings, the functional groups attached to the PAH can have a dramatic impact on the behavior of the proton reuptake (response time) after activation. Further work is in progress to optimize the response time of PAH by understanding the fundamentals involved in these processes. We expect to design a 'one of a kind' ion sensor that is controlled and reusable for ion detection.

Abstract Text

Recently scientific and industrial impact of nanoscience and nanotechnology in analytical electrochemistry has been growing. Electrochemical biosensors have been applied in many areas, such as food industry, agriculture, military, veterinary, clinical applications, and environment. Some challenging bioanalytical problems, such as sensitivity, specificity, reproducibility and reliability can be resolved by applying nanostructure-based electrochemical biosensors [1-4].

The glucose biosensors based on glucose oxidase (GOx) immobilized on a graphite electrode precoated by electrochemically deposited gold nanoparticles or electrochemically synthesized 3D gold nanostructures were developed. The optimal concentrations of gold nanoparticles, tetrachloroauric acid, GOx, and a redox mediator were selected, and analytical characteristics of glucose biosensors were assessed. The newly developed electrodes were successfully used for the determination of glucose in human serum samples.

Abstract Text

A nanoparticle platform for scintillation proximity assay (SPA) of ³H labeled analytes in aqueous environments was developed. ³H exhibits minimal effects on labeled analytes in terms of structure and function, and emits low-energy beta particles that may be detected via scintillation, a process that converts the energy absorbed from beta particles into photons emitted at visible wavelengths. The emission wavelength can be modulated by introducing one or more different scintillating fluors, or by altering the luminescent core, e.g. quantum dots, within the absorbing matrix. Such control allows wavelengths to be tuned according to application and providing means for multichannel detection. Polystyrene was used to form absorbing core nanoparticles into which one or more scintillators can be closely entrapped for effective energy transfer from matrix to scintillator. The silica shell provides amenable surface functionality for suspension stability and binding capabilities. Due to their small volume, SPA nanoparticles can potentially be used for real-time measurement of radiolabeled analytes in live cellular environments, where traditional scintillation counting techniques are impossible. SPA nanoparticles were surface functionalized with biotin to study specific detection of radiolabeled analytes using a biotin-protein binding model. Specific binding of radiolabeled NeutrAvidin to the biotinylated nanoparticles showed increased scintillation versus free ³H, resulting in specific detection of low concentration radiolabeled analytes.

Abstract Text

Proximity immunoassays (PIA), including proximity ligation assays (PLA), electrochemical proximity assay (ECPA), proximity Förster resonance energy transfer (pFRET), and proximity rolling circle amplification, are recently developed protein detection techniques with high selectivity and sensitivity. PIAs take advantages of the “proximity effect” of two antibody-oligonucleotide conjugates (Ab-N) or aptamer probes that recognize a target molecule simultaneously. The oligonucleotide tails of the bound probes then trigger downstream reactions for signal amplification or direct readout. Standard methods for Ab-N synthesis yield heterogeneous products of mixtures with a range of stoichiometries, giving inconsistency and unnecessary background in Ab-N based PIAs. Here we designed a method for controlling valency in Ab-N synthesis with magnetic beads induced surface isolation and click chemistry. The approach should allow a controlled number of well-separated azide modified DNA molecules to be captured by DNA-modified beads, followed by 1:1 antibody labeling. We first introduced alkyne modifications onto antibodies by the EDC-NHS reaction, followed by click reaction with the azide-DNA. These Ab-Ns were proven functional in pFRET assays for insulin in the nanomolar range (Figure A). Furthermore, DNA-modified magnetic beads (2 μm diameter) were synthesized using click chemistry and confirmed using flow cytometry (Figure B). With these tools in place, it should be relatively straightforward to synthesize Ab-Ns in batches of controlled valency (1:1, 1:2, 1:3, etc.). In particular, monovalent Ab-Ns should exhibit significantly lower background than the currently used multivalent Ab-Ns, with only modest signal reductions.

Abstract Text

The same liquid crystals (LCs) used in TV and computer screens can also be used for gas sensing. LC films provide a much simpler means to readout chemical interactions than instrumentation. A gas sensor is made by spreading a thin film of LC over a chemically functionalized surface. The detection chemistry aligns the LC molecules in one orientation before exposure to the target, and after interaction with the target it aligns the LC molecules in a different orientation. The change in LC orientation appears as a change in brightness when viewed through crossed polarizers. No power supply is needed.

This technology has been used to make dosimeters that measure ppb levels of H_2S over a period of hours. We now report an increase in sensitivity of two orders of magnitude, enabling detection of 100 ppb in less than 60 seconds of three target gases - H_2S , NO_2 , and NH_3 . These advances were made by optimizing the surface density of the chemistry that interacts with the target gas. This paves the way for highly sensitive, small, lightweight, low power gas sensors for environmental monitoring and safety applications.

Abstract Text

Ion mobility spectrometers (IMS) are widely used in different applications. The ambient pressure operation of these instruments yields the dependency on several environmental parameters. At Pittcon in 2013 we have already shown the great influence of humidity on the performance of IMS and discussed the necessary consequences. In this paper we will update and confirm the results with a further method for measuring the humidity in IMS.

One major advantage of IMS systems is the operation at ambient pressure, so no vacuum system is needed. This fact enables the instrument for miniaturization and handheld operation in the field under rough non laboratory conditions. As a measurement output a time of flight or mobility spectrum is generated. The mobility K of certain ions is a compound specific property and is calculated out of the drift time by $K=l/td \cdot E$. Up to now there is no established compensation method for humidity.

In the previous work we used, in order to measure the humidity level in the closed loop of an IMS, a moisture sensor from Michell Instruments, EA2-TX-100. The sensor based on a capacity measurement of hydroscopic layer on a ceramic substrate. In the recent work we used a sensor which based on the adsorption of water in a Phosphorpentoxid (P2O2) layer and the subsequent decomposition of the water. The sensor is operated with a defined voltage, which changes significantly with the decomposition of the water. This dependency has a close relation the humidity level and is used as an indicator.

In this paper we will compare the performance of the two humidity sensor at the boundary operating range in the lower ppm humidity level. We will show the comparison of theoretically predicted humidity levels deduce from clustering theory with the actual measurements of both sensors. The applicability of both sensors for use in an IMS as permanent sensors for humidity compensation issues will be discussed.

Abstract Text

Volatile compounds released by microorganisms can be used to discriminate between pathogenic and non-pathogenic classes of bacterial species. Such types of discrimination could be useful in cases where one needs to rapidly detect pathogenic microorganisms in food samples in order to avoid foodborne illnesses. Amines are a product of bacterial colonization and also may be markers to other biological dysfunctions; they can be useful analytes to discriminate between different classes of foodborne microorganisms. Colorimetric reagents have been used to discriminate different analytes. They enable fast responses are cheap, readily available and easy to operate compared with sophisticated analytical methods. Cellulose acetate (CA) is an ideal matrix for entrapment of the colour indicator since this polymer presents some important characteristics like stability, homogeneity, versatility and commercial availability; in addition, it can be an efficient support for locking-in dyes and may be used in food packaging applications. Our objective has been to solvent cast CA membranes to immobilise dyes and to use the resultant indicator membranes to discriminate different types of amines. We prepared the CA membranes with five pH indicators. We then obtained images using a mounted smartphone and extracted RGB values using in-house software [1] before and after contact with analytes. All the RGB values extracted from pictures were used as input for non-supervised pattern recognition methods. With subsequent mathematical treatment, it was possible to see a clear discrimination between the amines studied (isobutyl, isopentyl and triethylamine), without any misclassification. This demonstrates that the device could be an economical and fast procedure for determination of food microbial degradation within packaged foods.

Abstract Text

In this work, fluorescent quantum dots (QDs) and gold nanoclusters (Au NCs) are confined in a drop to develop a novel sensing platform for metal ions and organometals at trace level (detection limits in the range of micro-to-nano molar). A portable micro-fluorospectrometer was employed for fluorescence measurement. CdSe and core-shell CdSe/ZnS QDs were stabilized with hexadecylamine (HDA) and dispersed in an organic drop (n-octane, decane). Metal species were incorporated into the sensing drop following headspace single-drop microextraction. This integrated system allows the isolation of the target analyte, its preconcentration and recognition in a smart way. Advantages of the novel approach include increased selectivity (phase separation removes potential matrix effects) and sensitivity as well as low consumption of nanoprobes. Consequently, the generation of toxic wastes due to elements contained in the QD composition (e.g. Cd, Se) is kept to a minimum. In addition, no functionalization of the nanoprobes is required, their dispersion in the organic solvent together with a stabilizing agent being enough for sensing. Several metal species such as selenite, methylmercury, methylcyclopentadienyl-manganese tricarbonyl, etc. quenched the QD fluorescence following the Stern-Volmer equation. Significant quenching was also observed for non-metal compounds such as hydrogen sulphide. Au NCs stabilized in an aqueous drop with sodium dodecyl sulfate (SDS) and following the same approach as above have proved to be sensitive for the detection of inorganic mercury. The novel sensing platforms may open the door to on-site trace metal analysis and speciation, with a performance similar or even better in comparison with analytical techniques typically used in central labs.

Abstract Text

Single nucleotide polymorphisms (SNPs) are the main cause of variations in human genome. SNPs arise from damaged DNA or dysfunctional replication enzymes, and have the potential to cause apoptosis, carcinogenesis, and mutagenesis. These effects have motivated the development of techniques for SNPs detection. However almost all of the proposed methods consist of multi-step procedures, are limited to specific types of SNPs, some of these methods require expensive instruments, and some suffer from high level of interferences. In this work, we present a novel simple, inexpensive, mix-and-read assay that is general for the sensitive detection of all types of SNPs. Our technique utilizes the enhancement of terbium luminescence in ssDNA regions via effective energy transfer from excited, non-hydrogen bonded bases to terbium ions (Figure One). Thus, SNPs present in the sequence of a dsDNA lead to luminescence enhancement in the presence of terbium ions. The change in luminescence is directly correlated to the number of SNPs enabling the terbium-DNA complexes to be used for sensitive quantification of SNPs in dsDNA. We optimized the experimental conditions and the position of SNPs in dsDNA for maximum sensitivity. The results show that central SNPs cause the maximum instability to dsDNA with an exponential increase in the terbium luminescence with increasing the number of SNPs in the dsDNA (Figure One). The technique's quantification demonstrated a dynamic range of 0-72 SNPs in a dsDNA composed of 100 base pairs, with a limit of detection and limit of quantification of 3 and 9 SNPs, respectively. This assay proves that the terbium luminescence is a simple, fast and economic probe for the sensitive detection of SNPs in DNA.

Abstract Text

In molecular diagnostics, fluorescent probes are used for specific detection of genetic material associated with particular diseases, enabling physicians to diagnose diseases accurately and prescribe "personalized" treatments. Equipment for sensitive fluorescence detection are, however, typically expensive and bulky. Furthermore, additional optical elements are required to perform spectral separation when using multiple fluorescent probes for multiplex testing. The added optical elements inevitably reduce sensitivity, affordability and robustness of the system. A compact module for multi-spectral fluorescence detection can reduce the size, complexity and cost of fluorescence-based molecular diagnostic instruments. Capable of detecting below 1nM fluorescein, the low-cost multi-spectral fluorescence PixelSensor can help bring the power of molecular disease diagnostics to the point-of-care, in both the developed and developing worlds.

Abstract Text

In our preliminary studies, a new type of ion sensor was developed which contains a meta-stable merocyanine photoacid polymer that replaces traditional pH sensitive dyes (chromoionophores) and anionic sites (ion-exchangers) for ion detection.¹ Currently, we have improved our previous ion sensor by incorporating a newer type of meta-stable photoacid compound. Similar to its predecessor¹, the membranes containing the new photoacid compound has shown to actively exchange protons with calcium ions upon activation with visible light, and the competitive ion-exchange process can be followed by UV-Vis spectroscopy. Herein, we have improved the response time, limit of detection, and dynamic range. Also, this ion sensor highly discriminates other cations such as Na⁺, K⁺, and Mg²⁺. With respect to these improvements, the experimental values highly correlate to the newly developed theory based on a coupled equilibrium involving the phase transfer of the analyte and H⁺ with accurate assumptions that could extend the traditional ion-selective optode theory. Further work is in progress to improve its complete reversibility, limit of detection, response time, stability, and extend the sensing mechanism to different cations by understanding the fundamentals involved during phase-transfer equilibria. Thus, these results are bringing us closer for designing a controlled and reversible with fast response time ion sensor based on a meta-stable photoacid.

Abstract Text

Non-covalently crosslinked molecular imprinted copolymers were prepared to recognize nitrophenol in an aqueous solution. Free radical polymerization was used to create random copolymers that primarily consisted of n-isopropylacrylamide as the backbone monomer with recognition and crosslinking comonomers. Molecular imprinting was carried out in both dioxane and dimethylsulfoxide. The recognition monomer that is used to create the binding site within the polymer is 4-vinylpyridine. Two different types of non-covalent crosslinks were used throughout the polymer randomly to maintain the binding site conformation. One type of crosslink involved excess base, vinylpyridine, interacting with an acid co-monomer, acrylic acid or methacrylic acid. The second type of non-covalent crosslink involved pi-stacking interactions between benzyl or naphthyl comonomers. Binding was studied by equilibrium dialysis. The results show that non-covalently crosslinked polymers selectively bind selected isomers of nitrophenol with high affinity.

Abstract Text

An innovative ratiometric fluorescent indicator based on poly (N-isopropylacrylamide) (PNIPAM) responds to Cu(II) complexation. The polymer chain is divided into two portions. One portion is copolymerized with polyfluor 570: methacryloxyethyl thiocarbonyl rhodamine B (Rhodamine-B), the donor fluorophore, and N-((4'-methyl-[2,2'-bipyridin]-4-yl)methyl)-N-propylacrylamide (BiPy), the ligand which can complex Cu(II). The other portion is copolymerized with amine groups, which are functionalized with Alexa Fluor 647, the acceptor fluorophore. To improve the stability of the system, PNIPAM is grafted from a silica particle, the substrate. When temperature increases from 25°C, which is below the lower critical solution temperature (LCST) to 46°C which is above LCST, the acceptor/donor fluorescence emission ratio decreases slightly due to thermal quenching. The fluorescence emission of the fluorophores changes with addition of Cu(II) which bring positive charge to the backbone when binding with the ligands, causing the polymer chains to change conformation. That's because the efficiency of fluorescence resonance energy transfer (FRET) decreases with increased distance between the donor and acceptor. The ratio of donor and acceptor emission changes with different concentrations of Cu(II). At 25°C, when $pCu = -\log[Cu(II)]$ decreases from 7 to 4, the ratio decreases from 0.65 to 0.47. At 46°C, when pCu decreases from 7 to 4, the ratio decreases from 0.62 to 0.37. When another fluorophore pair fluorescein o-acrylate and Alexa Fluor 555 is adopted in place of rhodamine-b and Alexa Fluor 647, the ratio changes from 0.49 to 0.43 at both 25°C and 45°C. The system also works in wastewater effluent in that there is acceptor/donor ratio change upon addition of Cu(II). Therefore, the activity of Cu(II) can be sensed based on the efficiency change of FRET.

Abstract Text

Aerosil 200 silica nanoparticles are grafted to thermoresponsive poly(N-n-propylacrylamide) (PNnPAM) brushes, which are labeled with a fluorescence resonance energy transfer (FRET) donor, Polyfluor 570 Rhodamine B (Rhodamine), and an acceptor, Alexafluor 647 (647), via Reversible Addition-Fragmentation chain Transfer (RAFT) polymerization. The brushes are capable of selectively binding polar organics through molecular imprinting technology. Aerosil 200 silica nanoparticles can stay suspended in solution. Their reactive silanol groups make it possible to covalently conjugate the polymer brushes to the silica surface. RAFT is a form of living polymerization that allows us to locate the donor fluorophore in one block of the copolymer and the acceptor fluorophore on a second block, thereby generating P(NnPAM-co-Rhodamine)-b-P(NnPAM-co-647). PNnPAM brushes are thermoresponsive and they exhibit collapse in the broader temperature range of 5-22[degree]C after being imprinted. Our ratiometric indicator takes advantage of the thermal phase transition. We imprinted the copolymer at high temperature in aprotic organic solvent and then removed the template at low temperature in aqueous solution. After removal, the conformation of the copolymer changes when it selectively binds the analyte. This affects the extent of FRET between the donor and acceptor, leading to a change in acceptor to donor intensity ratio. Unlike traditional molecular imprinting technology based on covalent crosslinks, our binding site conformation is maintained by non-covalent acid-base and pi-pi stacking crosslinks. We observe selective binding of nitrophenol isomers with high affinity. This is confirmed by the fluorescence analysis and equilibrium dialysis. Our data suggest that our indicator can be applied to selective and sensitive sensing for polar metabolites and pharmaceutical compounds.

Abstract Text

The identification and quantitation of adulterants in cocaine samples are important not only for toxicological and clinical perspectives, but also for forensic proposed related to determine the origin of the drugs, since the analysis of different samples of seizure can be useful for police intelligence purposes (traceability of drugs and drug dealers) [1]. Aminopyrine (AMP) has been widely used as an analgesic and antipyretic drug and as model substrate for in vitro and in vivo investigations of drug metabolism [2] and recently has been reported in the literature its identification as an adulterant in cocaine seized samples [3]. In this work, the electrochemical response of AMP was evaluated using three different working electrodes (gold, glassy carbon, and platinum). The platinum electrode was chosen as the working electrode material due to the best analytical signal in comparison with other bare electrode materials. The best conditions for the oxidation of AMP on platinum surface was studied and based on this conditions an analytical curve (Fig. 1) with linear range from 100 to 1000 $\mu\text{mol L}^{-1}$ was obtained achieving a limit of detection of 30 $\mu\text{mol L}^{-1}$. The sensor response was evaluated for detection of AMP in cocaine samples seized by Brazilian Police performing an AMP spike and the recovery value obtained was $105 \pm 5\%$ ($n=3$). The interference to other contaminants commonly found in this sample [1] was studied and no interference was observed indicating the accuracy of the proposed method. Financial support: FAPESP, CNPq and CAPES.

Fig. 1 – SWV recorded in a 0.1 mol L⁻¹ phosphate buffer with platinum electrode. Parameters: step, 0.1 V and amplitude, 0.01 V. Inset: Analytical curve. Regression linear equation: $I_p (\mu\text{A}) = -1.21 \times 10^{-6} + 0.028 (\text{CAMP}/\mu\text{mol L}^{-1})$, $R^2 = 0.998$.

Abstract Text

Photothermal therapy based on near infrared-absorbing nanoparticles has emerged as a promising treatment for cancer during the past decade. However, complete eradication of tumor cells is difficult due to the heterogeneous laser heating of the nanoparticles inside the tumor. Here, we developed a method to improve the efficacy of tumor treatment by combining photothermal with photodynamic therapy along with magnetic field drug delivery assistance using silicon 2,3-naphthalocyanine dihydroxide iron-oxide gold nanostars (SiNC-IO-Au NSts). SiNC was entrapped in the hydrophobic pocket of the polymeric monolayer on the surface of IO-Au NSts, which allows direct cellular delivery of the hydrophobic photosensitizer via the lipophilic plasma membrane. Raman spectroscopy was used to quantify the amount of SiNC delivered to the cells. Combined photothermal therapy and photodynamic therapy with SiNC-IO-Au NSts was shown to be far superior than the photothermal therapy or photodynamic therapy alone. It was confirmed that photothermal-photodynamic therapy with magnetic field assistance was a successful method in the eradication of head and neck cancer due to synergistic effects. SiNC-IO-Au NSt enabled photothermal-photodynamic therapy with magnetic field assistance has the potential of preventing tumor reoccurrence and may have an important impact on the treatment of head and neck cancer in the clinic.

Abstract Text

Nanocrystallite magnetic particles are attractive due to many important applications like magnetic drug delivery, hyperthermia for cancer treatment, ferro fluids, magnetic storage data etc. Nanosized particles of cobalt ferrite have been synthesized by an auto combustion method. The citrate – nitrate solution was prepared under molar ratio of 1:1. The final product has been received by self ignition then as burnt powder was calcined at 950 °C. The formation and phase identification of the synthesized particles were confirmed by FTIR and XRD. The particle size was investigated by a Scanning Electron Microscope.

Abstract Text

Owing the importance of gold nanoparticles in catalysis, designing them has become a major focus of the researchers. Most of the current methods available for the synthesis of gold nanoparticles (GNPs) suffer from the challenges of polydispersity, stability and use of toxic and harmful chemicals. To overcome these limitations, we present a novel single step, biofriendly process for synthesis of fructose (monosaccharide), sucrose (disaccharide) and raffinose (trisaccharide) capped GNPs, wherein sugar is directly capped onto gold without the use of any secondary capping/stabilizing agent. Characterization of synthesized GNPs was done using various analytical techniques like transmission electron microscope (TEM), dynamic light scattering (DLS), SEM-EDS, and UV-Vis spectroscopy. The synthesized sugar GNPs (S-GNPs) were spherical in shape and in the size range of 15 ± 5 nm. p-Nitrophenol reduction assay was used to evaluate the catalytic reduction activity of various sugar capped GNPs. The effect of temperature and the size of ligand on catalytic activity were also evaluated at different temperature using UV-Vis spectrometer. Further, rate constant (k) was determined followed by its activation energy (E_a) and exponential (A) factor. Results of the study also helped to understand the relationship between sugar chain length (ligand) and catalytic activity. Given to the high activity and stability, S-GNPs might be useful as a catalyst for wide range of industrial and environmental applications. Results of these studies not only provide us a novel synthesis method but also yielded efficient catalytic agents. This research was support by KY NSF EPSCoR Grant 0814199, WKU research foundation.

Abstract Text

As the leading cause of cancer deaths in the United States, lung cancer claims more lives each year than the next three most common cancers combined and has a 5 year survival rate of approximately 16%. This research explores the ability of small (<5nm diameter) gold nanoparticles presenting RGD-containing ligands to target $\alpha v \beta 3$ integrin, a biomarker known to be overexpressed in activated endothelial cells and certain lung cancers. Variables investigated were the density of the peptides on the particle surface, the spatial confinement of the peptides by looping them back down onto the particle surface, the type of ligand used to passivate the particle, and the ability of the particles to target cells based on their $\alpha v \beta 3$ integrin expression. This was accomplished through clonogenic assays using a ^{137}Cs irradiator and comparing nanoparticle treated samples with those untreated or treated with Cilengitide, c(RGDf(NMe)V), which is currently in clinical trials. Cell survival data fitted to the linear quadratic model was used to calculate dose enhancement factors and confirmed the ability of both Cilengitide and the peptide-conjugated nanoparticles to target cells with higher $\alpha v \beta 3$ integrin expression. Although the peptide densities explored did not appear to impact the efficacy of the particles, significant differences were seen in the more spatially confined looped peptides, suggesting an increase in the binding affinity of the particles for the integrins. Finally, the particle passivating ligand, although not expected to play a role in the binding of the particle to the receptor, did impact the survival rate, and future studies will investigate this property.

Abstract Text

Redox enzyme-based reactions were applied for the synthesis of conducting polymer nanoparticles [1] and functional layers suitable for the design of electrochemical biosensors [2]. Glucose oxidase (GOx) E.C. 1.1.3.4. from *Penicillium vitale* was applied as biocatalyst, which is forming hydrogen peroxide that initiates polymerization of some conducting polymers. It was shown that this method is suitable for the synthesis of polypyrrole, polyaniline and some other conducting polymer based layers and nanoparticles. It was demonstrated that both dissolved and immobilized enzymes could be successfully applied for the enzymatic synthesis of conducting polymer-based nanoparticles. Here reported synthesis of nanostructures based on conducting polymers belongs to 'green synthesis' since except monomer required for the formation of conducting polymer any other environmentally dangerous materials are applied in this polymerization process. We also have demonstrated that formed nanostructures and nanoparticles shows good biocompatibility with living cells and when implanted in mice. We have demonstrated that during such kind of synthesis of nanoparticles and/or nanostructured layers the enzymes becomes entrapped within conducting polymer layer. In addition gold nanoparticles could be entrapped within formed conducting polymer layer.

Abstract Text

A biosensing platform based on metal nanoparticle surface plasmon enhanced fluorophore fluorescence was designed. It used a nanostructure of Ag@SiO₂-DNA-fluorophore to selectively detect metal ions and small organic molecules. DNA hybridization occurred in the presence of the targets through the formation of base-target-base complex; accordingly, the fluorophore (Cy3) was brought to the surface of Ag@SiO₂ core/shell nanostructures. Through controlling the thickness of the silica shell on the Ag nanoparticle, the fluorescence of Cy3 could be enhanced by the surface plasmon resonance of Ag nanoparticle for up to 2.5 folds. This metal-enhanced fluorescence (MEF) sensor provided high sensitivity and selectivity for the detection of Hg²⁺, Ag⁺, and coralyne. It may be developed as a new class of MEF biosensors for other metal ions and organic molecules analysis.

Abstract Text

The characterization, sizing, and quantification of metal-based nanoparticles (NP) in a variety of matrices using single particle-inductively coupled plasma-mass spectrometry (SP-ICP-MS) is becoming increasingly popular due to the sensitive nature of the technique. Nanoparticle events in the plasma are less than 0.5 ms in duration^[1]; however current quadrupole-based ICP-MS instruments are limited to instrument dwell times in the millisecond range and have data acquisition overhead that adversely affects data quality. Novel instrument settings and data processing techniques can be used to explore the benefits of continuous data acquisition rates as fast as 10^[5] Hz (or 10 μ s dwell times)^[2]. This talk presents data on the different effects data acquisition rate has on the quality of data that can be obtained by SP-ICP-MS. The effect of varying the dwell time and its influence on particle integration, particle counting, particle sizing, and background signal is discussed. Data on identifying the significant instrument settings and their implications on nanoparticle characterization is also presented.

Abstract Text

The remarkable performance of natural proteins motors have inspired scientist to create nanomotors capable of converting energy into movement and forces. Such nanoscale devices consist of a self-propelled structure equipped with sensing and/or actuating attachments (i.e. cargo loads or bio-recognition elements), and are capable of transporting cargoes in a rapid and controlled manner. Nanomotors are currently the subject of an intense interest due to their potential applications in nanomachinery, nanomedicine, fluidic systems, nanoscale transport and assembly, among others.

Nanomachines could offer innovative concepts in sensing and monitoring applications. The large cargo-towing force of modern micromachines, along with their ease of surface functionalization, can enable new target isolation ("Capture and Transport") strategies. Self-propelled functionalized nanomachines offer considerable promise for the selective isolation of target analytes from untreated samples, thus obviating laborious sample preparation steps. This offers considerable promise for further miniaturization of lab-on-a-chip devices, including operation in nanochannels, and simplification of the powering requirements of such microchip systems. Catalytic micromotors have also shown to display a chemotactic behavior in the presence of a gradient of the fuel concentration, with a directed movement and increased speed toward higher peroxide concentrations. Changes in the swimming behavior in the presence of hazardous chemicals can offer direct and timely visualization of chemical stress. Here we will describe the use of such microengines nanoparticles for motion-based threat detection and the possibilities in the development of new lab on a chip systems based on active transport, for diverse environmental applications.

Abstract Text

Currently green synthesis of silver and gold nanoparticles has generated a lot of interest in sustainable nanotechnology due to environmental implications. We have previously reported the synthesis of quercetin pentaphosphate (QPP) and quercetin sulfonic acid (QSA) using simple procedures and have characterized them with UV-vis spectroscopy, ¹H-NMR, ¹³C-NMR, ³¹P-NMR and LC-MS techniques¹. The solubility of QPP was found to be 840 mg/mL and aqueous solutions of both QPP and QSA were stable for over a period of 1 year. We hereby report the green synthesis of silver and gold nanoparticles using QPP, QSA and other naturally-occurring flavonoids, Quercetin, Apigenin and their derivatives QPP and Apigenin Triphosphate (ATRP). The major obstacles to flavonoid applications are the poor solubility of most flavonoids in common organic solvents. Therefore the derivatized phosphate flavonoids such as QPP and ATRP which are very soluble in water served as a precursor for green synthesis of silver and gold nanoparticles. The synthesized nanoparticles were characterized using TEM, EDX, Uv-vis spectroscopy, HR-TEM and selected area electron diffraction (SAED). The TEM studies depict that the particles sizes range from 2-80nm. Formation of AgNPs and AuNPs were confirmed by EDS spectra. Crystallinity is confirmed by the SAED spectra and the fringes observed in HRTEM images and the results are in agreement with the UV resonance plasma peaks.

Abstract Text

The main aim of NANOMICEX project is to reduce the potential risk upon workers' exposure to the engineered nanoparticles employed in the operative conditions of the inks and pigments industry. New surface modifiers are designed and developed to obtain less hazardous and more stable nanoparticles to achieve the goal. The work has focused on a set of nanoparticles such as metal oxides (MOs), quantum dots (QDs), silver nanoparticles (AgNPs) relevant to the ink and pigment industry. A complete characterization is conducted, followed by an exposure measurement in order to characterize and quantify any potential particle release in the production and processing activities. A comprehensive hazard assessment will allow the evaluation of effects on human and environmental models with comparisons between simple and modified nanoparticles carried out in the scope of the project. In this presentation, the relationship between the surface chemistry of metal oxide NMs such as ZnO, TiO₂ and Al₂O₃, QDs and AgNPs versus toxicity will be the focus. A number of ligands and polymeric structures with biological origin are covalently attached to the NM surfaces and their cytotoxicity is evaluated. It is found that there is a strong relationship between surface chemical structure of NMs and their toxicity.

Abstract Text

There is an enormous interest to use nanomaterials in widespread applications ranging from electronics and construction to medicine and consumer products. Although these materials provide major advantages regarding their unique physicochemical properties, a major concern has also been raised about nanomaterial toxicity to environmental and human health. Besides being time-consuming and expensive, the conventional techniques to determine nanotoxicity, however, have not been proved to be reliable at all conditions for all nanomaterials. Therefore, novel approaches are sought to evaluate nanotoxicity accurately. Among them, Raman Spectroscopy together with Surface Enhanced Raman Spectroscopy (SERS) are considered as alternatives to the conventional techniques. In this study, it is aimed to form a model to determine nanotoxicity with the help of Raman and SERS, followed by multivariate data analysis methods. Three model nanoparticles (single-walled carbon nanotubes, titanium dioxide and zinc oxide) are tested on two model cell lines (A549 and HDF). Additionally, for SERS studies, 13 nm gold nanoparticles are incubated with the cells. Raman and SERS are performed on living cells without any fixation procedure, bypassing the disadvantages such as fixative related peaks in the spectra and the change of cellular content distribution. The preliminary results indicate that it is possible to obtain a pattern from the multivariate data analysis, discriminating the nanoparticle treated and non-treated cells.

Abstract Text

The superparamagnetic core/gold shell nanoparticles have attracted from many fields and applications such as protein and enzyme immobilization [1], bioseparation [2], drug delivery and immunoassays [3]. Three different magnetic gold nanoparticles synthesized in two steps via wet chemical methods in a various surfactants and stabilizers at room temperature. In the first step superparamagnetic Fe₃O₄ iron oxide nanoparticles prepared with alkaline aqueous media. After washing steps and protonation with HClO₄, iron oxide nanoparticles used as magnetic core for the next step. Sodium borohydride and hydroxylamine hydrochloride used as reducing agent for gold shell formations on first and second nanoparticles. Seed-growth method with citrate stabilization was used for third nanoparticles. Transmission electron microscopy (TEM) images were obtained for three core-shell gold nanoparticles, results showed that two of gold nanoparticles were in spherical shape and third one is anisotropic shape with mean diameter of 20 nm, 15 nm and 23 nm respectively. X-ray diffraction (XRD) patterns indicated that the resulting iron oxide nanoparticles were pure Fe₃O₄ with spinel structure. Au patterns also observed after gold nanoparticles shell structure completed. Magnetic measurement by vibrating sample magnetometer (VSM) relieved that the saturated magnetization (Ms) of three god nanoparticles reached 50 emu/g, 37 emu/g, 27 emu/g and 56 emu/g respectively. All of the nanoparticles showed the characteristics of superparamagnetism. For magnetic nanoparticle synthesis, changes of size, shape and surfactants gave chance to adjust and control magnetic properties on nanoparticles. In this study we compare physical properties of three magnetic core-shell nanoparticles that were synthesized with different methods.

Abstract Text

With the development of nanotechnology and the use of nanoparticles, the need to characterize nanoparticles has also grown. Many types of nanoparticles are now being used, with one of the most popular being silica dioxide. Due to its unique characteristics, SiO₂ nanoparticles are being used in a wide variety of application areas. For the most successful implementation, the size and size distribution of these particles must be characterized.

Silica measurement with ICP-MS is challenging due to the presence of ¹⁴N₂⁺ and ¹²C¹⁶O⁺ which form in the plasma and have the same m/z as the most abundant Si isotope (m/z 28, 92%). As a result, the background at m/z 28 is very high, which inhibits low-level Si determination and could make detection of SiO₂ nanoparticles difficult. However, with Single Particle ICP-MS, the data acquisition rate is so fast, that the background is much lower than in conventional analyses.

This work will focus on the characterization of SiO₂ nanoparticles using SP-ICP-MS.

Abstract Title **Absorption Spectroscopy as Powerful Technique for the Characterization of Single-Walled Carbon Nanotubes (SWCNTs)**

Primary Author Ivo Stemmler
PerkinElmer

Date: Wednesday, March 11, 2015 - Morn
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Chris Lynch, Claudia Backes

Abstract Text

In the exploding field of nanoscience and nanotechnology, carbon nanotubes have attracted considerable attention owing to their unique mechanical and electronic properties for a broad field of potential applications.

SWCNTs are theoretically constructed by rolling up a graphene sheet into a cylinder with the hexagonal rings joining seamlessly. Depending on the way the graphene sheet is rolled up a huge diversity of SWCNT structures can be constructed differing in length, diameter and roll-up angle and with unique electronic properties, as they exhibit either metallic or semiconducting behavior.

UV/Vis/NIR absorption spectroscopy has proven to be a powerful tool in unmodified and processed SWCNT characterization, as a high information density related to the physical and electronic properties of the SWCNT sample is accessible by a readily available and inexpensive technique. Since various factors influence the optical properties of SWCNTs, absorption spectroscopy gives access to Key information.

A suitable UV/Vis/NIR spectrophotometer needs to deal with high absorbing (black carbon) liquids as well as with low absorbance values with best possible signal to noise ratio and low spectral bandwidths in Vis and NIR. By an experimental comparison with SWCNTs it could be shown that the UV/Vis/NIR spectrometer Lambda 1050 WB from PerkinElmer showed the best performance available on the market and is the best choice for this kind of experiments. The Lambda 1050 offers a double monochromator system with very low stray light and allows to analyze samples up to 8 A (absorbance units) in Vis and NIR. With such a system, the sharp SWCNT peaks which are superimposed on the high absorbing background can still be precisely determined in the whole spectral region. The high signal/noise ratio also allows very low sample concentrations, e.g. down to 0.2 µg/mL.

Abstract Text

Nanoparticles have been growing in use in a large number of application areas. Cosmetic products such as sun screens are one major application area. Nanoparticles are commonly used to enhance the protection from harmful ultra violet radiation by scattering the harmful radiation away from the skin. Characterization and quantitation of nanoparticles used in creams and lotions is a key element in understanding how homogeneously materials are distributed and the overall effectiveness of these nanoparticles. The unique use of UV/VIS spectroscopy coupled with a 150 mm integrating sphere and center mount sample holder provides important information to quantitate and compare the contributions of absorbance, large particle scattering, and nanoparticle scattering.

Abstract Text

Single Particle ICP-MS (SP-ICP-MS) is a new operating mode in the world of ICP-MS dedicated to the analysis of metal based nanoparticles which allows the differentiation between ionic and particulate signals, quantitation both the ionic and particulate fractions, measurement of particle concentrations (particles/mL) and, particle sizes and exploration of agglomeration and size distribution.

This study outlines the quantitation and characterization of element oxide nanoparticles (Al₂O₃, and CeO₂) commonly used in the nanoelectronics and semiconductor fabrication industry for the chemical-mechanical planarization (CMP) of semiconductor surfaces [1].

The characterization of the size distribution of CMP slurry nanoparticles, as well as the identification of larger particles, is an important aspect for the quality control of the photolithography process as they can impact the eminence of the silicon wafers. One of the most promising techniques for analyzing metallic nanoparticles is ICP-MS run in single particle mode (SP-ICP-MS). Due to its ability to measure both the dissolved concentrations of analytes and individual nanoparticles.

Abstract Text

Titanium dioxide nanoparticles have been manufactured and used in many products. Most sunscreens contain different amounts of titanium dioxide nanoparticles. Single particle inductively coupled plasma-mass spectrometry (SP-ICP-MS) is an emerging methodology for nanoparticle characterization and quantification. In this study, SP-ICP-MS was used to determine the particle size, size distribution, particle concentration, and mass content of titanium dioxide nanoparticles in commercial sunscreens. A PerkinElmer NexION 300/350 ICP-MS with Syngistix™ Nano Application software the market only dedicated software for SP-ICP-MS was used for the high throughput analysis. Seven different brands of sunscreens containing different amount of titanium dioxide were tested. The sunscreens were dispersed in 1% Triton aqueous solution first, then further diluted with ultra-high purity water, and analyzed by SP-ICP-MS. From the SP-ICP-MS analysis, size, size distribution, particle concentration, and dissolved Ti were obtained simultaneously. The primary particle size detected spans from 35-45 nm for different sunscreens. Mass content of titanium dioxide in sunscreen was determined by standard addition method. Since the primary particle size detected is 35-45 nm, a 40 nm titanium dioxide nanoparticle was chosen as standard to be spiked into the sunscreen at different concentrations. The titanium dioxide content measured by the standard addition method is close to the manufacture claimed titanium dioxide content. The major advantages of the SP-ICP-MS analysis are fast analysis, informative results, and easy sample preparation.

Abstract Text

The polymeric micro- and nanostructures are especially attractive for fluorimetric sensors preparation. This type of structures can be characterized by a wide concentration range of response and a relatively short response time.

In our work we proposed a novel type of nanospheres using alternating polymers, e.g. poly (maleic anhydride-alt-1-octadecene) or poly (styrene-co-maleic anhydride), as starting material. Simple synthesis approach yields nanospheres size ranging from about 120 nm to 250 nm. The spheres synthesized were used as fluorimetric ions - nanosensors using an optode approach. Thus obtained fluorimetric ion sensors were characterized by fast responses and were showing reproducible linear dependence of fluorimetric signal on change of logarithm of ions concentration in solution within the range from 10^{-5} M to 10^{-1} M (as receptor typical ionophore was used and chromoionophore as optical transducer). The unique linear dependence obtained was attributed to surface related phenomena on nanosphere/solution interface.

Abstract Text

Heart disease is the number one cause of death in the US and among the group, cardiac arrhythmia is the most common in clinical practice. The current treatment for drug resistant cardiac arrhythmia is by catheter ablation. The catheter ablation uses radiofrequency or cryoenergy to ablate a selected region of the heart interrupting the fibrillatory conduction and finally terminating arrhythmia. However, this therapy is non-specific and recurrence of arrhythmia is often observed. Also, cellular damage to benign neighboring cells cannot be avoided leading to complications such as esophageal fistula and rupture. Thus a more cell specific targeting treatment is needed for a safer and more efficient way to treat arrhythmia. Here, we introduce a new, cell specific ablative strategy for treating arrhythmia through targeted photodynamic therapy (PDT), assisted by a tailor made photosensitizing nanoplatfom. PDT is a clinically approved phototherapy, using light to excite a photosensitizer, so as to create reactive oxygen species (ROS) which, in turn, will kill the cells. PDT photosensitizers are fluorescent dyes that exhibit no toxicity in the dark but upon excitation with a certain wavelength of light create cytotoxic ROS that lead to cell death by either apoptosis or necrosis, depending on the light power. To a star shaped Poly-Ethylene-Glycol with 8 amine functional groups on the surface, a photosensitizer, Chlorin e6, and a targeting moiety, Cardiac Targeting Peptide (CTP), are conjugated. The size of the nanoplatfom is properly controlled to be able to pass the cardiac capillary vessels' fenestrations/pores whose size ranges from 6 nm to 25 nm. This photosensitizing nanoplatfom has shown great selectivity toward cardiac myocytes, over other cardiac cells, and specific ablation of targeted cardiac myocytes is observed both in vitro and in vivo. In summary, a highly cell specific PDT assisted by nanoplatfom can be an alternative novel therapy for cardiac arrhythmia.

Abstract Text

Multi-layer polymer materials are highly engineered materials that are utilized in a wide variety of different industries and confirming the quality and composition of these materials as well as troubleshooting any structural failures is important to the manufacturers of the materials as well as the industries that use them. Both FTIR and Raman spectroscopy provide information on molecular structure and chemical environment. Both can be used for microscopic analysis of the thin layers associated with these polymer composites materials. However there are certain advantages unique to each of these spectroscopic methods.

FTIR provides excellent information on functional groups and polar constituents. Many functional groups found in polymers such as esters, hydroxyls, and amides produce very strong and diagnostic peaks in the FTIR. Raman spectroscopy is very sensitive to small changes in molecular structure and chemical environment and can give access to molecular backbone information that is less readily apparent in the FTIR spectra.

This presentation will compare and contrast these various micro-spectroscopic techniques for the analysis of layered polymer materials. This will include FTIR mapping and imaging examples using transmission, reflection, and ATR methods as well as Raman mapping and imaging examples including confocal depth profiling. The advantages and challenges of each of these methods will be highlighted and discussed.

Abstract Text

Here we present a simple and fast optical transmission microscopy study on the wetting transitions on hierarchical polymer surfaces immersed in water. We analyze the influence of immersion time and the liquid pressure on wetting states of individual micro-cavities on these surfaces, as well as the lifespan of their superhydrophobicity. We show that transitions between the three wetting states (Cassie, Cassie-impregnating, and Wenzel) occur at a certain pressure threshold. Below this threshold, the transitions between the Cassie and the Cassie-impregnating states are reversible, while above the threshold, irreversible transitions to the Wenzel state start to occur. The transitions between the different wetting states can be explained by taking into account both the Young-Laplace equation for the water menisci in the cavities and the diffusion of dissolved gas molecules in the water. In addition, the wetting transitions had a stochastic nature, which may result from the diffusion of dissolved gas molecules in the water between neighboring cavities. Further, we compared the contact angle properties of two polymeric materials (COC and PP) with moderate hydrophobicity. We attributed the different water repellent properties of the two materials to a difference in the wetting of their nanostructures. The experimental observations indicate that both the diffusion of gas molecules in water, and the geometry of nanostructures influence the sustainability of superhydrophobicity of surfaces under water, understanding these factors can help improve the structural design of superhydrophobic surfaces.

Abstract Text

Recently carbon nanotubes (CNTs) have been widely explored as materials for flexible, transparent, and conductive coatings for applications in optoelectronics. The advances of printing techniques have enabled the production of CNT electronics on flexible substrates or large-surface-area substrates. However, characterizing the printed CNT electronics is still challenging, especially for evaluating the print resolution, film homogeneity, and film thickness. Scanning electron microscopy (SEM) and atomic force microscopy (AFM) have been used to measure CNT film surface roughness and film thickness, but only a small number of samples can be analyzed, and the sample preparation and analysis are complex, which make these tests suitable only for laboratory studies.

Brewer Science has been working on printing and characterizing CNT electronic devices for applications including transducers, conductive traces, and high-speed device sensors. In this work, a simple and novel optical method has been developed for characterizing printed CNT electronics. The film homogeneity, surface roughness, and thickness of CNT electronics on different substrates were analyzed by using optical microscopy and profilometry. Two-dimensional (2-D) images of CNT electronics were captured by the optical microscope, and the average thicknesses of the CNT films were measured with the profilometer. By correlating the gray-scale or pseudo-color-scale distribution of the 2-D images with the thickness measurement results, the film thickness distribution and relative surface roughness can be obtained. This method provides a simple way for large-quantity sample analysis for printed CNT electronics within a short period of time. Moreover, it does not involve any complex sample preparation and thus can be used for analyzing large-surface samples. The detailed results and conclusions will be presented at the conference.

Abstract Text

We describe a method to detect through tissue the chemically-induced changes in viscosity and de-gelation process of alginate gels using magnetically modulated optical nanoprobes (MagMOONs). The MagMOONs are fluorescent magnetic microspheres coated with a thin layer of opaque metal on one hemisphere. The metal layer prevents excitation and emission light from passing through one side of the MagMOONs, which creates orientation-dependent fluorescence intensity. The magnetic particles also align in an external magnetic field and give blinking signals when they rotate to follow an external modulated magnetic field. The blinking signals from these MagMOONs are distinguished from background autofluorescence and can be tracked on a single particle level in the absence of tissue, or for an ensemble average of particles blinking through tissue. This approach can potentially be employed in drug delivery systems based on enzyme-catalyzed breakdown of gel components.

Abstract Text

A component to understanding biological processes involves identifying the proteins expressed in cells as well as their modifications and the dynamics of processes. The technology to sequence proteins underwent significant disruption with the sequencing of genomes. Mass spectrometry has benefited from large-scale genome sequencing of organisms resulting in new methods for rapid and large-scale quantitative analysis of proteins. We've been developing mass spectrometry based methods for large-scale analysis of proteins in cells and recent developments will be discussed. Extrapolation of these analytical technologies to more complicated systems has allowed studies of brain function and disease. Application of these methods to the study of a depression model in rats will be described.

Abstract Text

Quantitative proteomics has made critical contributions to the determination of protein complex content and protein interaction networks. With the widespread use of quantitative proteomics, however, deeper insights into protein complexes can be obtained. Now, the tools exist to thoroughly analyze the dynamics of protein complexes when subjected to some form of manipulation. We have explored the use of deletion network analysis to determine the modularity of protein complexes and to accelerate the determination of uncharacterized protein function. To begin, little is known about how proteins interact and are organized within complexes. We developed a technique that combines biochemistry approaches, label-free quantitative proteomics and computational methods using wild-type and deletion strains to investigate the organization of interacting proteins within protein complexes. We have applied this approach to chromatin remodeling complexes and we find that we are able to experimentally determine modules within complexes. We continue to expand on these studies where we seek to determine the modularity in the entire yeast chromatin remodeling protein interaction network and we seek to define, analyze, and manipulate novel human protein complexes and protein interaction networks.

Abstract Text

Proteomics technology has advanced at a breathtaking rate since the development of soft-ionization techniques for mass spectrometry-based molecular identification over two decades ago. Now, the large-scale analysis of proteins (proteomics) is a mainstay in nearly all aspects of biological research including clinical research, where there is a high premium placed on molecular diagnostics and personalized medicine. While peptide-based proteomic strategies (bottom-up proteomics) were developed and optimized early and represent the gold-standard at present, we are now beginning to understand the limitations to bottom-up technology, namely the inability to characterize and quantify intact protein molecules from a complex mixture of digested peptides. To overcome these limitations, numerous labs have taken a whole protein-based approach to proteome research where intact protein molecules are the subject of analysis and full characterization and quantification can be facilitated. A discussion of these 'top-down' techniques and how they have been, and will likely be, applied to biological research of clinical relevance is the topic of this talk. With the unprecedented precision offered by mass spectrometry-based proteomics, both peptide- and whole protein-based strategies are poised to be used as complementary techniques to characterize complex disease phenotypes in the 21st century.

Abstract Text

The use of quantitative proteomic approaches within studies of virus-host interactions during infection provides a powerful mean for defining cellular defense mechanisms and for discovering new targets of antiviral therapeutics. By integrating quantitative mass spectrometry with molecular virology, microscopy, immunoaffinity capture, and bioinformatics, we characterized human proteins that regulate immune responses following viral infection.

In mammalian cells, the first line of defense against viruses involves sensing of pathogenic nucleic acids, such as viral DNA. The recognition of viral DNA is accomplished by specialized proteins, called sensors, which can bind to viral DNA and trigger intrinsic and innate immune responses. The human interferon-inducible PYHIN proteins (AIM2, IFI16, IFIX, and MND1) have emerged in recent years as critical regulators of immune response. We have characterized the antiviral functions of IFI16, the first host factor shown to detect viral DNA in nuclei of infected cells. As viruses have acquired effective mechanisms for blocking host immune signaling, we went on to define the virus-host interactions aimed at blocking IFI16 defense functions during infection with several herpesviruses. Furthermore, we constructed the interaction network for all PYHIN proteins, and this presentation will cover strategies for quantifying protein interactions, building functional interaction networks, and determining the roles of posttranslational modifications during infection. Based on the association of PYHIN proteins with other antiviral factors, we go on to characterize another previously unrecognized DNA sensor important for mounting immune responses to herpesvirus infection. Our studies underscore the value of integrative proteomics in deducing protein function based on interaction networks, as well as characterizing important immune functions mediated by human PYHIN proteins.

Abstract Text

Analyzing the metabolome is made difficult by the extreme complexity of samples, disparate polarities of metabolites, and large range of analyte concentrations. Sample preparation must also be considered carefully because metabolite concentrations can change rapidly. LC-MS has proven to be a valuable tool for metabolomic analysis. Polar metabolites can be challenging to determine because sensitivity and reproducibility of HILIC may not be sufficiently high, but retention on reversed phase columns is too low. For polar metabolites, we have investigated derivatization using benzoyl chloride and aniline. Benzoyl chloride labels amines and phenols and aniline labels carbonyls and phosphates. These reagents enhance retention and sensitivity substantially for reversed phase LC. Further, because ¹³C-labeled forms are available, stable isotope internal standards can be made for every analyte. Because of the broad reactivity of these reagents, they cover a large fraction of the polar metabolome. Using this approach has proven especially valuable for metabolite profiling where specific pathways are targeted. For example, an assay that monitors over 70 neurochemicals has been developed. This assay has been coupled with microdialysis to monitor in vivo neurochemical changes during behavior of different phenotypes of rats. This and other assays based on the technology has also proven useful for characterizing pathways in insulin secreting cells, plasma, and fruit flies.

Abstract Text

This presentation will cover work in three areas in which the author has been mainly involved. They are mid-FT-IR (and Raman), Near-IR (NIR), and Thermal Analysis. The mid-FT-IR applications will include trace level moisture determination in electronic gases, determination of sulfur oxide species in white liquor, and identification of ethylene core shell surrounding propylene spherical particles and determination of its thickness. The on-line mid-FT-IR, developed by using a system from Remspec, will discuss its use as a process R&D tool. The NIR projects, carried out in quality control and in process control, will demonstrate the unique benefits of NIR: minimal sample preparation, simultaneous determination of multiple components, no need for solvents and subsequent waste disposal, safer operations, time and cost savings, and automatic process control. Work on biomolecules carried out as a Humboldt Fellow at the University of Munich and the Max Planck Institute will be discussed next. It will conclude with thermo-gravimetric analysis (TGA) work carried out in collaboration with several co-op students by developing the finger print concept from FT-IR and fractional distillation from physical chemistry. The above topics will be gratefully interspersed with names of colleagues, mentors, and friends with whom the author has had the privilege of working.

Abstract Text

Raman spectroscopy is a nondestructive technique capable of providing information at the molecular level. In the present work we have investigated the cellular regions in neuroblastoma and ganglioneuroma using Raman spectroscopy, and compared their spectral characteristics with those of the corresponding normal adrenal gland. Raman spectra of frozen and paraffin preserved tissues were recorded and analyzed in conjunction with the pathological examination of the tissues. The spectral analyses of the data shows that the normal adrenal gland tissues have higher levels of carotenoids, lipids, and cholesterol compared to the neuroblastoma and ganglioneuroma frozen tissues. A comparison of Raman spectra of paraffin preserved and frozen tissues reveals that preserving the tissues in paraffin alters the molecular composition of the tissues, and in particular, entirely removes carotenoids, lipids, and cholesterol in the adrenal tissues. The Raman spectroscopic data has been quantitatively analyzed using chemometric methods of principal component analysis and discriminant function analysis, and the analyses show that Raman spectra can clearly classify the tissues into their pathological groups with high sensitivity and specificity.

Abstract Title **The Myth and Obstacle of Adhesive Bonding for Automotive Steel Body Panel Applications - From a Steel Researcher Perspective**

Primary Author Chann Cheng
ArcelorMittal USA

Date: Wednesday, March 11, 2015 - After

Time: 03:40 PM

Room: 244

Co-Author(s)

Abstract Text

Laboratory data show that adhesive bonding (particularly along with spot welding) is an effective and inexpensive way for light-weight-vehicle designs. However, since the early '90s, the general consensus among automakers, steelmakers, and adhesive suppliers is that bonding Zn-Fe hot-dip coated (Galvannealed) sheet steels using adhesives is catastrophic and infeasible. In 2007, a collaborative joint project between Dow Automotive and ArcelorMittal R&D was initiated to address the feasibility of using adhesive bonding on galvannealed steel panels for automotive body applications. The common unfavorable conception of adhesive bonding on galvannealed steel is identified as resulting mainly from erroneous judgment in galvannealed steel grade selection. Most previous adhesive bonding data were based upon results using Galvannealed Interstitial Free (GAIF) steel, which is primarily used for exposed car body applications, not for structural applications. The clean steel grain boundary of IF steel makes it highly formable but also highly susceptible to liquid Zn penetration/embrittlement that leads to weak steel/coating interface. On the contrary, Advanced High Strength Steels (AHSS) that are used primarily for structural applications display satisfactory adhesive bonding results due to consistently stronger interface strength. In this presentation, positive results from a series of adhesive bonding tests on different grades of GA AHSS will be presented along with residual stress measurements by X-ray diffraction to reveal the degree of liquid Zn penetration in the steel grain boundary.

Abstract Text

Rheology is the study of the flow and deformation of matter. In flow testing, one measures the viscous properties of a fluid material; in deformation testing, one obtains knowledge of a solid-like material's strength and elasticity. In actuality, the most common usage of commercial rheometers is to determine a material's viscoelastic properties since most materials fall within the extremes of being completely fluid-like and completely solid. The most common instrument for performing rheological measurements is the rotational rheometer. Part of the talk will contain rheology basics as they pertain to rotational rheometry. The development of the rotational rheometer from a historical perspective will also be discussed. One of the key classes of tests performed with the rheometer is dynamic oscillatory testing. This is the best way of measuring a material's viscoelasticity. Different dynamic methods will be discussed, and examples will be shown how rheological testing has resolved real-life applications issues. Some novel methods that are gaining popularity, such as Large Amplitude Oscillatory Strain, will be included.

Abstract Text

The overall goal of this USDA-ARS research is to promote and retain access of United States-grown crops to domestic and foreign markets through compliance with maximum residue level (MRL) regulations. General research includes: objective 1) the development and validation of methods for residue analysis (i.e., How do we detect the residues? – as related having confidence in any MRL), objective 2) the characterization of residues across a commodity, use patterns, and geography (i.e., How do the residues levels vary? – as related to an appropriate “ceiling” for an MRL), objective 3) tracing the formation and elimination of residues through production and marketing channels (i.e., How long do the residues last? – as related to specific contributions to the MRL), and objective 4) acquiring residue data from field trials following the application of a registered agrochemical (i.e., What is the expected maximum residue level? – as related to establishing an MRL tolerance in EU). Recent research findings will be presented and discussed.

Abstract Text

The movement of cargo in international trade has resulted in introduction of numerous exotic insect pests and pathogens into the USA. Collectively, these organisms cause billions of dollars annually in crop losses, damage to natural resources, control measures and eradication programs. Early detection is essential in preventing introductions and facilitating eradication efforts when introductions occur. Currently, USDA Animal and Plant Health Inspection Service and DHS Customs and Border Protection rely primarily on visual inspection to detect exotic pests. These measures are expensive and often fail to find pests associated with commodities and packing material. Advances in chemical detection capability have improved the ability to detect pests based on their unique chemical signatures. We report on the development of a versatile sensing platform using chemosensitive colorants for detecting characteristic volatile compounds associated with several insect pests of quarantine significance in the USA. This sensing platform may enable the detection and identification of infestations based on VOC signatures within a closed shipping container during transit. This would allow infested containers to be identified and rejected prior to arrival, thereby mitigating exposure or release of quarantine insects. These devices can thus protect the shipments themselves, as well as agricultural commodities and natural resources in the USA.

Abstract Text

As the trade of foodstuffs increases across the globe, preserving and protecting our commodities from pests is ever important. Postharvest fumigation is a valuable tool for achieving pest-free security and must be monitored to ensure its success. For example, measurement of the amount of fumigant that remains in the chamber over the course of fumigation is critical. Gas chromatography (GC) is frequently relied upon by regulators to verify the concentration of fumigant during phytosanitary treatment subject to international approval. Unfortunately, gas chromatographs must be outfitted with detectors respective to the fumigant. Therefore, many detectors are required in a laboratory to conduct the requisite analyses. Moreover, the operation of each GC detector typically requires the use of at least three different gases Helium (He), Nitrogen (N₂), Oxygen (O₂), and/or Hydrogen (H₂). The Shimadzu Tracera GC outfitted with a barrier discharge ionization detector (BID) overcomes this need for multiple detectors as well as the need for multiple operational gases. The BID, which operates with He only, is capable of detecting nearly every contemporary fumigant, including: methyl bromide (MeBr), phosphine (PH₃), propylene oxide (PPO), sulfuryl fluoride (SF), and ethyl formate (EF). In addition, physiologically-active gases can be detected via BID such as carbon dioxide (CO₂), carbon monoxide (CO), and Oxygen (O). This allows us to monitor critical aspects of a postharvest fumigation treatment to identify whether or not physiologically-active gases are influencing the efficacy of treatment. We compared the limits of quantification (LoQs) for commonly used GC detectors, including, flame ionization detector (FID), pulse flame photometric detector (PFPD), and BID respective to Mebr, PH₃, PPO, SF, and EF fumigants.

Abstract Text

California industry recently learned of residue reports, from several officially recognized analytical laboratories within the European Union (EU), which indicate certain loads of tree nuts from California were not compliant with maximum residue level (MRL) tolerances set by the EU for the fungicide, fosetyl-aluminum. A review of pesticide use data collected by California Department of Pesticide Regulation (CDPR) does not support a contribution of fosetyl-aluminum to the MRL exceedance. The residue reports from the EU corroborate the usage data from the CDPR report, as all exceedances were attributed only to the detection of phosphorous, the degradation product of fosetyl-aluminum, with no concomitant detection of fosetyl-aluminum itself. Analyses conducted by DFA of California, in cooperation with USDA/ARS, failed to detect any fosetyl-aluminum in tree nuts, but did detect phosphorous acid. These tests also uncovered issues with the EU methods of analysis, indicating that residues of phosphoric acid could be mistaken for phosphorous acid. We report the development of LC-MS methodology that yields unequivocal resolution of phosphorous and phosphoric acid in tree nut samples.

Abstract Text

Increasing import/export of foodstuffs in the international agricultural marketplace has led to increasing demand for fumigation treatments to insure that a given commodity is free of invasive species and diseases. With any new treatment, however, comes the need to quantitatively determine the residue of the fumigant remaining in the treated commodity. Fumigant residues are a potential trade barrier if the residue is in excess of what the receiving country has deemed permissible, a tolerance known as the maximum residue limit (MRL). Since fumigants generally range from highly volatile compounds, such as propylene oxide (PPO), to permanent gasses, such as methyl bromide (MB); residue levels are commonly determined by blending the commodity in the presence of solvent, letting the fumigant reach equilibrium between the solid, liquid, and gas phases and measuring the fumigant's headspace concentration. These methods are effective, but are also time-consuming, wasteful, and require carefully controlled extraction conditions. We present alternate methods for the determination of PPO and MB residues in multiple commodities using a headspace trap autosampler (Perkin Elmer, Turbomatrix) or solid phase microextraction (SPME). Using the Turbomatrix allows for the detection of PPO, as well as its toxic degradation products propylene chloro/bromo hydrin, at levels ~3 orders of magnitude lower than those observed with liquid extractions (60ng/g vs. 30µg/g). Analysis of MB residues using either the Turbomatrix or SPME sampling allows for sub-ppm levels of detection with a quick one-step, solvent-free preparation method, rather than extraction with a buffered solution, followed by several hours of equilibration.

Abstract Text

High-resolution Nuclear Magnetic Resonance spectroscopy (NMR) has been used in qualitative and quantitative for 60 years. Nowadays, this analyses uses expensive spectrometers based on high field superconducting magnets. Another class of NMR spectrometers based on cheap permanent magnets, known as time-domain NMR (TD-NMR) has been successfully used as a laboratory technique for quality control (QC) and quality assurance (QA) for more than 40 years. Nowadays, TD-NMR is an off-the-shelf NMR solution that is recognized as a standard international method for several agencies. Despite its recognized success in the laboratory application, it has not been widely used in non-invasive analysis of agrifood products in packing houses or factory floors. The major limitation has been the dimension of magnet/probe, to fit high volumes samples (~1L). The recent developments of TD-NMR industrial sensors, based on yokeless 0.23 T Halbach permanent magnet for 1 L sample, for atline and inline analyses of fresh fruits, meat and industrialized food products, direct in the packages, will be presented.

Abstract Text

Brazil has the largest market for pesticides in the world, and has the greatest potential for expansion. To avoid the risks of pollution the fountains, soil and damage to human health, 94% of the total number of primary plastic containers for agrochemical products sold in the country are disposed after being returned by farmers at more than 400 receiving units. Through this initiative, Brazil is a world reference in the correct final disposal of packaging phytosanitary measures, ahead of countries like Germany, France, Japan and United States. Only plastic containers rinsed after use can be recycled, this procedure removes more than 99.9% of the active ingredients, turning the packaging of pesticide, once considered special waste in common wastes. To ensure that the packages were washed according to the right procedures and that is not occurring contamination of soil and groundwater in units of receipt there is a residue monitoring program. In the laboratory, the plastic packaging are washed inside with deionized water. Water rinse residues has extracted by liquid/liquid partition or SPE and quantified by GC /MS, or injected directly in the LC/MS/MS. The concentration of pesticides must be less than 100 mg/L. For soil and groundwater the residues are extracted by ultrasonic and liquid/liquid partition, respectively, and quantification performed by GC/MS and LC/MS/MS.

Abstract Text

A few decades ago there were practically no pesticide residue analysis in Brazil. The main reasons were the lack of appropriate official food, health and agricultural surveillance legislation and qualified technical people. Nowadays, it is quite different: there are several laboratories with qualified staff and good facilities to perform pesticide analysis at international standards.

In the last fifteen years the Institute of Technology of Pernambuco (ITEP) has been supporting the fruit production through the analysis of pesticides residues. It is an Institute with the mission of providing technological support to Brazilian Agribusiness and Food Safety. The LabTox/ITEP is accredited under ISO/ IEC 17025 by the Brazilian accreditation board, INMETRO, a member of the International Laboratory Accreditation Cooperation (ILAC) and signatory to the International on Mutual Recognition Agreement.

With an adequate infrastructure detecting more than 500 compounds by mass spectrometry techniques (LC-MS/MS and GC-MS/MS) besides well trained MSc and PhD staff, LabTox / ITEP has an innovative and competitive role to support the food safety and fruit quality export programs.

In order to expand its action, LabTox/ITEP introduced a monitoring and inspection fruit program overseas; this program started in 2010 and performs as if it is the outside "eye" of the producer. It is an important tool for production, packing and shipping improvements.

Despite the late start and typical difficulties intrinsic of developing countries, Brazilian pesticide analysis laboratories are now proficient to support the agribusiness and, most important, protect the health and the environment.

Abstract Text

Strong coupling between the cell membrane and the recording electrodes is crucial for sensitive measurement of cellular electrical activities. We are interested in exploring nanotechnology and novel materials to improve the membrane-electrode coupling efficiency. The first approach involves developing vertical nanopillar electrode made of noble metals¹. The nanopillar electrodes deform plasma membrane inwards and induce negative curvature when the cell engulfs them, leading to a reduction of the membrane-electrode gap distance and a higher sealing resistance. The 3D topology of the nanopillar electrodes is crucial for its enhanced signal detection. The second approach explores a nanoelectrode of a new topology, namely nanotubes with hollow centers². The nanotube geometry further enhances membrane-electrode coupling efficiency and records larger intracellular potentials than nanopillar electrodes. The nanotube topology also significantly increases the time duration of intracellular access. Interestingly, the presence of high membrane curvature induced by vertical nanostructures, affects protein distributions and induces accumulation of certain proteins around them. Those results show a strong interplay between biological cells and nanosized electrode, which is an essential consideration for future development of interfacing devices.

Abstract Text

Insects have been extensively used as a model organism in genetics research and has significantly contributed to understanding molecular, cellular and evolutionary aspects of human behavior. However, chemical measurements of these mass-limited samples are still challenging. Research has focused on developing methods to obtain highly sensitive chemical quantification along with spatiotemporal information. The goal of chemical analysis is to relate neurochemical changes to either genetic mutations or to treatments that alter the state of the organism. Here, we develop methodology to rapidly quantify neurotransmitter and metabolite molecules. Chemical derivitization of biological molecules coupled with mass spectrometric detection will be used to measure neurotransmitter concentrations. The methods presented are broadly applicable and can be used with a wide range of analytes. Additionally, this scheme simplifies detection and makes rapid relative quantification possible, allowing comprehensive and rapid analysis of neurotransmitters. This enables the analysis of attomole amounts of neurotransmitters and metabolites. We investigated changes at individual cultured neurons from drosophila.

Abstract Text

Drosophila melanogaster or fruit fly has been a popular model in biological research and the study of human disease. The ease of genetic manipulation, a completely sequenced genome and a high degree of homology with the human genome are key factors in the continued popularity of the fly as a model system. The small size of the fly complicates its use as a model as the volumes available for analysis range from a couple hundred to tens of nanoliters from larval and adult flies. Method are described in this presentation to collect fly hemolymph or blood from individual flies for analysis. The determination of the chemical content of individual fly hemolymph requires the use of small volume compatible methods such as capillary electrophoresis (CE). CE has been used to quantify amino acid content in both larval and adult flies and has been performed to characterize the population distribution of various constituent amino acids. In these studies it is also possible to sample twice from an adult fly to study the effects of an experimental perturbation to an individual subject. Also, assay methods were improved to characterize thiol-containing amino acids and peptides in a study of oxidative stress with individual flies. This assay in conjunction with earlier amino acid analysis provided a means to explore the physiological effects of a transporter that affects basal glutamate levels in the fly. The characterization of the proteome of fly hemolymph has also been demonstrated with these exceedingly low volume samples. Proteins, predicted by genome or only observed at the transcription level, are reported using bottom-up proteomics. Novel fractionation methods were developed to aid in this characterization of hemolymph. New methods for separating hemocyte content from hemolymph allow the determination of amino acids solely from hemolymph plasma. The impact of the method of hemolymph collection including any anesthesia on observed amino acid content will be discussed. The methods of hemolymph analysis provide a look into this exceedingly small but important model for to understand behavior and disease.

Abstract Text

Drosophila melanogaster is a powerful model organism due to its simple maintenance, short life cycle, and impressive array of genetic tools. Our lab has pioneered using *Drosophila* optogenetics to evoke monoamine neurotransmitter release in combination with real time detection by fast-scan cyclic voltammetry. Channelrhodopsin-2, a blue light-activated cation channel, is expressed in neuronal subpopulations using the Gal4/UAS genetic system. Recent studies with pulsed stimulations have shown that serotonin and dopamine release are steady state at low frequencies and peak shaped at high frequencies. Uptake inhibition with fluoxetine removes the frequency dependence of release, proving uptake serves to regulate these extracellular concentrations. Recently, we have also used a new red-light activated channel, CsChrimson, for optogenetic control of larval neurons in discrete brain regions. Using CsChrimson, the kinetics of dopamine uptake and release are compared in the larval ventral nerve cord (VNC) and the protocerebrum. V_{max} and K_m are both an order of magnitude smaller in the protocerebrum than the VNC. Finally, we have used an ATP activated channel, P2X2, to examine the regulation of releasable pools of dopamine, which are regulated by both uptake and release. Unlike mammals, *Drosophila* do not have an additional storage pool that can be activated by cocaine. By using these new methods of neurotransmitter release to investigate the fundamental regulation of amine neurotransmission in the fly brain, we will gain a more thorough understanding of the role of monoamines in behavior and pathology.

Abstract Text

We have used in vivo voltammetry in the fruit fly, *Drosophila melanogaster*, to examine the competitive effects of methylphenidate on the actions of cocaine. Oral consumption of methyl-phenidate sufficiently blocks the *Drosophila* dopamine transporter and the blockage is concentration dependent. For untreated flies the rate of clearance changes 40% when the dopamine transporter is blocked with cocaine, for treated flies the number is 110%. In collaboration with David Krantz at UCLA, we have also taken the challenge to electrochemically measure neurotransmitter release from the smallest varicosities of a nerve cell. The nerve terminals found in the body wall of *Drosophila* larvae are readily accessible to experimental manipulation. We report the development of amperometry to measure release of the neurotransmitter octopamine from individual varicosities in the *Drosophila* larval system. Octopamine release was measured in the type II varicosities of *Drosophila* larvae. When octopamine is released from the varicosities during stimulation, it is immediately oxidized at a carbon fiber electrode and a current spike results. This provides an exciting new analytical method to study release at subcellular regions along neurons. Finally, we use mass spectrometry, both as a detector and for imaging, to determine the doses of methylphenidate when administered and to image this in the fly brain. We have discovered via imaging that many of the basic phospholipid species in the brain also vary, and spatially, in the brain following administration of the drug.

Abstract Text

For the last eight years, we have been using bioinformatics and MS based approaches to characterize HIV-1 vaccine candidates containing the surface envelope glycoprotein, Env. This protein is extensively glycosylated: It contains up to 30 different N-linked glycosylation sites and at least two potential O-linked sites. We have focused on characterizing the glycans at each of these sites using glycopeptide analysis strategies. By profiling a variety of different forms of the protein, we have answered several questions of high importance to vaccine developers, including: What is the glycan profile of the most native form of Env, that of a trimeric protein isolated from a membrane surface? Is there a unique glycosylation profile that is observed on more effective vaccine candidates? This presentation will highlight some of our most recent work in answering these questions, and we will use our Env analyses as an example of how mass spectrometry is a critical component in decoding the biological roles of glycans.

Abstract Text

The developments of analytical methods for proteins have produced highly effective tools for identification that are sensitive and comprehensive. The vast majority of proteins are post-translationally modified, however proteomics methods have not advanced as rapidly in this area. The most complicated post-translational modification is also one of the most common. Glycans are composed of up to 20 monosaccharide units as glyconjugates in proteins and lipids. Glycosylation is a modification where the structures are more complicated than that of the proteins. While sequences define the polypeptides, glycans are complicated by having many linkages, branching, and stereomeric residues. Understanding the roles of glycans depends on the ability to identify and quantitate hundreds of structures simultaneously. Research in our laboratory has focused on the rapid methods for the analysis of protein and lipid glycosylation while employing mass spectrometry and advanced liquid chromatography. These methods are employed in determining biomarkers for diseases including cancer and autoimmunity. They are also used for monitoring health by determining the biologically active components in mammalian milk.

Abstract Text

The influenza A virus (IAV) which is the primary causative agent for flu epidemics initiates infection by binding to airway epithelia through a coat surface glycoprotein called Hemagglutinin (HA). HA displays N-glycosylation at between 5 and 12 sites, depending on strain, which change rapidly to maintain infectivity and survive selection pressures from exposure to the host immune system. Limited knowledge on these viral coat protein glycosylation sites and glycosylation patterns is available, based mostly on the information about N-glycosylation sequons (NxS/T) from genetic databases.

A multidimensional analysis workflow, yielding complementary information on the glycoproteins, was used to produce results with an acceptable confidence level. Recombinant HA1 samples from commercial sources were subjected to bottom-up LC-MS analysis. Proteolytic glycopeptides were analyzed using reversed-phase LC-MS/MS coupled with online HILIC (Hydrophilic interaction liquid chromatography) enrichment to get site-specific glycosylation information. Peptides deglycosylated in the presence of H218O were subjected to a standard proteomics analysis combined with database searching to reveal the glycosylation sites. Released N-glycans were subjected to negative mode glycomics analysis using HILIC LC-MS.

Correlating the patterns of glycosylation on HA from IAV strains with the known virulence and zoonotic potentials will help understand mechanisms of viral evolution and role of glycosylation in viral fitness. The fact that HA variants contain up to 12 N-glycosylation sequons means that the number of possible glycosylation variants is enormous. As a result, confident quantification of glycopeptides requires high quality tandem mass spectra of both intact glycoproteins and deglycosylated forms. Our workflow takes advantage of overlapping information from complementary analyses to generate high confidence results.

Abstract Text

Defining clinically relevant biomarkers for early-stage hepatocellular carcinoma (HCC) in a high-risk population of cirrhotic patients has potentially far-reaching implications for disease management and patient health. Changes in glycan levels have been associated with the onset of numerous diseases including cancer. In the present study, we used liquid chromatography coupled with electrospray ionization mass spectrometry (LC-ESI-MS) to analyze N-glycans in sera from 183 participants recruited in Egypt and the US, and identified candidate biomarkers that distinguish HCC cases from cirrhotic controls. N-glycans were released from serum proteins and permethylated prior to the LC-ESI-MS analysis. Through two complementary LC-ESI-MS quantitation approaches, global profiling and targeted quantitation, we identified 11 N-glycans with statistically significant differences between HCC cases and cirrhotic controls. These glycans can further be categorized into four structurally-related clusters, matching closely with the implications of important glycosyltransferases in cancer progression and metastasis. The results of this study illustrate the power of the integrative approach combining complementary LC-ESI-MS based quantitation approaches, to investigate changes in N-glycan levels between HCC cases and patients with liver cirrhosis.

Abstract Text

Protein glycosylation is an important and common posttranslational modification (PTM). More than 50% of human proteins are believed to be glycosylated to modulate the functionality of proteins. Aberrant glycosylation has been correlated to several diseases, such as inflammatory skin diseases, diabetes mellitus, cardiovascular disorders, rheumatoid arthritis, Alzheimer's and prion diseases, and cancer. Many approved cancer biomarkers are glycoproteins that are not highly abundant proteins. Therefore, effective qualitative and quantitative assessment of glycoproteins entails enrichment methods. This presentation describes and discusses the use of different glycoprotein enrichment methods, including lectin affinity, hydrazide chemistry, and hydrophilic interaction chromatography. The use of these enrichment methods in assessing the qualitative and quantitative changes of glycoproteins in different diseases will be presented and discussed. The importance of glycoprotein enrichment techniques for the identification and characterization of new-reliable cancer biomarkers will be highlighted in this presentation. The use of these enrichment methods to assess the glycosylation of specific glycoproteins that play important biological functions, such as HIV gp 120, collagen and prostate specific antigen, will be described and discussed.

Abstract Text

The enumeration and characterization of circulating tumor cells (CTCs) in the peripheral blood may provide important prognostic information and might help to monitor efficacy of therapy: a real-time liquid biopsy. Since current assays cannot distinguish between apoptotic and viable CTCs, it is now possible to apply a novel ELISPOT assay (designated 'EPISPOT') that detects proteins secreted/released/shed from single epithelial cancer cells. Cells are cultured for a short time on a membrane coated with antibodies that capture the secreted/released/shed proteins that are subsequently detected by secondary antibodies labeled with fluorochromes. In prostate cancer patients (n=48), we used prostate-specific antigen (PSA) secretion as marker to detect PSA-secreting cells and observed that 83% and 42% of M1 & M0 cancer patients, respectively, had CTCs with a difference in the CTC median (29 for M1 & 9 for M0) and found that a significant fraction of CTCs also secreted fibroblast growth factor-2 (FGF-2), a known stem cell growth factor. More recently, in colon cancer, a considerable portion of viable CTCs detectable by the Epispot assay is trapped in the liver as the first filter organ in colon cancer patients. The enumeration of CK19-RC by the CK19-Epispot assay in 75 colorectal cancer patients revealed viable CTCs in 65.9% and 55.4% (p=0.04) patients in mesenteric and peripheral blood, respectively, whereas CellSearch detected CTCs in 55.9% and 29.0% (p=0.0046) patients. In mesenteric blood, the number of CTC was significantly higher than in the peripheral blood. Our clinical data showed that localized colon cancer patients with a high level of CTCs have an unfavorable outcome (n=60). In conclusion, the EPISPOT assay offers a new opportunity to detect and characterize viable CTCs in cancer patients and it can be extended to a multi-parameter analysis revealing a CTC protein fingerprint.

Abstract Text

Circulating tumor cells (CTC) in the peripheral blood are potential biomarkers for cancer diagnosis and prognosis. However, CTC are extremely rare in the bloodstream, typically a few CTC in billions of normal blood cells, making their detection very challenging. To address this, we have developed a couple of multivalent binding schemes with microfluidic devices that are able to efficiently isolate cancer cells. One scheme is to create an optimized ensemble of aptamers and antibodies that function as a multivalent adhesive domain for the capture and isolation of cancer cells [1]. Due to their differences in size, aptamers and antibodies bind to different surface receptors on cells. As a result, their cooperative interactions with tumor cells result in higher cell capture efficiency than with either antibodies or aptamers alone. When incorporated into a microfluidic device, the ensemble showed not only high capture efficiency, but also superior capture selectivity at a high flow rate. The second multivalent binding scheme is to employ gold nanoparticles (AuNPs) as an efficient platform for assembling a number of aptamers, resulting in multivalent binding between a few aptamers with one tumor cell [2]. Up to 95 aptamers are attached onto each AuNP, and an increase of 39-fold in binding affinity with cells is obtained for AuNP-aptamer conjugates when compared with aptamers alone. In a flat channel microfluidic device, the capture efficiency of human acute leukemia cells from a cell mixture has increased from 49% using aptamer alone to 92% using AuNP-aptamer. In addition, we have employed microfluidic devices for detecting CTCs from peripheral blood samples of metastatic pancreatic cancer patients using CTC definition approved by FDA. We tested the potential utility of our devices for monitoring the patients' response to anti-cancer drug treatment, and we found that the CTC numbers correlated with the clinical outcome.

Abstract Text

While metastatic disease causes ~90% of all cancer-related deaths, determining the role of various cancer cells, either from the primary tumor or those in circulation (circulating tumor cells, CTCs), in the metastatic process has been difficult due to the continuum of phenotypes they possess and/or the rare nature of these cells, especially CTCs. To assist in studies based on the use of rare CTCs that may be involved in metastasis, an integrated microfluidic system was designed, fabricated and evaluated. The system consisted of a CTC selection unit, an electrical detector for CTC impedance counting, an imaging unit for phenotyping single cells and a molecular analysis unit for detecting mutations or expression profiling certain genes of the CTCs. The CTC selection unit contained a series of 190 nL fluidic channels the walls of which were decorated with antibodies or aptamers used to recognize and select various sub-populations of CTCs from a single sample. The cell selection unit could process 7.5 mL of whole blood in ~20 min with a selection recovery of 97% and purity >80%. The CTCs could be released from the selection surface and initially counted by measuring impedance signatures of single cells that traversed through a pair of electrodes; CTC viability could be determined simply from the polarity of the impedance signature. The CTCs' mRNA transcripts from certain genes, following impedance enumeration, were expression profiled using digital (single-molecule) counting that provided exquisite analytical sensitivity. The use of the system for determining the molecular characteristics of CTC sub-populations were evaluated for various cancers, including pancreatic cancer. For pancreatic adenocarcinoma, two sub-populations were analyzed; those with a more epithelial phenotype and those with an invasive phenotype with clear differences in their gene expression profiles.

Abstract Text

Given these many therapeutic advances in medical oncology, the need to tailor treatment recommendations to each individual has never been greater. However, this personalization of cancer therapies requires biomarkers that 1) predict therapeutic benefit; 2) identify emerging mechanisms of resistance; and 3) tailor subsequent treatment strategies to continually evolving tumors. Successful development of predictive and pharmacodynamic biomarkers suitable for these purposes requires frequent sampling of tumor cells prior to, and throughout, the course of therapy. Circulating tumor cells (CTCs) are shed into peripheral circulation from primary and metastatic tumor sites and may represent a source of cells suitable for these purposes, without the need for invasive tumor biopsies. There is a need to develop technology with the capability to extract multiple analytes including protein, RNA and DNA, for the same molecular assays performed on tumor biopsies. Here we present, an exclusion based sample preparation CTC capture platform with integrated analysis known as VERSA (Vertical Exclusion-based Rare Sample Analysis) to allow further evaluation of proteins and nucleic acids. We demonstrate VERSA's capabilities within prostate cancer focusing on the analysis of the androgen receptor (AR), which is a known driver of prostate cancer progression. Several AR targeting therapies have been developed and shown to be effective but there is now a critical need to evaluate and target mechanisms of resistance to these therapies. Using the VERSA platform we captured CTCs positive for the epithelial cell adhesion molecule (EpCAM) from castrate-resistance prostate cancer patients and quantified AR nuclear localization, as well as AR splice variant and AR dependent gene expression in CTCs as potential therapeutic biomarkers.

Abstract Text

Circulating tumor cells (CTC) have provided researchers with ample information about metastatic cancer. However, the exact mechanisms of metastasis are not definitively known. Mounting evidence indicates that CTC utilize the same pathway through which immune cells are recruited to sites of inflammation. This pathway involves a variety of adhesion molecules, including those in the selectin family. In this chapter, we discuss how these adhesion molecules, namely E-selectin, can be used to recapitulate the early steps of CTC adhesion in vitro to achieve capture and characterization of CTC from patient blood samples. We also discuss how this interaction may be exploited to target and kill CTC in vivo.

Abstract Text

Laser-induced breakdown spectroscopy (LIBS) has evolved as an important analytical technique for the detection and identification of elemental constituents by virtue of the atomic emission lines that are routinely captured in the visible region of the electromagnetic spectrum. However, certain environmental sensing applications demand higher specificity than can be achieved through the conventional LIBS approach. The transient thermal contrast that results by virtue of laser-deposited energy is known to produce a manifold of thermal infrared emissions containing the spectral fingerprint of the species that are present in the matrix. I hypothesized that similar molecular emissions would evolve when materials at the fringe of the LIBS plasma are thermally desorbed and heated by the plasma while retaining their integrity such that they emit their characteristic mid-infrared spectrum. In recent years we have undertaken empirical investigations of the thermal emission resulting from LIBS events in order to capture and characterize those molecular signatures that present concomitant to the LIBS phenomenon. The value of these recent laser-induced thermal emission (LITE) experiments is that they elucidated the time basis of the thermal emission under laser heating circumstances, revealing a critical time frame on the order of 100 ms during which the transient, non-equilibrium spectral signatures of molecular species are recoverable. I will discuss the origins of the hypothesis leading to these LITE experiments that have demonstrated its validity, and posit the exploitation of this phenomenology for environmental sensing applications.

Abstract Text

Laser induced breakdown spectroscopy in the long wave infrared (LWIR) region can provide information on presence of specific chemical bond associated to certain materiel of interest, since many molecular vibration mode fall in to the LWIR region. Research activities have demonstrated the feasibility of acquiring LWIR spectra representative of the materials. However, the proof of concept setup requires long time and significant about of sample to acquire the spectra. To explore further the potential of LWIR LIBS as an effective detection method, we designed and built LWIR LIBS instrument that integrates excitation laser and mercury cadmium telluride (MCT) linear array with readout IC. The usage of MCT array bounded to readout IC greatly reduced the size of the instrument and acquisition time, from tens of minutes down to a few seconds. The operation of the instrument is fully controlled by computer and microcontroller, whereas allowing user to specify all operation parameters. LWIR spectral of many materials were collected, such as KCl and energetic compound NH₄CLO₄. Acquisition of spectrum excited with single laser pulse was also demonstrated.

Abstract Text

In an effort to augment the atomic emission spectra of conventional laser-induced breakdown spectroscopy (LIBS) and to provide an increase in selectivity, mid-wave to long-wave infrared (IR) LIBS studies were performed on several inorganic and organic chemicals. LIBS signature molecular emissions of target compounds are observed for the first time in the IR fingerprint spectral region between 4-12 μm . The IR emission spectra of select organic and inorganic chemicals closely correlate with their respective standard FTIR spectra. Intact and/or fragment sample molecular species evidently survive the LIBS event. The combination of atomic emission signatures derived from conventional UV-VIS-NIR LIBS with fingerprints of intact molecular entities determined from IR LIBS, promises to be a powerful tool for chemical detection.

Abstract Text

Emissions from the laser-induced breakdown spectroscopy (LIBS) plasma were examined in the region from 750 nm to 2000 nm. A Nd:YAG laser at 532 nm and 75 mJ per pulse was used to initiate the plasma. The detector was an InGaAs 1024 element diode array cooled to -100 C. A f/4 spectrometer with gratings blazed for this region was used as the dispersive element. Survey spectra of soils, uranium, and other selected samples were taken in air and in a flow cell purged with argon at the local pressure of 0.84×10^5 Pa. Strong infrared lines of neutral aluminum, carbon, potassium, silicon, sulfur and uranium, as well as once-ionized lines of calcium were observed out to 1670 nm. Time resolved measurements were performed with uranium samples in air and argon to study the temporal decay of the uranium lines and to search for molecular features. Detection limits of the IR system were compared with those obtained from a standard ICCD-spectrometer arrangement.

Abstract Text

Mid infrared time-resolved emission spectra were recorded from laser induced carbon plasma. These spectra constitute the first extension of carbon materials LIB spectroscopy into the mid infrared range. The carbon plasma was induced using a Q-switched Nd: YAG laser at pulse energy of 50 mJ at 1064 nm. Pulse width was 5 ns, repetition rate 10 Hz. The laser beam was focused to a spot size of 0.2 mm on graphite pellets mounted on a translation stage. Mid infrared emission from the plasma in atmospheric pressure helium gas was detected by a LN₂ cooled HgCdTe (MCT) detector in the range 8-11.6 [micro] using a 7.4 [micro] long-pass filter. The spectrometer was a 0.15 m focal length one with grating blazed at 8 [micro]. LIB spectra were also taken in argon and also in nitrogen. Ten spectra were averaged using a boxcar. The resultant spectra were digitally smoothed. Even though gate delay of 10-20 microsecond and gate-width 16 microsecond were used there were strong backgrounds in the spectra. Part of the background may be due to radiation from hot carbon particulates. This background was empirically reduced using a baseline fit to the spectra. At a time delay of 2 microsecond no emission bands were seen. The thermal radiation due to the spectrometer housing was found negligible. Superimposed on this background broad bands were observed, the form and position of which were dependent on the ambient gas. In argon, for instance, bands were observed around 8.3, 9.5, 10 and 10.6 [micro]. Carbon atomic lines C I may occur in this region, but these have small line strengths whereas a C II line with vacuum wavelength of 10457 nm could be seen in our spectra. Doubly ionized carbon has strong lines between 7900 and 9060 nm but high ionization is not expected under our experimental conditions. The width of the infrared bands is much larger than the spectral resolution of about 80 nm that indicates molecular origin. No linear carbon molecules (from 3 to 10 carbon atoms) have IR active vibrations in this range and the C₂ molecule cannot be detected as it is IR inactive. The infrared bands were thus compared to vibrational features of carbon clusters on the basis of quantum chemical calculations, previous carbon cluster infrared emission spectroscopic analyses in the literature and large carbon molecules observed in infrared astronomy. A plot of the carbon plasma in argon is shown here.

Abstract Text

People with type 1 diabetes (T1D) must administer insulin exogenously due to the destruction of their pancreatic β -cells. Endogenous insulin is stored as a crystalline hexamer in β -cell granules along with C-peptide, a 31 amino acid peptide that is subsequently secreted from these granules in amounts equal to insulin. Exogenous co-administration of C-peptide with insulin has proven to reduce diabetes-associated complications in animals and humans, including complications related to microvascular blood flow and tissue health. Hypotheses for reduction in complications have included activation of eNOS and an increase in nitric oxide (NO) production in various tissues. However, the exact mechanism of C-peptide's beneficial effects after secretion from the β -cell granules is not completely understood, thus hindering its development as an exogenously administered hormone. Here, we show that C-peptide alone does not affect bloodstream cells. Monitoring organ-to-tissue communication using a 3D-printed microfluidic device revealed that zinc and C-peptide are being delivered to erythrocytes by albumin. Upon delivery, erythrocyte-derived ATP increased by >50%, as did endothelium-derived NO, which was measured downstream in the 3D-printed device. Our results suggest that hormone replacement therapy in diabetes may be improved by exogenous administration of a C-peptide ensemble that includes zinc and albumin. We anticipate our results to be a starting point for more sophisticated studies involving C-peptide and insulin replacement therapy for people with T1D.

Abstract Text

The regulation of oxygen levels in the brain is critical for normal function. Measurement of oxygen with microelectrodes provides insight into cerebral blood flow and metabolism, the two processes that are responsible for the supply and consumption of molecular oxygen. Our work has examined the regulation by neurotransmitters of cerebral blood flow, and the consumption of energy by neuronal activity. Additionally, we will demonstrate a microfabricated electrode that can be used to measure cerebral blood flow.

Abstract Text

According to the US Centre for Disease Control in the US each year 1.7 million people suffer a traumatic brain injury (TBI) of whom 52,000 die, 275,000 are hospitalised and 1.3865 million are treated in the emergency room before release. TBI contributes to 31% of all injury related deaths in the US [1]. There is a pressing need to develop more effective clinical strategies for the emergency room and intensive therapy unit stages of clinical care. New analytical devices can be at the forefront of these new strategies [2].

We have developed a new class of clinical instrument that monitors in real-time electrical, physical and chemical information from the injured brain [3]. The system then searches for patterns of changes characteristic of the onset of secondary brain injury. Chemically we monitor changes in metabolism (glucose, lactate and pyruvate) and tissue excitability (potassium) using electrochemical biosensors and ion-selective electrodes respectively placed in a microfluidic manifold controlled by custom build electronics. The system is completed by an automatic calibration system built using a microfluidic circuit board (LabSmith Inc.) The microfluidic device analyses the dialysate stream from a clinical microdialysis probe (M Dialysis) placed near the site of brain injury using a cranial access bolt. The bolt also allow placement of a Clark electrode and temperature LiCOx probe (Integra) to give real-time measure brain oxygenation ($pbtO_2$).

By carefully comparing the relative timing of changes in these chemical signals, we can probe dynamic changes in brain metabolism in response to transient secondary insults to the injured brain (detected by the electrical and physical monitoring of the brain). We are optimistic that such an approach offers the prospects of individualised patient based therapies.

Abstract Text

Technical advances are making it possible to create tissue microenvironments on platforms that are compatible with high-content screening strategies. Recent collaborative work by our group has led to the development of microfabricated devices to enable culture of organized cellular structures which possess much of the complexity and function of intact intestinal tissue. Up to now, functional assays and screens for dietary factors, pathogens and drugs that affect the epithelia of the small and large intestines have been relegated to using traditional cell-culture methods and cancer-derived cell lines; however, these cells do not recapitulate many of the features of primary tissue, thus prohibiting physiologically relevant discovery. Breakthroughs in stem-cell biology now enable single stem cells or intestinal crypts isolated from primary mouse or human intestine to grow and persist indefinitely in defined 3D culture conditions to form organotypic structures generically termed enteroids. These 3D structures contain all of the expected lineages of the intestinal epithelium from which derived. Enteroid culture is conducted in large format culture dishes that render the cultures low-throughput, cost-prohibitive, and unquantifiable for screening. Our microengineered arrays and fluidic devices allow prolonged culture and experimental manipulation of these organotypic cultures. We have recently used organoids to generate millimeter-scale primary intestinal epithelium in vitro that more closely mimics the polarized 3D in vivo microarchitecture. These arrays can be interrogated by any of a variety of techniques including fluorescence, immunohistochemistry and genetic analyses. With the confluence of advances in bioanalytical technologies and protocols for long-term organotypic culture, these platforms are envisioned as next generation systems for high content assays of drug- and toxin-interactions with the intestinal epithelia.

Abstract Text

One of the major thrusts in our research is exploring electrochemical measurements of cell metabolism and physiology. Clearly cellular dynamics and metabolism is a developing area where new instrumentation could have a significant scientific impact. In this regard, we created the multianalyte microphysiometer (MAMP) that employs electrochemical sensors to monitor near real-time metabolic rates of living cells in a microfluidic chamber with a concentration on cellular bioenergetics. In recent years, we have applied the MAMP to answer a wide variety of scientific questions with biomedical collaborators in neurology, immunology, and toxicology. At the same time, we are redesigning our previous MAMP instrumentation into completely Lab-on-a-Chip format entitled the “microclinical analyzer” (MCA). This MCA instrumentation is at the heart of the instrumented organs-on-a-chip multi-disciplinary effort of a DARPA, NIH UH2, and 2 DTRA grant awards that arise from the specific thrust of the current White House initiative to replace drug toxicology testing in animals with human tissues and organs. Coupling these microclinical analyzers with various organs on a chip will be the focus of this talk. Organs include the brain on a chip, the lung on a chip, the liver on a chip, and possibly others.

Abstract Text

Coal tar is a viscous, complex mixture resulting from the pyrolysis of coal and has a wide range of uses from dermatologic products to fuel and asphalt sealants. When distilled, several creosote fractions can be collected and the remaining material is called "coal tar pitch". It is commonly recognized that coal tar and creosote contain thousands of compounds. Yet studies on the environmental chemistry of these materials have been limited to the toxic polycyclic aromatic hydrocarbons (PAHs), the most abundant class present. Other compounds have been identified but generally limited to tentative identification with gas chromatography/mass spectrometry (GC-MS). To provide an expanded list of compounds in coal tar that would be invaluable to understanding the source, transport, and fate of these materials as well as constraining toxicological impacts, we analyzed field samples from coastal Texas using comprehensive two-dimensional gas chromatography (GCxGC) with flame ionization detection and time-of-flight mass spectrometry. The latter technique provides superior separation and quantification of GC-amenable molecules. By analyzing the whole extract of our field samples, we identified over 3000 peaks. (GC-MS only identified 250 peaks). We then fractionated the whole extract with silica gel chromatography into eight fractions. Analysis of each fraction led to the identification of over 10,000 peaks, although at trace levels, including numerous nitrogen-containing heterocyclic PAHs. The end result was a new and unprecedented inventory on the molecules present in coal tar samples that will lead to an increased understanding of a fossil-fuel product used almost exclusively in the environment.

Abstract Text

Increasingly complex processes are used in refineries and petrochemical plants to transform heavier and unconventional oils into various products: ultrapure gases leading to technically advanced polymers, cleaner fuels, lubricants, bitumen... In order to optimize these (catalytic) processes, oils and hydrocarbon cuts have to be described at the molecular level. The origin of several polymer properties and efficiency of additives in polymers can be studied through their molecular characterization.[1,2]

The diversity of molecules found in oils and in polymers has stimulated the development of innovative chromatographic and mass spectrometric approaches to generate “fingerprints” at the molecular level. In this talk, we will present some of our latest developments in this field: Concerning heteroatom and metals containing molecules in crude oils, the complete distillation series of various crude oils have been studied using Gel Permeation Chromatography Inductively Coupled Plasma High Resolution Mass Spectrometry (GPC ICP HR MS).[3] Size distribution of sulfur, vanadium and nickel containing molecules or aggregates within an oil cut can then be determined, compared and studied through a refining process.

The coupling of atmospheric solid analysis probe (ASAP) with ion mobility-mass spectrometry (IM-MS) has been shown to be an efficient tool for the characterization of oil cuts,[4] polymers, polymer blends[1] and additives.[2] This approach affords the coupling of a direct ionization technique that does not require sample preparation, with a bi-dimensional separation method. It is therefore a useful tool for the rapid generation of molecular fingerprints from complex matrix samples.

Abstract Text

Characterization of aromatic compounds is very important in many research areas such as environmental, material, energy, and food researches. Especially it is important to understand petroleum compounds. Mass spectrometry has been widely used for characterization petroleum compounds. Especially, high resolution mass spectrometry presented by Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT-ICR MS) is a powerful technique to characterize compounds in complex mixture such as petroleum. The high resolving power and mass accuracy of FT-ICR MS enables accurate identification chemical compounds. In the high resolution mass spectra obtained from crude oils, over 10,000 peaks can be routinely identified. The elemental formulae of the compounds can be calculated and identified. However, to understand chemistry of the compounds, it is important to be able to assign structures to the identified elemental formulae. Therefore, in this study, the combination of HPLC, high resolution mass spectrometry and 2D NMR is proposed as a powerful technique to characterize petroleum compounds.

Abstract Text

Petroleomics is the characterization of petroleum at the molecular level. For sufficiently complete characterization of the organic composition of petroleum and its products, it should be possible to correlate (and ultimately predict) their properties and behavior. However, the comprehensive characterization of petroleum samples is still one of the most complex analytical challenges faced today and it mostly due to the lack of a universal analytical technique.

To overcome this limitation much progress has been accomplished by separating the matrix into distinct boiling point cuts, as described by the Boduszynski. He asserted that crude oil composition increases continuously with regard to aromaticity, molecular weight, and heteroatom content from the light distillates to non-distillables. The combination of distillation cuts with the molecular characterization provided by chromatographic and mass spectrometry analyses results in exhaustive characterization that provides compositional data that strongly supports the Boduszynski model. A more recent exhaustive characterization of ring number-separated fractions from a series of boiling point ranges has significantly expanded the molecular composition characterization of the aromatic components.

Although the molecular characterization provided by ultrahigh resolution mass spectrometry by direct infusion of crude oils may not provide a comprehensive characterization of species, it can provide insights and useful information if a comparative approach is undertaken. In this talk, we shall discuss how one can correlate and predict bulk properties of petroleum based on mass spectrometry analysis. We shall also describe our current efforts toward a new theoretical progression model that relies on direct infusion FT-ICR mass spectra of a whole crude oil and/or a distillation cut as an input, from which we are able to determine and extrapolate with high accuracy the molecular compositional space for a wide boiling point range.

Abstract Title **Recent Advances in Mass Spectrometric Characterization of Asphaltenes**

Primary Author Hilkka Kenttamaa
Purdue University

Date: Wednesday, March 11, 2015 - After

Time: 04:10 PM

Room: 265

Co-Author(s)

Abstract Text

Asphaltenes are a problematic component of crude oil that causes clogging of oil recovery pipelines and fouling of catalysts during crude oil processing. A better knowledge of their structures is imperative for addressing the problems they cause and also for finding potential uses for these compounds. Recent mass spectrometric studies of asphaltenes from around the world have shown that most ionized asphaltenes produce strikingly similar mass spectra upon collision-activated dissociation. However, previous studies of CAD of ionized model compounds have shown little resemblance to CAD of real ionized asphaltenes. We report here results obtained upon examination of new types of model compounds and different types of asphaltenes studied by using several different approaches.

Abstract Text

Sum frequency generation (SFG) vibrational spectroscopy has been applied to investigate buried interfaces involving polymers and proteins, supplemented by attenuated total reflectance (ATR)-FTIR. General methodology has been developed to probe buried polymer/metal interfaces, which are important for anti-corrosion coatings and packaging for modern microelectronics. SFG and ATR-FTIR have been used to examine molecular interactions between antimicrobial peptides and model cell membranes, and membrane associated proteins. Surface immobilized peptides and enzymes have also been studied at the solid/liquid interface in situ. Detailed correlations between the structure and function of these interfacial biological molecules have been obtained.

Abstract Text

Scanning angle (SA) Raman spectroscopy is applied to study polymer films to simultaneously measure polymer thickness, chemical composition, structure and locate buried interfaces with tens of nanometer spatial resolution in the axial direction. The technique uses a prism on which the polymer is coated. Raman spectra are collected as the incident angle of the excitation laser is precisely varied from 30-70 degrees. This angular range spans above and below the critical angle for total internal reflection at a sapphire prism/polystyrene interface. SA Raman spectra of 10 nm to 2 micron polystyrene, polycarbonate or poly(3-hexylthiophene) films are collected with second acquisition times and signal-to-noise ratios that exceed 100. SA Raman spectroscopy is used to determine the interface location in bilayer films of polystyrene and polycarbonate. Comparing SA Raman and profilometry measurements, the average percent difference in the total bilayer thickness is 2.4% for films less than 2200 nm thick. The average percent difference in the thickness of the polystyrene layer, which reflects the interface location, is 2.5% when the polystyrene layer is at least 250 nm thick. SA Raman spectroscopy is a versatile method applicable whenever the chemical composition, structure and thickness of interfacial thin films needs to be measured with high axial resolution. This research is supported by the U.S. Department of Energy, Office of Basic Energy Sciences, Division of Chemical Sciences, Geosciences, and Biosciences through the Ames Laboratory. The Ames Laboratory is operated for the U.S. Department of Energy by Iowa State University under Contract No. DE-AC02-07CH11358.

Abstract Text

Objective: Study the dynamics and structure of PTEN associated with laterally heterogeneous lipid bilayers using single molecule microscopy.

Background: Phosphatase and tensin homologue deleted on chromosome 10 (PTEN), is one of the most frequent genes deleted/mutated in a wide variety of tumors. PTEN acts as an antagonist to PI 3-kinase signaling, thereby affecting cellular processes such as cell proliferation and survival. PTEN activity is regulated by dynamic shuttling between the cytoplasm and the plasma membrane.

Methods: We use FTIR spectroscopy to monitor the secondary structure of PTEN and PTEN-L associated with complex lipid environments. In addition, we apply single-molecule TIRF microscopy and stopped-flow fluorescence measurements to observe PTEN molecules as they dynamically associate/dissociate and laterally diffuse along the lipid bilayer membrane. PTEN lipid binding is investigated using supported lipid bilayers of binary and ternary lipid mixtures of phosphatidylcholine (PC) with physiological relevant levels of phosphatidylserine (PS), phosphatidylinositol-4,5-bisphosphate (PI(4,5)P2) and/or phosphatidylinositol (PI).

Results: Using single molecule trajectories of PTEN molecules we find significant differences in PTEN dynamic behavior when bound to different membrane environments. Interestingly, we determine the existence of three membrane bound states with different diffusion coefficients. To gain insight into the molecular mechanisms of PTEN membrane association, we compared the lipid binding of wt-PTEN, PTEN-(Δ 1-15aa) and the recently discovered, PTEN-L with a 173 aa N-terminal extension. We find profound differences in the dynamic behavior of these PTEN derivatives at the membrane. In addition, we will present structural data of PTEN-L associated with plasma membrane lipids.

Abstract Text

The controlled adsorption of proteins to defined monolayers has application in sensor and nanotechnology applications where selective adsorption and manipulation of the orientations of targeted species is of interest. Metal-chelating monolayers offer opportunities to manipulate the adsorption of metal-binding proteins and peptides, and in previous investigations of the binding of myoglobin to Cu(II)-charged 1,2-distearyl-rac-glycero-3-triethyleneoxideiminodiacetic acid (DSIDA) monolayers via scattering methods, reorganization of the lipid layer was observed, although the molecular origins of this disruption could not be probed. In the studies reported here, vibrational spectroscopy methods were developed to shed molecular insights onto the origins of the monolayer disruption. Analysis of time-resolved planar array infrared reflection-absorption spectra (PA-IRRAS) revealed that a Cu(II) ion-chelated DSIDA lipid monolayer (Cu²⁺-DSIDA) was readily disrupted by adsorption of myoglobin as demonstrated by a blue shift of 1.7 cm⁻¹ and a lower intensity in the vas(CH₂) stretching mode of the lipid monolayer over a period of five hours.

In addition, we have used AFM-IR to investigate the interface between two and three concentric layers of a coaxially electrospun polymer nanofiber. The combination of atomic force microscopy (AFM) and infrared spectroscopy (IR) is a powerful tool that provides chemical and conformational information at a spatial resolution of 50-100 nm. Using an AFM-IR (Anasys) instrument we have studied cross sections of two and three layered fibers embedded in epoxy to assess the interaction between layers and the difference in crystalline content of the various layers. The potential of this technique for studying buried polymer interfaces will be discussed.

Abstract Text

Emulsions are very important in many industries including: oil refinery, cosmetics and food. The stability and properties of the emulsions are determined by the oil/water interface, which can be stabilized with surface-active species, such as surfactants or nanoparticles. The behavior of these species at the oil/water interface is known to effect emulsion formation and stability and can also be dependent on various other parameters such as concentration, ions, and additional cosurfactants and polymers. This presentation will describe our vibrational sum frequency scattering spectroscopy studies of surface-active species at the emulsion interface with a specific focus on the surfactant AOT. Its molecular structure, solvation and alkyl chain conformation as measured at the surface of a reverse emulsion particle suspended in an organic solvent, regular emulsion particle suspended in water and at the planar organic/water interface will be discussed as will the effect of counterion and particle size on the interfacial.

Abstract Text

A career goal is difficult to plan. Many excitement and accomplishment in one's career are difficult to plan, however, the success of one's career goal mostly comes from motivation and proactive action to become successful, hardwork, and support from your family, friends, and community networking. It is interesting to review my career path starting from \$80 dollar in 1976 to arrive in Los Angeles Airport from Taiwan to study separation science with Professor Calvin J. Giddings at the University of Utah. With hard work and dedication to explore the fundamental of separation science, my path from a graduate student to establish my own company will be discussed. My time with Varain Associates, my venture into a small startup company, the merge of Lee Scientific with Dionex, the startup of FFFractionation company for Professor Giddings, the founding of my own MicroTech Scientific in Sunnyvale, California, the sales of MicroTech Scientific, and the Start up of AcuTech Scientific in US and Taiwan three years after my retirement had happen so fast. The excitement of the frontier research and innovation, the creation and the birth of new products, the mass production and expanded applications of the new products, the hard work and the networking to bring it to the real world keep the spirit high to achieve personal career goal of each Team members . My experience for getting funding for the start up in US and Taiwan will be discussed.

Abstract Text

Water sources, including those in developed countries, continue to contain high levels of arsenic (As), at concentration levels exceeding the WHO drinking water guideline of 10 µg/L. Chronic exposure to arsenic through the consumption of these waters has been recognised to cause a world environmental health disaster, by putting 100 million people at risk of cancer and other arsenic-related diseases. This paper will report on the construction of a printed quantum dot sensor, using a paper-based or low cost optically transparent polymer coated substrate, with a dual quantum dot measurement system. A particle based ink will be discussed with an immobile carrier substrate for additional affinity ligands and a capture matrix for quantum dot sensors. A 3-D 'porous-plug' structure is produced to ensure complete and uniform interaction with the sample. The "ion-selective inks" have a carrier fluid which has been developed such that:

- It has viscosity suitable for fluidjet printing
- Forms uniform drops
- Does not dry at the print head nozzle but dries completely after printing.
- Enables particles to stay in suspension for sufficient time to allow printing.
- The total mass and volume occupied by the components of carrier solution for the ink are relatively low to allow for maximum loading capacity of the ink by the solid-phase ligand and sensor carrier.

QD nanoparticles are typically responsive to metal ions, mainly resulting in fluorescence quenching. The challenge here is therefore to achieve ion-selectivity for arsenic detection. CdTe core QDs and CdSe/ZnS core/shell QDs are compared and a dual QD system proposed to identify interfering ions such as Cu²⁺ and Zn²⁺. Taking inspiration from biology, peptide sequences have been sought to show affinity binding to As(III). Due to their high affinity towards complexation with As(III), glutathione (GSH) peptides were selected and are attached to the QDs, using carbodiimide chemistry. The ion-selective response is reported.

Abstract Text

Imaging of thrombosis in animal models has advanced the understanding of pathophysiology, however gaps in knowledge still exist partly because of a deficiency of appropriate analytic tools. Existing methods almost exclusively use intravital microscopy with antibody-labeled coagulation proteins, cells, and cellular components. The limited quantitative potential of this approach necessitates the development of robust tools to visualize thrombosis at the platelet level by probing specific markers of platelet activation. Platelets possess receptors for serotonin on their surface and a serotonin transporter to re-uptake and secrete it during platelet activation, providing a suitable marker for monitoring platelet activation and thrombosis progression.

We have designed enzyme-based, ratiometric phosphorescent nanosensors specific to serotonin. The described non-ionic surfactant triblock copolymer-based nanosensors are comprised of a hydrophobic chain of poly(propylene oxide) flanked by a hydrophilic poly(ethylene glycol), and contains an O₂-sensitive phosphorescent dye and reference. The surface of the nanosensors contains conjugated monoamine oxidase (MOA), which converts serotonin by an O₂-mediated mechanism. We optimize the sensitivity, specificity over competing analytes, response time, and sensor lifetime of these nanosensors to yield tunable and reversible sensors of soluble serotonin via phosphorescence measurement of O₂ consumption by MOA. We demonstrate that these nanosensors can quantitatively measure serotonin released from cultured platelet precursor megakaryocytes during IL-1-stimulated activation. These novel site-specific phosphorescent nanosensors can supply spatio-temporal information about serotonin release during thrombus development, providing a useful tool to advance our understanding of the pathophysiology of thrombotic complications.

Abstract Text

Microfluidic paper-based analytical devices (μ PADs) are becoming increasingly popular as simple to use and low-cost analytical tools for clinical or environmental applications. Our group has been focusing on drop-on-demand inkjet printing technology for both the patterning of microfluidic structures and the deposition of reagents required for analysis.

In most cases of μ PADs realized up to date, highly porous materials composed of untreated cellulose fiber networks (e.g. filter paper, chromatography paper) have been applied, where the sample liquid is transported by wicking through the 3-dimensional network of fibers. While this concept has proven to be very successful, it has the disadvantage of being relatively slow. Depending on the configuration, the time required for the sample to completely wet a μ PAD can take up to several minutes. Compared to fully enclosed conventional microfluidics, μ PADs are commonly systems open to the environment, where liquid wicking competes with evaporation. As a consequence, comparably large sample volumes are required to guarantee the full wetting of the devices.

Here, we present an alternative approach to μ PADs based on standard copy paper. In contrast to the devices mentioned above, microfluidic structures are patterned on the surface of hydrophobized copy paper. For this purpose, tetramethyl orthosilicate (TMOS) solution is inkjet printed to form hydrophilic flow channels. With this type of flow channel, significantly faster sample flow rates are achieved, due to a mechanism differing from simple capillary force-based wicking, allowing for shorter analysis times with smaller sample volumes. While in previously reported μ PADs relying on filter or chromatography paper the sample is transported inside the paper network, the newly developed system relies on surface wetting. Finally, the use of copy paper instead of filter paper strongly contributes to the cost-reduction of μ PADs, since the paper substrate is a significant cost factor.

Abstract Text

After a long history and conflicting views, solid contact (SC) liquid membrane ion-selective electrodes (ISEs) emerged as reliable potentiometric sensing devices with unique advantages. The main motivation for the development of SC electrodes is miniaturization through microfabrication. Solid contact microelectrodes are expected to be robust, maintenance free or single use that does not need calibration.

In the light of these expectations it is surprising that most papers describe the properties of the SC electrodes only after extensive, sometimes complex, equilibration/conditioning processes. However, in certain applications (single use sensors), short equilibration time is essential. In other applications (in vivo measurements requiring sterilized sensors), complex and long conditioning may not be feasible. In addition, understanding the limits of the beneficial effects of conditioning is important (experimental conditions, time). Finally, if the electrode properties change during use and storage (wet or dry) it is important to know how can the original properties restored (reconditioning).

We studied the equilibration processes of freshly prepared potassium, sodium and hydrogen ion-selective electrodes with inherently conductive polymers (CPs) as inner contacts. As conductive polymers poly (3,4-ethylenedioxythiophene), poly(3-octylthiophene), and polypyrrole were used. The CPs were deposited over gold, platinum and glassy carbon substrates by drop casting, electropolymerization or by cyclic voltammetry. The electrodes were characterized by their equilibration time, (the time instant when the potential drift drops below a threshold value), short- and long-term stability. Finally we evaluated the reproducibility of the equilibration process following the complete exsiccation of the solid contact electrodes.

Abstract Text

Label-free detection of polyions such as sulfated polysaccharides (e.g., heparin) and arginine-rich proteins (e.g., protamine) is challenging owing to the lack of fluorophores, chromophores, or redox active groups in these polymeric species. Polymer membrane electrodes doped with appropriate ion-exchangers or lipophilic salts have proven to be useful sensors for detecting such polyions. [sup]1,2[/sup] However, chromatographic separation is required when different polyions co-exist, or the polyion sample contains significant levels of interfering ions. In this presentation it will be demonstrated that a fully reversible polyion sensor can be used as a simple potentiometric detector to monitor separated polyions eluted from a chromatographic column. A polymer membrane doped with tridodecylmethylammonium-dinonylnaphthalene sulfonate (TDMA/DNNS) is employed as the membrane electrode detector and is operated in a triple-pulse mode. This allows for the fully reversible detection of either polycations or polyanions eluting in the eluate from the column, depending on the direction of the initial current pulse used in the detection pulse sequence. In proof-of-principle experiments, homogeneous poly-arginines of different lengths are separated by using a heparin-sepharose affinity chromatography with a NaCl gradient, and these poly-arginines are detected as positive EMF bands as they elute from the column. The same system can also be applied to monitor the separation of arginine-rich polypeptides produced by thermolysin-catalyzed digestion of protamine. Based on the strong electrostatic interaction of polycations and polyanions, it will further be shown that the polyion-sensitive pulstrode can also be employed for the indirect detection of polyions separated on chromatographic columns using a post-column polyion reagent approach.

Abstract Text

Heparin is widely used as an anticoagulant during procedures such as cardiac/vascular surgery and kidney dialysis. Adverse reactions, including many deaths, resulted when tainted heparin was accidentally used for the treatment of patients in 2007-08. The contaminant that was responsible for the adverse reactions was later identified to be a high charge density polyanion polysaccharide called oversulfated chondroitin sulfate (OSCS)[1]. After this incidence, testing of solutions of heparin for purity before using for patient treatment has been a requirement. However, since OSCS has similar chemical structure and anticoagulant activity as heparin, it cannot be detected in heparin solutions by typical bioactivity assays. Thus, currently, only costly and complex techniques, proton nuclear magnetic resonance (NMR) spectroscopy and capillary electrophoresis (CE) are mandated by FDA to screen for such contaminants in heparin. Simple and more easily available potentiometric polyion sensors were recently reported for the detection of OSCS in heparin.[2] However, these are single use disposable devices and direct quantitation of the contamination level is difficult. We present here pulsed chronopotentiometry with polyion-selective electrodes as a simple, reversible and reliable method of detection of high charge density contaminants in heparin solutions. In our preliminary work, as low as 1% dextran sulfate, a high charge density polysaccharide (similar with OSCS in structure), has been detected in heparin solution at 2.3 mg/ml.

Abstract Text

Developing ion selective electrodes (ISEs) with a nanomolar detection limit for online monitoring of the neurotransmitter acetylcholine (ACh) in biological fluid is presented here. Our strategy depends on optimizing the ISE inner filling solution by buffering the activity of ACh and consequently reducing the transmembrane ion flux. This has been achieved through utilizing the outstanding complexation properties of water-soluble p-sulfonatocalixarenes towards the quaternary ammonium ACh cation to form host-guest inclusion complex. UV-spectroscopy was used to investigate the formation of the proposed complex and its leaching to the outer sample solution was tracked. The performance characteristics of the developed ISE revealed a linear range from 1 mM to 1 nM with LOD of 7.6×10^{-10} M which is lower than the ACh basal physiological level. Moreover, the developed ISE showed good temporal resolution and selectivity for ACh in the presence of the anticipated biological ions. To investigate the ability of the ISE to detect ACh in real samples, ACh has been determined in artificial cerebrospinal fluid (aCSF) samples spiked with ACh at a concentration comparable to its physiological level.

Abstract Text

Super-resolution chemical imaging via Raman spectroscopy offers chemical specificity, affording the ability to multiplex numerous label-free analytes while providing a spatial chemical distribution on sample. However, spontaneous Raman is inherently weak making trace detection and thus super-resolution imaging extremely difficult, if not impossible. To circumvent this and allow for a trace detection of the few species present in each sub-diffraction limited location, we have developed a coherent fiber-optic imaging bundle based surface enhanced Raman scattering (SERS) probe consisting of 30,000 individual fiber elements. When tapered, etched and coated with metal, they allow circular Raman chemical images with 20 μ m diameters to be obtained from the array of 50 nm individual fiber elements. An acousto-optic tunable filter is used to rapidly scan or select frequencies of interest for multi or hyperspectral analysis.

Although the 50nm fiber element dimensions of this probe are capable of inherently providing spatial resolutions of approximately 100nm, further increases in the spatial resolution can be achieved by using a rapid, 2-step dithering process. Using this process, two additional images are obtained one-half fiber diameter apart in the x- and y- plane. A piezostage drives the movement of the stage and allows accurate and reproducible shifting of the images. These images are then deconvoluted from each other to further increase the spatial resolution to one-third of its original value. This talk will describe super-resolution chemical imaging using these probes and the dithering method as well as its applications in label-free imaging lipid rafts and other applications within biology.

Abstract Text

Raman imaging is fast becoming one of the key pillar techniques used in material characterization due to its sensitivity, speed, spatial resolution and highly detailed chemical and structural information content. The advantages of Raman imaging of advanced materials are illustrate particularly well for the analysis carbon based nanomaterials (carbon nanotubes, graphene and graphene oxide), thin films and coatings. Raman imaging provides a wealth of information beyond just simple identification and includes detailed structural information. Raman imaging can be used to distinguish between different states of materials such as crystalline, amorphous, and nano-structured materials as well as observing subtle effects such as changes induced by applied stress such as those observed in thin layers of silicon deposited on germanium doped silicon substrates. This presentation will highlight Raman imaging results on several of these materials with a detailed discussion on the information that is contained in the resultant images.

Co-Author(s)

Abstract Text

The physical and biological properties of organic solids can be profoundly affected by crystal form. Experimental measurements by second harmonic generation (SHG) microscopy suggest rapid transitioning through metastable crystal forms at the earliest stages of crystallization before ultimately producing the most thermodynamically stable crystal form. This trend supports a >100 year old theory by Wilhelm Ostwald that has historically been challenging to test. Advances in measurement capability are described from coupling SHG microscopy directly into a beamline for synchrotron X-ray diffraction. The regions of interest identified by SHG microscopy were targeted for X-ray diffraction, enabling structural analysis of pg quantities of crystalline material. By confining crystallization to small volumes, inkjet printing places crystallization under kinetic control. As such, metastable crystals forms that would otherwise transition to stable forms could be kinetically trapped to provide snapshots of structures present during the early stages of crystallization. When inkjet printing racemic amino acid solutions, the XRD measurements confirmed spontaneous resolution of the crystal forms into separate homochiral crystals when crystallization was performed under kinetic control through inkjet printing. Metastable crystal formation has also been observed in nominally centrosymmetric materials, including crystals of a centrosymmetric dye molecule. These results may allow for new, efficient routes for chiral resolution in chemical syntheses.

Date: Wednesday, March 11, 2015 - After

Time: 03:25 PM

Room: 240

Co-Author(s) Anthony Lagalante

Abstract Text

Currently, the most commonly used method for characterizing binding materials in paint cross sections is GC-MS; however, the analysis requires an extensive extraction and derivatization process and is destructive to the sample. Recently, research has been focused on developing less-destructive methods to determine paint binding media. ToF-SIMS has proven to be one effective method for the simultaneous identification of both binding materials and pigments in cross section. However, ToF-SIMS requires a high vacuum and a high energy ion beam in order to produce secondary ions for imaging. Desorption electrospray ionization [DESI], on the other hand, can be operated in atmospheric conditions, as ionization is induced by a charged solvent spray using a front end source that can be fitted to most mass spectrometers. In this talk, preliminary results for the DESI-MS identification of binding materials such as oil, egg tempera, and acrylic media will be discussed. DESI-MS can be used to create isobaric images to visualize the location of different binding material in a prepared cross-section with a spatial resolution of approximately 100 μm . This DESI-MS method has also been successfully used to analyze a cross section from a 17th century baroque painting currently undergoing restoration at Villanova.

Abstract Text

This presentation will give an overview of the non-destructive, qualitative elemental analysis of high-Z particles embedded in a mineralogical sample using two laboratory-based X-ray techniques: micro X-ray computed tomography (micro-CT) and confocal micro X-ray fluorescence spectroscopy (confocal micro-XRF). Traditional micro-XRF instruments are limited in that they cannot distinguish surface from sub-surface particles. The limitations of micro-XRF can be overcome by confocal micro-XRF, which allows for spatial discrimination of X-ray fluorescence signals in all three spatial axes as well as particle detection and elemental identification at depth. Data is acquired by rastering the sample; hence, large samples can require days to fully acquire a 3D elemental image. This analysis time can be significantly reduced by screening the samples using micro-CT, a non-destructive X-ray imaging technique. This technique rapidly collects absorption contrast images of a sample and reasonable 3D data sets can be acquired within a few hours. While discrete elemental information is difficult with micro-CT, particles composed of high-Z elements can be differentiated from particles composed of low atomic number elements based on X-ray attenuation. Using the particle location information, the prescreened particles can be targeted individually for in situ elemental analysis which rapidly decreases the time required to locate and elementally identify particles of interest. In this case study, a cylindrical mineral sample was imaged non-destructively using micro-CT. Two high-Z particles ($\sim 20 \mu\text{m}$ in diameter) were located (one surface particle and one sub-surface particle) and elementally identified using confocal micro-XRF. These results show that coupling these two X-ray based imaging techniques allows for the spatial location, size measurement and elemental identification of high-Z particles within a matrix, in a non-destructive manner.

Date: Wednesday, March 11, 2015 - After

Time: 04:05 PM

Room: 240

Co-Author(s) Andrew E. Wright, Paul Mack, Richard G. White, Tim Nunney

Abstract Text

X-ray photoelectron spectroscopy (XPS) is a powerful surface analytical technique that provides unique chemical state information on the topmost ~2-10 nm of solid materials. In-depth compositional information can be obtained up to depths of several micrometers when XPS is combined with argon ion beam sputtering for depth profiling analyses. However, ion beam sputtering of most organic and polymeric materials, and certain inorganic materials, can often be problematic when using monatomic argon ion beam sources because of chemical damage caused by the ion beam sputtering process. This damage greatly reduces the chemical information to be learned from XPS depth profiling. Recently developed argon cluster ion beam sources offer exceptionally gentle sputtering compared to monatomic sources and produce much less chemical damage when used to depth profile or sputter-clean ion beam-sensitive materials. Hence, cluster ion sources allow materials that are unstable under monatomic ion bombardment to be successfully depth profiled. This presentation will discuss applications of a unique combined monatomic and gas cluster ion source (MAGCIS) that can be operated as either a traditional monatomic argon ion source or as an argon cluster ion source, thereby allowing a full range of material types to be successfully analyzed. XPS depth profiling results from a variety of biological, organic, and inorganic materials will be described with comparisons to results obtained for samples analyzed using monatomic argon ion sputtering. Results obtained with argon cluster ions were consistent with minimal ion beam damage and preservation of important chemical state information in the resulting XPS spectra.

Abstract Text

Over the past decade, the inundation of the US with illicit drugs and the continued erosion of attitudes regarding the harm of such drugs have resulted in an increase in their abuse along with prescription drugs. Military veterans represent a special case, in that some 476,000 have received treatment for post-traumatic stress disorder and developed drug dependence. Treatments for drug dependent patients include drug dose lowering, medications to remove drug dependence and/or alleviate drug-related symptoms. Veteran Affairs hospital physicians must frequently test patients to identify discontinuation of medications or any recurrence of drug use, and adjust treatment appropriately. These tests most often involve collecting and sending a urine sample to a clinical lab for analysis by gas chromatography coupled mass spectrometers. Results are usually returned in 1 week, a delay that makes timely adjustment of treatment difficult. In an effort to develop an analyzer that can determine drug use at the time of VA hospital or clinic visits so that treatment can be adjusted, we have been developing a surface-enhanced Raman spectroscopy (SERS) based assay that can detect and identify numerous drugs in saliva at ng/mL concentrations within 10 minutes. Measurements of representative illicit, prescribed, and over-the-counter drugs in saliva by SERS, with a focus on cocaine, will be presented.

Abstract Text

Surface-enhanced Raman scattering (SERS) is a promising analytical technique for the detection and characterization of biological molecules and structures. In this presentation, approaches for label-free protein detection using SERS will be discussed. The sample preparation step is the key point to obtain strong and reproducible SERS spectra from the biological molecules and structures. When the colloidal suspension is used as a SERS substrate for the protein detection, the electrostatic interaction of the proteins with the nanoparticles is described by the nature of their charge status, which influences the aggregation properties such as the size and shape of the aggregates, as well as orientation of nanoparticles in the aggregates, which is critical for the SERS experiment. However, when the solid SERS substrates are fabricated, SERS signal of the proteins that are background free and independent of the protein charge. Pros and cons of using colloids and surfaces as SERS substrate will be discussed for label-free detection of proteins using SERS.

Abstract Text

The May 2013 mailing of Ricin to President Barack Obama, New York City Mayor Michael Bloomberg and, Director of Mayors against Illegal Guns Mike Glaze once again demonstrated the need for a bioagent analyzer to protect US citizens at home and the military abroad. Despite the substantial effort to develop bioagent analyzers, current analyzers 1) are too slow (e.g. PCR, 1 measurement/hour), 2) have high false-alarm rates (e.g. immunoassays), 3) lack sensitivity (e.g. Raman), 4) are not field-usable (e.g. GC-MS), or 5) cannot be multiplexed to identify multiple species (e.g. PCR). In an effort to overcome all of these limitations, we have developed a sample system that selectively binds specific bioagents and produces surface-enhanced Raman spectra. Personnel at the US Army's Edgewood Chemical Biological Center have used this sample system coupled with a compact, portable Raman spectrometer to measure 100 B. anthracis Ames spores in 20 minutes. These measurements, along with measurements of other Bacilli that demonstrate discriminate analysis, will be presented.

Abstract Text

Both surface plasmon resonance (SPR) and total internal reflection ellipsometry (TIRE) has been successfully applied for the evaluation of protein-protein interaction. TIRE combines the assets of both spectroscopic ellipsometry and surface plasmon resonance (SPR). Therefore, it has a significant advantage due to simultaneous measurements of two ellipsometric parameter Ψ and Δ which are related to the amplitude and phase shift of p- and s-components of polarized light respectively [1,2]. In here presented research total internal reflection ellipsometry (TIRE) and SPR has been applied for the evaluation of: (i) kinetics of biosensing layer formation, which was based on the immobilization of fragmented and intact antibodies, and (ii) kinetics of antigen interaction with the immobilized antibodies. The ellipsometric parameter Ψ showed much higher sensitivity at the initial phase of Au-protein and protein-protein interaction, while the parameter Δ was more sensitive when the steady-state conditions were established. The optical response of ellipsometric parameters in TIRE method has shown that the sensitivities of Ψ and Δ were different at different stages of biomolecular layer formation.

Abstract Text

In the biopharmaceutical industry, it is needed to make high concentration (>100 mg/ml) protein formulations. So, to understand the characteristics and their changes of protein as solute in non-ideal solution may contribute to give important suggestions for improvement of stability of biomedicine solutions.

In this study, Raman spectroscopic measurements of lysozyme solution as model system over a wide range of concentrations (2.5 mg/ml – 300 mg/ml) were carried out to investigate the molecular structure and the interaction of protein in highly concentrated solution. In this wide range of concentration, the specific Raman bands (Amide I, Tyr and Trp) were focused on and analyzed. The experimental results revealed that the molecular interaction changes in the stepwise processes as an order of magnitude of the distance between molecules changes. These results suggest that the practically effective marker bands are capable of evaluating appropriate formulation of the highly concentrated solution of protein, and also suggest the potential of Raman spectroscopy which will bring progress not only in molecular science in the concentrated, e.g. crowded condition but also in the protein process industry, such as biopharmaceutical field.

Abstract Text

The thermal denaturation mechanism and secondary structures of two kinds of human insulin nanoparticles, which are produced by supercritical fluids with ethanol or DMSO solutions, are investigated by applying principle component analysis (PCA), two-dimensional (2D) correlation spectroscopy and all-atom molecular dynamics (AAMD) simulation. 2D correlation spectroscopy combined with PCA enables improved characterization of the structural changes in biomolecules on a detailed molecular level. AAMD simulation method is a powerful tool that enables the examination of complex systems and processes at the atomistic level. The results of the PCA, the 2D correlation spectroscopic analysis, and the AAMD calculations clearly revealed that the thermal denaturation mechanisms and the degrees of hydrogen-bonding in the spherical and rod-shaped insulin nanoparticles were different. The details of differences of two kinds of human insulin nanoparticles will be discussed in this presentation.

Abstract Text

Synchrotron infrared nano-spectroscopy (SINS) enables spectrochemical imaging over the full mid-infrared range with sub-40 nm spatial resolution (Bechtel et al. PNAS 2014, 111:7191-7196). With SINS, we have now extended our micro-scale assessment of fungal wall composition with nanoscale comparisons of wall and exudate composition. Fungi are ubiquitous micro-organisms that collectively have profound effects, both positive and negative, on the environment and on human biology. Fungal cells are protected by walls that enable penetration of their surroundings, plus exudates that include adhesins and hydrolases. Despite concerted efforts to resolve and identify the chemical constituents of cell walls and fungal exudates, much remains completely unknown. One of the key challenges is that the hyphal wall composition changes along the length of the hypha as the cell matures. Fungal wall sugars are not found in animal cells, so wall biosynthesis pathways are good anti-fungal drug targets. In this study, we are examining walls and exudate in wild type, *ugmA* knockout, and alpha-glucan synthase knockout *Aspergillus* strains. We have preliminary evidence that (1) exudate contains both carbohydrate (adhesion) and protein (nutrient acquisition) and (2) carbohydrate composition is radically changed in strains lacking genes responsible for biosynthesis of critical minor compounds; results can be correlated with molecular cell biological composition studies. We report here results of the first nanoscale FTIR imaging study (well beyond the diffraction limit), together with AFM morphological analysis, of fungal cell walls and exudate.

Abstract Title **Optimizing an Infrared Spectroscopic Method for QC Analysis of Botanical Dietary Supplements**

Primary Author Dean Brown
Molecular Spectroscopy Technical Services, LLC

Date: Wednesday, March 11, 2015 - After

Time: 04:05 PM

Room: 275

Co-Author(s) Ian Robertson, Justin Lang

Abstract Text

Botanical dietary supplement manufacturers are now subject to the FDA regulatory guidelines for good manufacturing practices. The cGMP's require verification of all incoming raw materials, and compliance with 21 CFR Part 11 for electronic record and signatures. The pharmaceutical industry relies upon validated Pharmacopeia methods for testing, however; this is not the case for dietary supplement manufacturers. One accepted way of identifying raw materials is to analyze the sample by infrared spectroscopy. A spectrum of standard material is collected and compared statistically to a spectrum of the unknown sample for quality of fit.

The raw materials may be sourced from various locations around the world and their characteristics may fluctuate due to harvest, weather, and soil conditions from country to country and year to year. These sources of variability will be observed in the infrared spectrum of the material and will decrease the probability of correctly identifying the material. A variety of different infrared sampling techniques were applied to the samples in order to determine the optimum method for performing this analysis. The spectra obtained from the botanical dietary ingredients were challenged to test the suitability of infrared spectroscopy to recognize and verify an individual dietary ingredient.

Chemical extraction of the material from the sample matrix can be performed prior to infrared analysis, but is a lengthy process. The paper proposes a rapid method of accomplishing the same result by digitally extracting the spectrum of the raw botanical material from the bulk material, thereby reducing the problems of product variability and greatly enhancing the ability to positively identify the material.

Abstract Text

In liquid phase microextraction, high enrichment factors (EFs) can be obtained using an acceptor phase of small volume. By hanging an acceptor drop at the separation capillary tip, single drop microextraction (SDME) can be in-line coupled with capillary electrophoresis (CE). The small surface-to-volume ratio of the drop enables high EFs to be obtained in a short time. One practical issue in SDME is how to keep the drop attached to the capillary stably. Here, we present novel but extremely simple in-tube microextraction (ITME) using the liquid inside the capillary as an acceptor phase, without forming a drop at the capillary tip. In this report, we demonstrate headspace (HS) extraction-ITME-CE fully automated using a commercial CE instrument. As a first example of HS-ITME-CE, chlorophenols in an aqueous sample solution were extracted into the acceptor plug in a separation capillary, simply by placing the capillary filled with a basic run buffer in the HS above the sample, and then electrophoresis of the extracts in the capillary was carried out. Owing to the robust nature of the acceptor phase, the extraction temperature and time ranges of HS-ITME can be extended significantly, compared to HS-SDME. The EFs for chlorophenols in a standard solution were up to 1100 under an optimal HS-ITME condition of 80°C for 15 min and the limits of detections (LODs) obtained using a built-in UV detector were about 4 nM. HS-ITME-CE was also applied to extract neutral organic pollutants such as BTEX (benzene, toluene, ethyl benzene, and xylene) from an aqueous sample using an acceptor plug of a surfactant solution. The extracts were then analyzed with a micellar electrokinetic chromatography mode of CE. The EFs for BTEX obtained with 20 min HS-ITME at room temperature were about 340 and the LODs were about 3 ppb.

Abstract Text

Phospholipid bilayers have been employed very successfully for some time in capillary electrophoretic (CE) separations. They have been shown to be highly stable, semi-permanent, coatings and are ideally suited to prevent the adsorption of proteins and other molecules to the capillary surface. The phosphocholine lipids also offer a unique level of electroosmotic flow (EOF) control. These zwitterionic surfactants, such as 1,2-Dilauroyl-sn-glycero-3-phosphocholine (DLPC), are able to yield a significantly suppressed EOF under typical separation buffer conditions, but when calcium is added to the separation buffer, the EOF is reversed.

The need for calcium to be present in solution with the phospholipids has long been known, and calcium is crucial for the formation of stable phospholipid bilayers. The influence of excess calcium on the EOF, resulting in not only a reversal, but also an increase in the magnitude of the EOF. This indicates that the presence of the calcium ion in the separation buffer leads to a partitioning of some of the calcium into the phospholipid bilayer, increasing the cationic charge of the bilayer and altering the EOF. This leads to the question of how other metal cations might influence the magnitude and direction of the EOF when present in the separation buffer.

To answer this question we have investigated the influence of a range of metal chloride salts on the EOF that is achieved when they are included in the separation buffer in the place of calcium. As anticipated, the charge of the metal cation plays a significant role in the magnitude of the EOF, with trivalent cations such as cerium drastically increasing the EOF. Unexpectedly, not all divalent cations yield an equivalent magnitude for the EOF. This presentation will detail our results of these investigations as well as our study of the stability of the bilayers with these different cations, and their application to the separation of various anionic and cationic proteins.

Abstract Text

Low-cost microfluidic devices have been widely researched as potential ways to making medical diagnostics and therapeutic monitoring more accessible to low income and low resource areas of the world. Current approaches to low cost device manufacture involve the assembly of materials such as chromatographic paper into microfluidic devices in multiple manufacturing steps or using microfabrication techniques such as UV-photolithography, which are expensive and difficult to scale up. In prior work, we demonstrated a textile weaving-based approach that makes use of this scalable and readily accessible technology to manufacture microfluidic devices in a single step. Liquid flow was tuned in these devices by manipulating the wetting characteristics and chemical treatment imparted to yarns in a seamless manner along the length of the fabric. In recent work, we leveraged this tuning ability to manufacture fabric-based electrophoretic devices for the separation of mixtures of proteins. Electrophoresis is widely used for the pre-concentration, separation and assay of protein analytes in complex samples. We present the ability to tune separation resolution using the surface properties (wetting characteristics) and the packing density (number of yarns per unit area) of both woven and knit fabrics. A seamless transition in yarn surface properties and packing density may then be used to perform protein sample pre-concentration followed by separation in a single fabric device, with potential applications in the detection of low abundance (rare) protein markers from clinical samples at the point-of-care or in low resource settings.

Abstract Text

Due to its transparent nature, inexpensive fabrication, and ability to reversibly seal to a variety of substrates, polydimethylsiloxane (PDMS) based microfluidic devices have been fabricated for studying biological systems; however, PDMS is not the best substrate for cell studies due to issues with cell adhesion and absorption of hydrophobic molecules. PDMS is also gas permeable, which makes studying gaseous and lipophilic molecules, such as nitric oxide (NO), very difficult to analyze. Therefore, it is crucial to develop more robust microfluidic devices that integrate cell culture and analysis. Polystyrene (PS) has been studied as an alternative microchip substrate, as it is hydrophilic and more biologically compatible than PDMS. A new method of fabricating all-PS devices was developed by etching channels into PS bases. Various bonding techniques (heating, submerging in boiling water, and laminating Shrinky-Dinks) were explored to determine a simple, cheap method to bond two PS substrates. By laminating, there is the ability to make a range of all-PS devices: with and without electrodes and encapsulated tubing. Micrographs of etched channels (straight and intersected channels) were taken using confocal and scanning electron microscopy. Electrophoresis was conducted using a three-sides PS (etched twin-tee pinched channel) and one-side PDMS device. The average plate count was 1,185, with a peak height RSD of 3.8% (n=6). Microchip-based flow injection analysis, with dopamine and NO as analytes, was used to characterize the performance of all-PS devices with embedded tubing and electrodes. Cell immobilization studies were also conducted to assess all-PS devices ability for cellular analysis.

Abstract Text

This work is carried out as part of the COMMON SENSE European FP7 project. The COMMON SENSE project aims to provide a reliable sensing platform for in-situ measurements on key marine water quality parameters relating to eutrophication, heavy metal contaminants, marine litter and underwater noise. The COMMON SENSE nutrient sensor is based on a combination of microfluidic analytical systems, colorimetric reagent chemistry, low-cost LED-based optical detection, and wireless communications.

The reliable quantification of nutrients in marine environments is challenging due to the low concentration of these solutes in the ocean and the nature of the matrix in which they are held. Initial studies are focussed on validating a method for the sequential determination of nitrite and nitrate in marine environments. Coupled with the traditional well established Griess–Ilosvay reaction for the determination of nitrite, a vanadium chloride (VCl₃) solution is used as the reducing agent. The method shows potential as an alternative to the toxic cadmium column for the reduction of NO₃⁻ to NO₂⁻ in marine water as results indicate that there are no apparent interferences from variances in salinity. The method was tested on a series of samples with varying salinities and sample matrices (costal, estuarine and freshwater), the method is low cost, reproducible and requires low volumes of sample and reagents.

Abstract Text

We present a microfluidic breadboard approach for electrophoretic separations with contactless conductivity detection, based on miniature off-the-shelf components such as syringe pumps, valves, and pressure controllers. For demonstration of its versatility, different configurations with a variety of interlocking components were implemented for very different purposes: capillary zone electrophoresis of cations, the simultaneous separation of cations and anions by dual-capillary zone electrophoresis, the separation of small carboxylic acids by gradient elution moving boundary electrophoresis (GEMBE) and the separation of cationic amino acids by isotachopheresis. Further variations are possible with the breadboard approach. Similar to lab-on-chip devices, the system allows fast separations, as demonstrated by the separation of cations within 35 seconds. On the other hand, it does not require any special manufacturing techniques as it can be assembled from commercial parts, the separation length can be readily adjusted, it is highly versatile and allows the use of superimposed pressures in both directions for added flexibility. The entire system weighs approximately 10 kg, costs less than 15,000 \$, and fits into a 25x35x30 cm box. For the automated operation of the whole system, a graphical user interface software was developed, that simultaneously controlled an Arduino microcontroller and a LabSmith electronic interface board. The software was based on the open source package Instrumentino [1], recently developed in our group.

Abstract Text

The literature reports shows that trans fatty acids derived from industrial hydrogenation process of vegetable oils is expressed in elaidic acid. Thus, they are included in the nutritional tables, since it comprises 80-100% of trans fatty acids present in processed products that use hydrogenated vegetable fat [1]. The traditional method for fatty acid analysis is gas chromatography (GC). However, in general way, due to laborious step of sample preparations associated to high analysis time (about 60 minutes) necessary to GC approach, alternative methodologies such as capillary electrophoresis (CE) have been considered in the last two decades for different matrixes [3]. Within this context, in the present work, will be presented the general inherent fundamentals and characteristic of cis-trans fatty acids analysis by CE, giving special focus to the total trans fatty acids analysis using direct UV detection.

Abstract Text

Since its introduction in the early 1980's, capillary electrophoresis (CE) has become an important separations technique with numerous applications. CE possesses many advantages including high separation efficiencies, fast run times, and small sample requirements. Unfortunately, CE suffers from poor concentration sensitivity and exhibits a low tolerance for matrix components, often necessitating sample processing prior to analysis. Combining separations with mass spectrometry detection has become increasingly critical in many bioanalytical applications. Coupling CE with electrospray ionization (ESI) further reduces salt tolerances and can lower sensitivity via sheath flow, compounding the necessity for sample treatment prior to analysis. Unfortunately, CE still lags considerably behind liquid chromatography (LC) with regards to sample processing, preventing widespread adoption of the technique. Based on the previous limitations of coupling sample processing with CE, a microfluidic platform presents a very promising candidate for an integrated CE system. Microfluidic technology is well suited towards integrating multiple functionalities and can precisely manipulate small volumes with zero dead volume. Furthermore, lab-on-a-chip technologies are amenable to automation, resulting in improved reproducibility and throughput. In this study, we present a novel design coupling microfluidic SPE with microchip CE-ESI with the goal of a fully integrated analysis system combining the sample processing power of LC with the speed and separation performance of CE. The design is reproducible, requires low sample consumption, and has shown a 100-fold improvement in sensitivity while maintaining high separation efficiency and MS compatibility. Furthermore, this design is potentially adaptable to many different applications by utilizing alternate stationary phases, resulting in a fast, high throughput, fully integrated universal platform for sample analysis.

Abstract Text

Electrochemical aptamer-based (E-AB) sensors using aptamers as recognition elements have attracted tremendous attention and efforts recently. The specificity, selectivity and high binding affinity provided by aptamer-target interactions coupled with the rapid and sensitive interrogation supported by electrochemical measurements enables a powerful diagnostic tool with rapid response time. However to date, most work demonstrating E-AB sensors is performed using macro-electrodes, thus limiting their ability to be integrated into for example, microfluidic and point-of-care diagnostic systems. Here we report the development of micro/nano-scale E-AB sensors for the detection of ATP with improved analytical performance over existing macrosensors. Specifically, we find that incorporation of nanostructured gold surfaces through deposition of metal nanoparticles onto 25 [micro]m gold electrode creates sensors with higher sensitivity (0.2 vs. 0.04 % signal change/[micro]M ATP) and binding affinity (0.2 [micro]M vs. 0.8 [micro]M) over macroscale sensors. This new small-scale sensor platform is suitable for the development of portable, aptamer-based point-of-care diagnostic devices and will enable the detection of small molecule targets with unprecedented spatiotemporal resolution. We believe this to be a general trend for the development of micro- and nanoscale E-AB sensors.

Abstract Text

The DNA biosensors are powerful tool in bioanalysis. Guanine (G), electrochemical oxidation signal is the most easily observed during DNA oxidation. Changes in G concentrations, the kinetics of electron-transfer reactions or its oxidation potential, are considered indicators of various mutations as well as various interactions with chemical compound. Unbound G oxidation mechanism is complex, complicated and still not well researched.

The structure of the electrode material affects the structure of the adsorbed layer and the nearby solvent. This implies different character of G-electrode surface, G-solvent, and G-intermolecular interactions in the adsorbed layer when changing from one electrode material to the other, and as a result of these variations, also changes in the oxidation kinetics of G may be expected.

Regarding the above-mentioned facts biocompatible and biodegradable materials has been reported as promising and potential materials to overcome the poor and unstable performance of guanine sensor on the bare glassy carbon support, encountered in development of DNA biosensor. Application of various materials consisting of the multiwall carbon nanotubes, the platinum nanoparticles, the mesoporous silica nanoparticles, the hydrogels and the conducting polymers to the construction of sensing layer in guanine biosensors led to the increase the active area by at least order of magnitude compared to the bare glassy carbon support matrix holding guanine. The use of a 3D materials minimize the negative influence of the irregularity in the distribution of the guanine sensing layers and show catalytic effect of oxidation reaction of guanine too. A very good agreement of the data obtained with such independent techniques as electrochemical methods, scanning microscopy and Raman spectroscopy, showed improved electrochemical behaviour of the newly designed guanine biosensors.

Abstract Text

Neurons communicate via the processes of releasing and taking in chemical messengers. These neurotransmitters are packaged in nanometer-size synaptic vesicles located in the cell. Quantification of vesicular transmitter content is important in order to study mechanisms of neurotransmission and malfunction in disease and yet this it is incredibly difficult to measure these small quantities in the attoliter volume of a single vesicle. We describe a new approach to electrochemical cytometry to carry out measurements of the total amount of catecholamine transmitters present in individual synaptic vesicles while still in the cytoplasm single cells. We have applied this method to measure the content of vesicles from PC12 cells and have shown the levels in a single dense core vesicle to range from a few thousand to millions of molecules. In addition, these levels can be changed with pharmacological manipulation indicating a new mechanism for discovery of neuroactive drug candidates.

Abstract Text

Photoremoveable protecting groups, such as p-hydroxyphenylacyl (pHp), have many possible applications in the bioanalytical sciences because of their ability to block the biological activity of a molecule and then restore that activity in a spatially and temporally precise way by application of light. In the past, pHp has been used to protect molecules with very acidic moieties, such as carboxylic acid groups on glutamate or GABA; however, it has not often been used successfully with less acidic moieties such as phenols or sulfhydryls, which are found in a large number of relevant biological compounds. For example, mercaptans, a well-known class of glutathione peroxidase inhibitors, requires a free sulfhydryl group in order to retain its inhibitory activity. As such, it would be advantageous to develop a method to photoprotect this class of compounds at the biologically active sulfhydryl so that hydrogen peroxide levels could be modulated with spatial and temporal precision in tissues. In this work, we synthesized a pHp-MCS ester derivative, protected at the sulfhydryl, and characterized the resulting compound both chemically and photochemically.

Abstract Text

Room Temperature Ionic Liquids (RTILs) are an exciting class of solvents, receiving much attention in recent years as a replacement for conventional solvents in electrochemical applications. In previous work, we have shown that nanostructures of molecular and RTILs domains were present in mixed solvents. Such heterogeneity has been shown to have significant effect on the electron transfer processes. As of this date, little work has been done on studying the multi-electron transfer of metalloporphyrins in these media. In this investigation, the electrochemical reduction of iron fluorinated porphyrin was carried out in mixed RTILs/organic solvents. The voltammetric analysis showed significant stabilization of the third reduction wave in the mixtures, emphasizing a charge effect of the electrogenerated species. UV-visible spectroelectrochemistry allowed studying the stability of the reduced iron species in the electrolysis timescale. Formation of RTILs/organic domains in mixtures is expected to affect the stability of the reductions products. ¹⁹F-NMR analysis allowed the investigation of the effect of such nanostructures on the chemical shifts of the fluoro signals. The occurrence of nano-structural heterogeneity at low concentrations of RTIL in mixtures would obviate the problem of their high viscosity and facilitate their use for electrochemical purposes at a lower expense.

Abstract Text

The prevalence of arsenic in ground water and the large number of water sources used for drinking and irrigation makes remote sensor networks highly desirable. The ideal approach should be highly independent of operator intervention; i.e., not require any sort of calibration or blank electrolyte for background correction. To achieve calibration free measurement, a finite volume stopped-flow thin-layer cell (SF-TLC) can exhaustively pre-concentrate dissolved metals in about a minute. The plated metals are subsequently measured by anodic stripping coulometry (ASC). Unlike most previously reported ASC approaches which rely on linear sweep voltammetry or chronopotentiometry, a potential step (PS) ASC variant is utilized to simultaneously strip the deposited metals.

The use of a double PS-ASC also allows in situ blank subtraction. To achieve selectivity, several deposition potentials are used to selectively pre-concentrate a chosen metal. This method has demonstrated measurement of 500 ppb As(III) to better than 10% error even in the presence of high interferent levels (1.3 ppm Cu²⁺, 500 ppb Cd²⁺, 500 ppb Pb²⁺, and 5 ppm Zn²⁺). Similar performance is possible for As(III) spiked Ohio River water after pH adjustment. This performance is 1-2 orders of magnitude higher than the EPA and WHO recommended limit for arsenic (10 ppb).

This presentation will describe how use of microelectrode arrays (MEA) within the SF-TLC offers improved detection limits. Additionally, MEA design (size and spacing of the individual microelectrodes) will demonstrate that exhaustive pre-concentration within the SF-TLC is possible within about a minute. The combination of these approaches will be demonstrated to allow measurements of less than 10 ppb As(III) in a 2-4 μ l volume in about two minutes, without any calibration or need for a blank electrolyte and in the presence of other metal interferents.

Abstract Text

Heavy metal contamination of the environment caused by increased industrialization is a well-documented, but nonetheless serious problem facing society due to the negative effects these materials have on human health and safety (1). Most analytical techniques require transport of the sample from the field to the laboratory in order to perform analysis, which increases the risk of sample contamination caused by changes in composition. Recently, we have introduced a new methodology for the trace detection of heavy metals: electrochemical x-ray fluorescence (EC-XRF) (2). Here we present an advance of EC-XRF for the real-time identification and quantification of heavy metals (in situ electrochemical x-ray fluorescence). In an in situ EC-XRF experiment, heavy metals are deposited on the surface of a conducting polycrystalline boron-doped diamond electrode while being simultaneously analyzed using x-ray fluorescence spectroscopy. The electrochemical deposition serves as a pre-concentration step, while the XRF measurement provides irrefutable chemical information regarding the identity of the sample. The unique electrochemical cell geometry, which is based on the wall-jet electrode, allows for high rates of mass transport that serve to improve the detection limits of liquid samples compared to conventional XRF (Figure 1). We investigate a variety of parameters on analytical quality, including flow rate, deposition time and potential using Pb as a model system. We also show the possibility of multiple detection using mixed solutions of Pb, Hg, and Cd. The major advance is the potential of the technique to perform analyses in the field without sample pre-treatment or complex reagent addition.

Abstract Text

Botanicals are plants or parts of a plant that are used for their flavor, scent or therapeutic properties. The sale and consumption of botanical products has dramatically increased over the past two decades as consumers trend to what are perceived to be natural and high quality botanical products over other manufactured products. The safety of these products, especially products considered to have medicinal or therapeutic properties (i.e. supplements, nutraceuticals or phytomedicines) is often in question. The primary regions of spice and tea production around the world (India, Bangladesh, Turkey, China, and Indonesia) have often been cited as having less stringent safety and quality standards in regards to consumer products. Products from these regions have been studied many times and often have been found to contain a variety of adulterants and contaminants including mycotoxins, pesticides, illegal additives, toxic organic compounds and heavy metals.

In this study, commonly used spices or botanicals in the US (Cinnamon, Mustard Seed, Fenugreek, Ginger, Paprika, Nutmeg, Red Pepper, Black Pepper, Cumin and Turmeric) in various forms and preparations were studied by ICP-MS to determine the presence and level of heavy metal contamination. Many botanical products can often fall into multiple product categories such as spices, teas, condiments and medicinal preparations. Botanical products were selected to cover the range of preparations and uses. Organic varieties when available were also compared to traditionally cultivated botanicals. The botanicals were purchased at a variety of locations including: farmer's markets, ethnic markets, chain Supermarkets, herbal/health food stores, online and discount stores. Samples were digested using microwave digestion and analyzed using ICP-MS.

Abstract Text

The use of dietary supplements is on the increase globally even in the developed countries. Unfortunately, these products are prone to contaminants such as pesticides, microbes, heavy metals, chemical toxins, and common conventional drugs. This observation has triggered interest in their safety Adelinesuyien et.al. (J. Tradit. Chin. Med. (2013) 33(1): 119-124) detected high level of Mn (18.545 mg/L) and low levels (<1mg/L) of other heavy metals (Cu, Cd, Pb, Fe and Zn) in 4 commonly consumed Chinese herbal medicines. Harris et. al. (Sci. Total Environ. (2011) 409: 4297–4305) found that wild plants contained higher levels of heavy metals than cultivated samples. They also found based on assumption of likely mode of consumption that majority of the samples tested contained levels of heavy metals that would not be of concern. However, using conservative scenario of consumption, 69% of the samples contained heavy metals that could contribute to elevated levels of exposure. Given the differences of potential exposure between the 'likely' and 'conservative' scenarios, the authors recommended more research and monitoring of heavy metals. In our investigations we studied mineral and heavy metal content of three brands of herbal supplements commonly consumed in Indiana. We will report on human exposure to these trace elements based on manufacturer daily recommended intake of the herbal supplements, we will compare this to the recommended daily intakes and use principal component analysis to determine what elements helps to cluster them in any pattern.

Abstract Text

A new analytical method based on slurry sampling combined with a direct hydride generation (HG) for the determination of arsenic and selenium in rice samples was developed. The generated hydrides were introduced to a inductively coupled plasma – atomic emission (ICP-AES) spectrometer. This relatively simple analytical procedure has been shown to give total amounts of arsenic and selenium very close to the results obtained by the determination of these elements after a total decomposition of organic matter and further dissolution of the rice samples.

Some basic figures-of-merit including accuracy and precision of this slurry sampling hydride generation method were additionally studied using a certified reference material. The analytical results were fully comparable.

Abstract Text

Near-infrared spectroscopy is a powerful tool for detecting adulteration of food ingredients at economically relevant levels. A single rapid measurement can provide qualitative material identification and quantitative property prediction as well as screening for contamination by undesired materials.

Traditional methods for adulteration screening are either targeted, in which a calibration is built for each adulterant, or non-targeted, in which adulteration is inferred from a poor fit to a model of good-quality material. Both of these methods are valuable, but each has drawbacks.

Targeted methods offer the ability to estimate detection limits and give the best sensitivity, but are time-consuming to develop and are limited to the materials for which they are calibrated. Non-targeted methods do not require calibration for each adulterant, but it is difficult to determine detection limits and the sensitivity is reduced because the method contains no information about the spectral structure of the adulterant.

In this submission, we describe an algorithm that attempts to combine the best elements of targeted and non-targeted approaches while minimising their shortcomings. Combining a principal components model of the un-adulterated material with a library of adulterant spectra permits much greater sensitivity than SIMCA, but requires only a fraction of the method development time of quantitative methods like PLS.

Abstract Text

Persistent organic pollutants (POPs) are lipophilic, and can collect in the fatty tissues of living organisms. For this reason, they bioaccumulate through the food chain and can be found in edible oils and oil-containing foods. Testing oily samples for POPs can be problematic due to the high background created by the fats present. Common extraction techniques such as liquid-liquid extraction use nonpolar solvents, which results in a great deal of fatty matrix being coextracted with the analytes. Clean up using large solid phase extraction (SPE) cartridges of silica or alumina is often required for these types of samples prior to chromatographic analysis.

In this presentation, we will present an extraction method for POPs from oily samples that utilizes a new dual-layer SPE cartridge.

Specifically, the method will be applied to the extraction of polychlorinated biphenyls (PCBs) from fish and soybean oils, and polynuclear aromatic hydrocarbons (PAHs) from butter. Undiluted sample is weighed directly onto the cartridge, and elution of the analytes is performed in a single step using acetonitrile. The extract is then concentrated and analyzed directly by GC-ECD or GC-MS/SIM. In the case of the fish oil and butter samples, a secondary cleanup was performed using a small silica gel SPE cartridge. The details of the method will be explained, and the presented data will show good recovery and reproducibility of spiked replicates. The proposed method demonstrated advantages in sample cleanup versus other common sample preparation strategies.

Abstract Text

The purpose of this study was to develop and validate a method for analysis of pesticides and toxic chemicals in different food matrices using dispersive solid phase extraction. Trace amounts of pesticides and toxic chemicals in different food matrices were determined by modified QuEChERS (Quick, Easy, Cheap, Effective, Rugged, and Safe), which employed a C18 sorbent, primary secondary amine (PSA), and magnesium sulfate anhydrous in conjunction with a patented compound known as Carbon X for the dispersive solid-phase extraction (dSPE). The carbon X used in this method is similar in design and function to carbon coated silica compounds that better absorb matrix and reduce absorption of analytes of interest. The study was validated on a variety of matrices from vegetables to high fat content foods. Each matrix was fortified with pesticides and toxic chemicals at high and low levels for screening and confirmation, respectively. The extract was then analyzed by gas chromatography-mass spectrometry (GC-MS) or by liquid chromatography-tandem mass spectrometry (LC-MS/MS). Triphenyl phosphate (TPP) was used as internal standard for quantification in both methods. Preliminary data showed promising results with good recoveries and low relative standard deviations obtained for different matrices.

Abstract Text

Full-automated high resolution 1H-NMR spectroscopy offers unique screening capabilities for food quality and authenticity by combining non-targeted and targeted screening in one analysis (15 - 20 minutes from acquisition to report). An advantage is its absolute reproducibility and transferability for laboratory to laboratory, which is not equaled by other methods currently used in food analysis. NMR reproducibility allows statistical investigations e.g. for detection of variety, mixing of varieties, geographical origin and adulterations, where smallest changes of many ingredients at the same time must be recorded. Reproducibility and transferability of the solutions shown are user-, instrument- and laboratory-independent. Sample preparation, measurement and processing are based on strict standard operation procedures which are substantial for this fully automated solution. The non-targeted approach to the data allows detecting even unknown deviations, if they are visible in the 1H-NMR spectra of e.g. fruit juice, wine, honey or edible oils. The same data acquired in high throughput mode are also subjected to quantification of multiple compounds. The fully automated 1H-NMR methodology will shortly be introduced and then results on fruit juices, wine and honey will be presented and the advantages of the fully automated 1H-NMR solutions shown. The method has been proven on fruit juices and wine, where so far unknown frauds could be detected. In addition conventional targeted parameters are obtained in the same analysis. This technology has additionally the advantage that NMR is completely quantitative and concentration calibration only has to be done once for all compounds.

Abstract Text

An immunomagnetic separation (IMS) method was developed for separating Salmonella typhimurium bacteria from large-volume samples of raw eggs. An egg was homogenized with a blender. The homogenized egg material was diluted with a 0.05% Triton X-100 solution to make a 200 mL sample mixture. Anti-Salmonella typhimurium antibody coated magnetic micro particles (MMP) were used to trap the Salmonella bacteria in the sample mixture. The Salmonella-trapped MMP were separated from the egg sample mixture by using a large magnet. An enzyme-linked immunosorbent assay method was adopted and revised for detecting the bacteria trapped onto the MMP. A horseradish peroxidase (HRP) labeled anti-Salmonella typhimurium antibody was used to label the trapped bacteria, and a Sureblue™ solution was used as a substrate. The color compound resulted from HRP-catalyzed reaction was detected with UV/Vis absorption spectrometry using a 1 cm sample cell. This simple method can detect 1.4×10^7 Salmonella typhimurium cells in one raw egg (7.0×10^4 Salmonella typhimurium cells/mL in a sample mixture) without any pre-enrichment. The results presented in this paper demonstrate the feasibility of using IMS for separating bacteria from large volume complex samples, which could be adopted for detecting bacteria in other type samples in food safety inspection.

Abstract Text

Determination of traceability in cured ham process is being a difficult task. In this study, we used Synchrotron XAS analysis to direct determination of Fe and Zn species in ham muscle and Zn species in visible fat (intramuscular fat) of Iberian dry-cured ham, IDCH.

Ham samples were obtained from certified IDCH from south of Spain at different curing time ranging from three to forty months. XAS spectra obtained at both Max Lab and ALBA Cells Synchrotrons allow the direct identification of Fe and Zn species in target samples containing low concentrations of Fe and Zn that have not been altered by extraction techniques. Corresponding spectra of individual reference compounds included both organic and inorganic species of Zn(II), Fe(III) and Fe(II) usually present in mammalian meat products.

Results for iron indicate that both organic and inorganic compounds are present in IDCH muscle, three main facts were observed: (1) inorganic iron is always found in less proportion than organic iron, (2) remarkable differences on iron species are found between surface and bulk muscle samples and (3) percentage of Iron (II) species increases with curing time.

With respect to Zn, findings can be summarize as follows: (1) inorganic species were found relatively higher than organic species in IDCH muscle, (2) this difference increases in fat samples, (3) difference between surface and bulk samples are lower than those obtained for iron species. Correlation between results obtained and IDCH curing time will be presented.

Abstract Text

The level of CO₂ inside meat packages is an indicator of freshness. If the CO₂ level changes during storage it is a clear indicator that bacteria are growing inside the package and/or the package is not well sealed and the modified atmosphere has been compromised. However, currently there is no available non-destructive way to know the CO₂ concentration inside the package (1).

To this end, the objective of SmartPack project is to exploit the development and integration of a CO₂ sensor in meat packages using the imaging and communications capabilities of SmartPhones for monitoring the freshness of packaged foods.

An alternative approach to the popular one based on the acidity of the CO₂ molecule is employed. The switchable-hydrophilicity solvent, N,N,N'-tributylpentanamidine (TBPA) is used, this molecule is able to reversibly bind CO₂ according to the following scheme: TBPA + CO₂ + H₂O \rightleftharpoons TBPA+ + HCO₃⁻

This reaction involves a large change in the polarity that can be visualised by means of a solvatochromic dye (2). Three solvatochromic dyes have been tested to find the optimum system for CO₂ detection.

The performance of the freshness indicator is studied under different conditions, carrying out calibrations at different temperatures and relative humidities using UV-vis spectrophotometry.

Promising results have been found, the next step is to print the CO₂ sensor on plastic films currently used for meat packaging and the final goal of this project is to develop the Smartpack App that will allow the CO₂ concentration in the package to be tracked simply by taking a picture of the membrane with a smart phone.

Abstract Text

For the food industry, it is important to produce reliable products that are free of hazard and preserve them for long periods. Many microorganisms can grow in food without causing any physical changes like odor, color, texture on food and, at the same time, produce metabolites that threatens human health causing illness and even deaths. New techniques need to be developed for inactivation of molds that cause losses during storage of products and produce the carcinogenic substances called mycotoxins.

In this study, a lab-scale fluidized bed reactor was designed implying a low temperature-atmospheric pressure plasma source and the effect on mold decontamination was investigated. Fluidized bed atmospheric pressure plasma reactor system was characterized based on fluidization velocity, bed height and L/D ratio parameters and the decontamination process was carried out on the model food contaminated in a controlled manner with the aflatoxin-producing mold (*Aspergillus flavus*, *Aspergillus parasiticus*) spores. For this purpose, hazelnut, which have an important place in Turkey's imports was selected as "model food".

The fungal load on the sample was compared before and after plasma process carried out at variable parameters as treatment time and discharge powers. All the parameters above were optimized so that the performance of reactor was determined.

Atmospheric plasma treatments for 1 and 5 min. resulted in a reduction of *A. flavus* population on hazelnuts about 2 and 4.5- \log_{10} cfu/g, respectively. In the case of *A. parasiticus*, atmospheric plasma treatments for 1 and 5 min. resulted in a reduction about 2 and 4.2 \log_{10} cfu/g, respectively.

The background microflora (mold and yeasts) of hazelnuts were treated with atmospheric plasma for 5 min and resulted in a reduction of natural background population to an undetectable level from initial population of about 3.5 \log_{10} cfu/g.

The alterations occurred after plasma process on morphological structures of *A. flavus* and *A. parasiticus* spores were demonstrated with Scanning Electron Microscope (SEM).

Abstract Text

The construction of a wireless communication contact closure signaling system, using newly available electronic components, is described that allows the contact closure start signals from either of two liquid chromatographs to be sent wirelessly to four mass spectrometers and several other detectors, liquid chromatography pumps, and syringe pumps. This new system allows a wide variety of experiments to be performed using two liquid chromatographs, four mass spectrometers, two analog-to-digital converters, an evaporative light scattering detector, a corona charged aerosol detector, and two syringe pumps. Experiments can be reconfigured using only the flips of a few switches to change from multiple parallel mass spectrometry experiments, such as liquid chromatography with 'quadruple parallel mass spectrometry', a so-called LC1/MS4 experiment, to column-switching experiments using two liquid chromatographs and up to four mass spectrometers, LC2/MS4. Additional control of external electronically controlled switching valves involved in column-switching experiments and fraction collection is demonstrated.

Abstract Text

Directly ionizing foods for mass spectrometric (MS) analysis can be a quick way to screen for contaminants. Techniques, such as DART-MS, can rapidly detect intentional (melamine) or inadvertent food contaminants (photoinitiators) without chromatography or sample preparation. Using direct ionization the entire sample is ionized, yielding a complex MS response. Assigning a signal to an analyte can be difficult since measuring m/z does not provide structural information. Direct MS can even 'lose' selectivity by mixing ion signals. Ion fragmentation and high resolution MS (HRMS) can 'add back' selectivity/specificity of direct MS, but may diminish the speed or ease of screening for food contaminants. Little experimental data exists demonstrating the adequacy or figures of merit for these direct MS approaches. Similarly, it has not been established whether direct HRMS sample screening will reduce time or effort for food contaminant analysis.

DART-MS was used to screen food, packaging, and cosmetics for targeted (photoinitiators, plasticizers) and untargeted (food contact materials) contaminants. Traditional chromatography-MS analysis (including quantification) of these samples was compared to DART-MS screenings. The effect of DART-MS criteria was examined, including thresholds, and mass accuracy/resolution on accuracy of the direct-MS screening, and the workload. Targeted screening of other food and packaging by DART-MS missed many true positive samples (>20% false negative) when more than two characteristic ions were required to be detected and/or when one of the ions was required to be a pseudo-molecular ion ($M+/-X$). DART-MS data and screening accuracy for foods, cosmetics, and food packaging will be presented.

Abstract Text

Non-nutritive sweeteners are often used in combination in order to limit undesirable tastes such as bitterness. The list of allowed sweeteners varies from country to country due to various health concerns, and new sweeteners are being developed and/or incorporated into foods frequently. Sweeteners are commonly added to beverages, dried fruits and hard candies as alternatives to sugar. There is a need for a multi-sweetener screening technique to save laboratory time and effort. Direct ionization-Mass Spectrometry (direct-MS) techniques allow near instant mass spectrometric (MS) analysis of samples with little or no sample preparation. Direct-MS can identify a wide variety of target analytes, and permits post-hoc analysis for contaminants not originally targeted, making it a quick, flexible screening tool in a busy regulatory environment. Direct ion sources like the DART™ allow samples to be introduced directly into the ionization beam, and resultant high resolution or tandem mass spectra are collected for rapid identification. There is a need for a fast sweetener screening method for the sensitive and selective determination of these analytes in a variety of foods.

In the current study, DART is applied to the identification of 14 sweeteners of regulatory interest in beverages, dried fruits and hard candies. This novel screening method is very useful as a tool for food safety labs to determine if imported and domestic products require additional quantitative/confirmatory analyses. Such a screening technique is not currently available and will allow for rapid assessments of products needing additional testing in order to ensure compliance with U. S. regulations. Data presented here will show efforts to develop a faster, cheaper, DART-MS method to screen a large number of foods for sweeteners.

Abstract Text

Charge detection mass spectrometry (CDMS) is useful for characterizing the size distribution of large, variable-mass particles such as aerosols, polymers, biomolecules, and even intact cells. The technique relies on the measurement of image charge as highly-charged analyte particles pass near or through a conductor. This is conventionally done using a series of metal tubes. Using a larger number of tubes in series improves the S/N and the accuracy of the charge and mass measurement, although this arrangement is time-consuming to assemble. A much simpler method is to pattern sets of electrodes on printed circuit boards (PCBs). We show that a set of two patterned PCBs arranged as a “sandwich” functions with the same sensitivity as metal tubes. The PCB approach is significantly simpler and less costly to implement.

As a particle passes through an electrode, the image current produced gives the charge on the particle. An arrangement of two such charge detectors separated by a retarding DC potential allows the m/z of the particle to be determined. The measured m/z combined with the measured charge allows calculation of the absolute mass of the particle. We demonstrate that this arrangement of charge detectors and retarding fields can be patterned onto a single PCB device (a two-PCB sandwich). Data are presented for polystyrene microparticles of various sizes and also bacterial spores (*B. subtilis*).

Abstract Text

RNA likely played a key role in the emergence of life due to its abilities to store information, catalyze chemical reactions, and self-replicate; however, it is unclear how the nucleotides were selected and why only four came to dominate modern RNA in life on Earth. In order to study the influences on abiotic polymerization of RNA from monomeric nucleotides, the nucleotides are typically chemically activated, such as with an imidazole group, and allowed to react in the presence of a catalyst such as montmorillonite clay. Our studies indicate that an unactivated nucleotide can be incorporated into the growing strand, most likely terminating the polymerization reaction. This effect is observed only for some nucleotides and not others. A key consideration in these studies is the analysis of the polymerization products. Traditionally, researchers have employed HPLC and gel electrophoresis (GE) to analyze the RNA products. More recently, investigators have also employed MALDI-TOF MS. We are combining MALDI-TOF MS and capillary electrophoresis to study the inclusion of unactivated nucleotides in the polymer products as well as to determine the lengths of the polymer products. Additionally, we are using CE to separate the RNA strands by sequence as well as by length. Using this approach, we hope to obtain more detailed information about the efficiency and chemical selectivity of the polymerization reactions.

Abstract Text

The RNA World Hypothesis states that RNA was the stepping stone from the prebiotic world to the first life on earth. It hinges on the ability of monomeric ribonucleotides to abiotically polymerize; however, little is known about the processes leading to selection of particular ribonucleotides for inclusion in RNA polymers or their interactions, such as self-assembly, that would modulate their availability for incorporation into growing RNA strands. In addition to the four ribonucleotides in modern RNA, others may have also been included in precursors to modern RNA. One such candidate is inosine monophosphate (IMP) which is of interest because of its likely presence on early earth and its ability to form hydrogen bonds with itself and other ribonucleotides, leading to base pairing as well as formation of alternate structures such as hydrogen-bonded tetrads. Here we describe investigations of IMP monomer that is activated with an imidazole group on the 3' carbon (ImpI) and probe its ability to polymerize with itself and with other unactivated nucleotides (GMP, CMP, AMP, UMP, and IMP) in the presence of montmorillonite clay (MMC), which catalyzes abiotic RNA polymerization, and salts. MALDI-TOF MS is used to analyze the polymerization products from these reactions.

Abstract Text

While mass spectrometers have long been workhorse instruments in laboratory settings, there are numerous field measurements that would benefit from handheld mass spectrometry including safety, security, and environmental monitoring. However, pumping requirements for mass spectrometers have resulted in transportable or fieldable instruments that fall short of handheld forms. Eliminating the turbomolecular pump utilized in these instruments would significantly reduce the system size, weight, and power (SWAP) as well as enhance robustness.

Towards this end, we are developing high-pressure mass spectrometry (HPMS), defined as operation with pressures above 100 mTorr. HPMS reduces pumping requirements through elimination of turbomolecular pumps while enabling instrument platforms with small SWAP. Miniaturized ion traps on the sub-millimeter scale have been used to expand the operating pressure range of the mass analyzer in excess of 1 Torr.

Single CITs and arrays of CITs were fabricated from metal via wet etching with critical dimensions as small as 100 μm . Mass spectra obtained with single CITs, operated at RF drive frequencies up to 60 MHz, displayed unit resolution at operating pressures of 1 Torr of ambient air. CIT arrays demonstrated similar resolution while maintaining the signal intensity of larger traps. To reduce critical dimensions further, CITs were microfabricated in silicon. These silicon-based CITs also demonstrated unit resolution at 1 Torr of ambient air. Further studies into their performance as a function of ambient air pressure will be shown. Through our ion trap development, mass resolution comparable to full scale mass spectrometers is now possible with HPMS.

Abstract Text

TO-15 has been around since the 1990s using a mass spectrometer and automated VOC trap pre-concentration system to analyze atmospheric and now soil gas samples using stainless steel canisters. The analysis was initially designed to have detection limits on the low part per billion volume (ppbv) range although many of the risk level concentrations are more than a factor of 10 to 1000 times lower. Performing this method reliably at this low part per trillion volume (pptv) concentration range is challenging and requires very unique approaches to canister cleanliness, calibration, water management and mass spectrometer operating conditions. This presentation will address these issues and suggest the best procedures this laboratory has found to reliably analyze gas samples at pptv concentrations.

Abstract Text

Visualization of transdermal drug delivery is important for cosmetic companies that provide topical products containing mild active ingredients. Fluorescent microscopy, CLSM (confocal laser scanning microscopy), and TOF-SIMS (time-of-flight secondary ion mass spectrometry) have been typically used for those purposes. The conventional methods, however, have a distinct disadvantage in which biopsy samples are required to obtain a cross-sectional drug penetration image across skin. We present in this study a novel mass spectrometric visualization method to generate pseudo cross-sectional skin images for fast and non-invasive transdermal drug delivery evaluations. After applying an aliquot of a topical cream containing 1% of 4-methoxy salicylic acid potassium salt (4MSK) to the inner forearm of a healthy male volunteer, skin samples were collected by the tape-stripping (TS) technique. Using the standardized TS procedure, stratum corneum (SC), the most outer barrier layer of epidermis, was collected as a sheet on an adhesive tape. After collecting several SC layers by repetitive TS operations, two-dimensional desorption electrospray ionization / mass spectrometry (2D-DESI MS) was utilized to obtain planer distribution information of 4MS(K) penetrated into SC. The collected data was processed by a patent pending method to create a pseudo cross-sectional skin image showing 4MS(K) penetration through SC layers. Potentials and limitations of the approach will be discussed on the presentation.

Abstract Text

[i]Histoplasma capsulatum[/i] ([i]Hc[/i]*) is a dimorphic fungus and causes a respiratory infection known as Histoplasmosis which may develop into a progressive infection, especially for immunocompromised persons. One of the first lines of defense against *[i]Hc[/i]* is macrophage (M ϕ) yet *[i]Hc[/i]* has the ability to avoid immune defenses by replicating within the M ϕ . One of the body's responses to this infection, using the *[i]Hc[/i]* strain G217B, is the simultaneous sequestration of Zn and generation of Reactive Oxygen Species through NADPH within M ϕ s as shown by Vignesh et al. The goal of this work is to determine if *[i]Hc[/i]* compensates during the immune response by expressing more Zn importers and importing more Cu and incorporating Cu into Zn metalloproteins to maintain function. This information will provide greater understanding into the M ϕ host defense mechanism upon infection from the perspective of fungus.*

Metal acquisition was examined under altered growing conditions by manipulating the cell media using a chelating resin. Metal profiles were compared through total metal analysis by ICPMS and the proteomic responses were compared using SEC-HPLC-ICPMS. Select chromatographic fractions were collected, further purified by anion exchange chromatography, and then analyzed by tandem mass spectrometry for protein identification. An *[i]Hc[/i]* database was developed using predicted putative proteins of Hc strain G217B and used to generate a list of predicted metalloproteins using known metal binding domain information. Due to the organism and strain specificity of this database, this application will aid in characterizing the Cu and Zn metalloproteomes of *[i]Hc[/i]* and the approach could be applied to other microbes. Further work includes quantitative proteomics to compare metalloprotein expression in *[i]Hc[/i]* under altered growing conditions. Protein targets include Zn importers as well as Cu and Zn proteins selected from HPLC-ICPMS experiments.

Abstract Text

Cell surface N-glycoproteins play extremely important roles in cell-cell communication, cell-matrix interactions and reactions with environmental cues. Global analysis is exceptionally challenging because many N-glycoproteins are present at low abundance, such as receptors that only have several copies per cell, and they are membrane proteins with a small portion of them being water soluble and exposed to the outside of cells. Here we have developed a novel strategy integrating metabolic labeling and copper-free click chemistry methods and mass spectrometry-based proteomics techniques to analyze cell surface N-glycoproteins comprehensively and site-specifically. A sugar analogue containing an azido group, N-azidoacetylgalactosamine (GalNAz), was fed to cells to label glycoproteins. Glycoproteins with the functional group on the cell surface were further bound to biotin via copper-free click chemistry under physiological conditions. After protein extraction and digestion, glycopeptides with the specific biotin tag were enriched by NeutrAvidin conjugated beads. The enriched glycopeptides were treated by PNGase F in heavy-oxygen water, and the corresponding N-glycan was removed and asparagine (Asn) was converted to aspartic acid (Asp) and tagged with ^{18}O for MS analysis. In our experiment, we identified 144 unique N-glycopeptides containing 152 unique N-glycosylation sites in 104 proteins in HEK293T cells. As expected, over 90% of identified glycoproteins are membrane proteins, which are highly enriched. Many sites are located on important receptors and transporters on the cell surface. The experimental results demonstrated that the current method combining metabolic labeling, copper-free click chemistry and MS-based proteomics techniques is effective to identify the cell surface N-glycoproteome comprehensively and site-specifically.

Abstract Text

Monoclonal antibodies are an important class of therapeutic agents that are in widespread use for the effective treatment of many human diseases. We have used a number of mass spectrometers (Synapt G2 and OrbiTrap Exactive EMR) and ion mobility instruments (Synapt G1 modified to an RF-confining drift-cell and a Synapt G2 travelling wave system) to characterise the NIST monoclonal antibody humanised IgG1k molecule, under native-MS and buffer conditions. All glycoforms are resolved on all observable charge states, however only on the OrbiTrap instrument are the glycoforms fully resolved to baseline. Mobility measurements were made in both helium and nitrogen drift-gases on an RF-confining drift-cell device with derived collision cross-section values for charge states +21 to +26 range from 6696 Å² to 6892 Å² in helium and 7223 Å² to 7403 Å² in nitrogen. This small and gradual increase in collision cross-section can be attributed to a combination of increasing ion-induced dipole interaction between the charge protein and the neutral drift-gas and the enlargement of the protein due to the repulsion of the surface charges. The higher charge states (+27 to +29) show a significant amount of gas-phase unfolding. Molecular dynamic simulations on the NIST monoclonal antibody PDB coordinate structure (HOS, Marino) indicate that the gas-phase structure undergoes a significant amount of compaction. Theoretical collision cross-section calculations on the optimised molecular dynamic derived NIST mAb structure are highly consistent with both helium and nitrogen instrument derived collision cross-section values. Collision induced unfolding experiments were also performed on the +25 charge of the NIST monoclonal antibody standard and could potentially be used as a means of providing additional structural information in addition to a single and limiting, gas-phase derived collision cross-section measurement.

Abstract Text

Small molecule neurotransmitters such as dopamine have been implicated in many neurodegenerative diseases, including Parkinson's Disease and Alzheimer's Disease. Thus, an understanding of dopamine signaling and distribution is critical. Additionally, in primary neuronal cultures, single-cell measurements have been complicated by the inability to identify cell types prior to measurement. By using a *Drosophila* line with GFP-expressing dopaminergic neurons and cultivating primary cell cultures, we are able to identify neurons of interest with fluorescence microscopy and perform targeted single-cell analysis on both living and fixed cell cultures. Amperometric measurements were made using carbon-fiber disk microelectrodes to measure potassium-stimulated dopamine release. Dopamine oxidation at the electrode surface results in a current spike that is proportional to the amount of neurotransmitter released and allows for quantification of discrete exocytotic events from live neurons. MALDI-MS measurements were performed using a benzoyl chloride labeling reaction (increasing the sensitivity of this method by an order of magnitude), with a CHCA matrix applied using a commercially available airbrush. Using a ~5 [micro]m diameter laser beam and employing oversampling techniques, we are able to measure neurotransmitters at the subcellular level. This type of measurement at the single cell level has never before been accomplished with dopaminergic cell targets.

Abstract Text

The nervous system is dynamic and heterogeneous in space and chemical content. Determination of often subtle effects of food, exercise and behavior on neurochemical parameters of the brain requires information rich assays. Such assays employ direct mass spectrometry, magnetic resonance spectroscopy and liquid chromatography-mass spectrometry detection. The different requirements for each method lead to compromises such as selecting a single approach or the use of multiple groups of animals to be used. Here we investigate the influence of dietary supplements on neurochemistry of the brain. We used MRI, followed by micro-volume localized magnetic resonance spectroscopy (MRS) of hippocampal brain regions of live anesthetized mice. The same hippocampi are prepared and sequentially analyzed by SIMS imaging, MALDI-MS imaging, and immunohistochemistry. Additionally, 1 mm in diameter punches from the hippocampi are excised and investigated using quantitative LC-MS. These assays produce complementary and, in some cases, overlapping information on hippocampal metabolite composition and localization. For example, GABA and glutamate levels observed in live animals by MRS are verified in LC-MS measurements. Such workflow generated broad metabolite coverage including classical neurotransmitters and lipids, provided distribution information for a number of compounds, and allowed for quantitative measurements of physiologically active molecules both in live animals and in corresponding brain structures after brain extraction.

Abstract Text

This work considers the introduction of USP 232/233 the new regulations covering trace metals content of pharmaceutical products^[1]. These chapters look at regulatory limits for elemental impurities within pharmaceutical formulations. Issues have arisen over heavy metal content^[2] and poor recovery results for the volatile elements from the dated preparation techniques stated in the current elemental impurities USP chapter 231^[3]. This also coincides with the recent International Conference on Harmonization (ICH) Q3D regulatory limits for elemental impurities within pharmaceutical regulations. Concern has arisen because of differences in both sets of regulations and how these will be applied to pharmaceutical products. Issues have arisen because of the lack of a consistent analysis method, the lack of a digestion/extraction technique and the lack of an available solid reference material.

The work concentrated on the analysis of the elements As, Cd, Pb, Hg(Class 1) and Mo, Co, Se and V(Class 2A). This work involved the use of a microwave digestion system, (CEM SPD) as a method for tablet preparation and the analytical technique of ICP-MS for sample analysis. The optimisation of a Thermo X Series ICP-MS involved looking at several parameters to determine an optimum set of conditions for analysis based on signal to background ratio. The LoD and LoQ for each element were determined. The technique was applied to standard reference material, excipients and formulated products and the results will be discussed. A comparison of ICP-OES and ICP-MS was made.

Abstract Text

Base Excision Repair (BER) is one of the essential DNA repair pathways within the body. BER has a focus on non-bulky DNA lesions, such as oxidized or alkylated bases. If the body's BER pathway is dysfunctional, it can lead to gene mutagenesis resulting in several diseases such as various cancers. Many enzymes involved in BER have affinity towards only a small number of lesion types and contexts. However, endonuclease VIII-like 1 (also known as NEIL1) has been shown to act on a variety of substrates, particularly oxidized thymine and guanine bases. NEIL1 exists in two isoforms within the body, differing only in a single residue. Generated by mRNA editing, the edited form of NEIL1 exhibits different substrate specificities and excision efficiencies compared to the unedited form. As the enzyme responsible for the mRNA editing, ADAR1, is upregulated under oxidative stress, it is possible that edited NEIL1 is generated as a response to these conditions. In addition, oxidative stress has been linked to cancer and other diseases in the past, making the levels of NEIL1 isoforms an interesting target for both functional studies as well as a potential cancer biomarker. In this study, NEIL1 isoform levels were determined via affinity purification-mass spectrometry. Isoform levels were compared across healthy cells, cells exposed to oxidative stress, and established breast cancer cell lines.

Abstract Text

Presence of multiple peptide isomers in a sample mixture can complicate peptide sequencing and may result in incorrect amino acid sequence matches and/or low sequence coverage scores. Ion mobility (IM) is gaining attention as a rapid separation technique that can be used to separate isomers prior to tandem mass spectrometry (MS/MS) analysis. However, limited IM resolving powers may result in unresolved ion populations. Recently, we demonstrated that “pure” collision-induced dissociation (CID) mass spectra of IM unresolved isomers could be extracted using chemometric deconvolution of post-IM/CID data [J. Am. Soc. Mass Spectrom. 23, 1873 (2012)]. In this presentation, we will demonstrate the utility of post-IM/CID deconvolution to improve sequencing of a four-component mixture of IM unresolved peptide isomers (sequences: RYGGFM, RMFGYG, MFRYGG, and FRMYGG).

Peptides will be mixed at different molar concentrations and ionized using electrospray ionization (ESI) on a traveling-wave IM time-of-flight (TOF) mass spectrometer. Doubly-charged peptide ions (m/z 365.67) will be isolated in the quadrupole mass filter prior to IM separation. After IM, peptide ions will be fragmented using CID and applying a 22 V potential difference between the IM cell exit and entrance of a stacked ring ion guide. Fragment ion masses will be determined using the TOF mass spectrometer. Data will be analyzed using in-house developed automated IM deconvolution (AIMD) software [J. Am. Soc. Mass Spectrom. 25, 1810 (2014)].

A successful deconvolution of CID mass spectra from a four-component peptide isomer mixture is provided in Figure 1. For example, it is shown that deconvoluted CID mass spectrum of FRMYGG matches its corresponding pure isomer which should provide dependable sequencing match scores. Results from de novo database searching software to assess the sequencing scores for IM convoluted peptide mixtures, IM deconvoluted peptide mixtures, and pure peptide isomers will be discussed.

Abstract Text

Lightweight fiber-reinforced plastics (FRPs) are ideal substitutes for heavier metal constructions in a variety of industries. In particular, carbon fiber-reinforced plastics (CFRPs) are used increasingly in aircraft/aerospace and marine industries as well as the automotive industry. The main objective is to save energy by lowering fuel consumption. In order to guarantee a long lifetime, an FRP has to be tested under various conditions including thermal treatment, mechanical stress and different atmospheres. With DSC (Differential Scanning Calorimetry), the glass transition and the exothermal curing reaction of a thermosetting resin as the polymer matrix for an FRP can be determined and quantified. Cure monitoring by DEA (Dielectric Analysis) is not restricted to a lab environment; it can also be employed for in-process curing of the thermosetting resins and composites. A multi-channel DEA with a fast data acquisition rate can be connected with disposable IDEX (interdigitated electrodes) comb sensors or reusable sensors such as a Tool Mount Sensor. These can be positioned in a mold for resin transfer molding (RTM), or in a press for prepregs or for sheet molding compounds (SMCs), or they are used for infusion processes or in autoclaves at elevated temperatures and pressures. With DMA (Dynamic-Mechanical Analysis) the glass transition, possible post-curing, and stiffness and damping behavior of an FRP specimen can be measured as a function of temperature, time and frequency. An increasingly-used noncontact method for determination of thermal conductivity in and perpendicular to the fiber orientation is LFA (Light/Laser Flash Analysis). Various sample holders and accessories are available for in-plane and through-plane measurements on different geometries of the FRP. The measurement results presented here demonstrate the capabilities of different thermoanalytical and thermophysical techniques for comprehensive thermal characterization of FRPs such as CFRPs.

Abstract Text

Photoactive azobenzene-containing polymers have generated long-lasting interest and are often investigated using polarized spectral methods. However, the low time resolution of conventional polarized infrared spectroscopy limits its application to slow photoinduced kinetics. To overcome this, we are using polarization modulation infrared structural absorbance spectroscopy (PM-IRSAS), which provides both orientational and conformational information at a 200 ms time resolution, to investigate the photoinduced orientation of both the polymer segments and azobenzene chromophores in thin films of two supramolecular complexes. These complexes are based on hydrogen bonding between poly(4-vinylpyridine) (P4VP) and azobenzene derivatives 4-phenylazophenol (PAP) and 4-hydroxyl-4'-cyanoazobenzene (HCA). Our results show that the in-plane orientation ($\langle P_2 \rangle$) of the azobenzenes decreases with increasing the chromophore content upon irradiation with a polarized 488 nm laser for both P4VP/PAP and P4VP/HCA, the latter having higher $\langle P_2 \rangle$. The residual orientation after the thermal relaxation also decreases with increasing azobenzene content in P4VP/PAP but it increases for P4VP/HCA. The main chain of P4VP barely orients in P4VP/PAP, while photoinduced and residual orientation were only observed for the H-bonded pyridine rings in P4VP/HCA. In this case, the polymer orientation increases with increasing HCA content. Further investigation of this surprising difference in the photoinduced behavior of these two complexes and comparison with birefringence data will also be shown.

Abstract Text

Rare Earth Elements (REE) have become indispensable in many electronic, optical, magnetic and catalytic applications due to their specific properties like magnetism and phosphorescence as well as their ability to both donate and accept electrons. Production of high purity REE is now required for advanced technology applications. Therefore, it is important to be able to determine impurity level. In REE mining process, the extracted REE contains many other REE and due to the line-rich spectra emitted by these elements in ICP-OES, the quality of the final result may be compromised. The quality of the results will also be more important when the application involves Nd Fe B magnetic materials. The application of permanent Nd Fe B magnets ranges from hybrid vehicles and wind power generation to handheld wireless devices or computer disc drives. Accuracy of purity determination may also be compromised due to the line-rich spectra emitted by Nd and Fe. This may not only compromise the quality of the material but also related applications. In this presentation, the interest of High Resolution ICP-OES is demonstrated for trace analysis of REE at the ppm level in Cerium oxide and Gadolinium oxide matrices. Results obtained for the determination of trace elements in Nd Fe B magnetic materials are presented. All results and wavelength profiles for both matrices, in addition to recoveries on spiked samples and stability tests are shown.

Abstract Text

Finding which samples are similar to each other is a task often encountered in many areas of material analysis, from looking at polymorphs and salt forms in preformulation to determining similar groupings of data in competitive analysis or formulated products. There are many approaches to clustering data and depending on the analysis, There can be different definitions as to what constitutes a similar group.

A significant part of defining various groups involves the analyst's review of the resulting groups. Once the groups are defined with some confidence, that knowledge can be used to help determine the proper class for new samples. This talk will look at the Euclidean Distance algorithm, some of the limitations in this approach and the data review steps required when clustering data. Examples will include Vibrational, NMR and XPRD data.

Abstract Text

Perfluoroalkyl compounds are known to exhibit a hydrophobic character on the material surface, although the C–F bond has a large dipole, which should make the molecular surface polar and hydrophilic. This inconsistency has long been a chemical matter to be solved. In the present study, a stratified dipole-arrays model is proposed: the ‘molecular polar surface’ can fully be hidden by forming a two-dimensional (2D) aggregate of the perfluoroalkyl (Rf) groups, which is spontaneously induced by the dipole-dipole interaction arrays due to the helical structure of the Rf group. On this model, a ‘short’ Rf group should play a role of a single Rf group having a hydrophilic character; whereas a ‘long’ Rf group should spontaneously form a hexagonal aggregate. To examine this model, Rf-introduced myristic acids having various Rf lengths are synthesized, and their aggregation properties are analyzed by using the Langmuir monolayer technique aided by a precise infrared spectroscopic analysis.

Abstract Text

Liquid crystal materials find very broad technical applications. Thermotropic liquid crystals were selected by international organisations for Thermal Analysis (ICTAC, GEFTA, ASTM) for temperature calibration of Differential Scanning Calorimeters (DSC), especially in the cooling mode. In the following paper, typical results are shown for this application. Because of the influences of temperature cycling that were observed, the thermal stability of liquid crystals was tested by Thermogravimetric Analysis (TGA) and the decomposition products were analyzed using a GC-MS directly coupled to the TGA. The selected liquid crystal materials were demonstrated to be well suited for temperature calibration of DSC instruments. The reproducibility of the melting, mesophase transitions, and crystallization depends strongly on the applied temperature limits. The volatile products are identified by coupled GC-MS as fragments of the LC molecules at low temperature, and the molecule ions at higher temperature.

Abstract Text

Our research group has been studying the properties and applications of a carbon material discovered from the pyrolysis of asphalt; GUITAR (Graphite from the University of Idaho Thermolyzed Asphalt Reaction). From various microscopic, spectroscopic and electrochemical characterizations, this material has proven unique and different from other carbon materials, including graphite and graphene. Apart from asphalt, various starting materials including food products have also been successful in the TAR process. Deposition of GUITAR films is chemical vapor based and the formation is conformable to nature and texture of substrate. In this presentation, four major electrochemical properties that distinguish GUITAR from other carbon materials will be discussed. In property (i), the standard heterogeneous electron transfer rate constant across the basal plane (BP) of GUITAR with Ferricyanide of 0.01 cm/s is 2-7 orders of magnitude greater than other BP-graphites. In property (ii), the anodic potential limit of 2.1 volts vs. SHE is 400-700 mV greater than graphites. In property (iii), the hydrogen overpotential in 1 M Sulfuric acid exceeds other graphitic materials by ca. 500 mV. In property (iv), it was determined that the edge planes (EP) of GUITAR are in a chemically different environment than other edge graphitic materials. Based on these properties, application of GUITAR in vanadium redox flow battery will also be discussed.

Abstract Text

Analysis of samples with high salt content is common in many application fields. Brine, which is a saturated solution of salt, i.e. a solution containing up to 30% sodium chloride, is used in the food industry for food preservation in both human and animal nutrition. Analysis for heavy metals at trace level in such a solution is then necessary for food safety purposes. Brine analysis is also performed in the chemical industry for the production of products such as chlorine, caustic soda, soda-ash, pure sodium and pure magnesium. It is not only about the quality of the intermediate or final product but also the safety of the process. For example, an excessive amount of magnesium in salt brine of electrolytic cells causes hydrogen evolution that may form an explosive mixture causing damage and also toxic chlorine release. Recently, the exploration of shale oil has led to the need for the analysis of flowback water that may contain high concentrations of salts, chloride and bromide.

Due to the high salt content, the analysis of such samples using ICP-OES may be complex and may imply dilutions, increasing the risk of errors and limiting the sensitivity of the technique. Radial viewing instruments with vertical torch are usually preferred due to their enhanced stability with such samples compared to axial viewing or dual view instruments. However, standard radial instruments have a limited sensitivity for most of these applications.

The performance of a radial viewing ICP-OES with unique features, 3 mm i.d. injector, sheath gas and Total Plasma View, allowing for the measurement of the whole Normal Analytical Zone of the plasma for improved sensitivity is demonstrated in this poster. Results obtained from an undiluted 25% sodium chloride sample are shown with a detection limit in the range of $\mu\text{g/L}$, as well as the recovery test and long term stability.

Abstract Text

3D printing or additive manufacturing has found extensive use in engineering and biotechnology. The impact of 3D printing continues to grow beyond these fields with the emergence of new technologies and materials along with increasing media coverage of 3D printing applications and improving availability of 3D printers. Recently, 3D-printing has been used to make microfluidic devices for chemical mixing, gradient generation, and sensing applications. Here we show that a desktop 3D-printer based on fused filament fabrication (FFF) can be used to prepare microfluidic devices similar to those that have been reported using more expensive 3D-printing methods. We also demonstrate low-cost, easy-to-prepare, 3D-printed microfluidic devices for biosensing based on flow-injection amperometry. Devices are printed using poly(ethylene terephthalate) and feature threaded ports to connect polyetheretherketone (PEEK) tubing via printed fittings prepared from acrylonitrile butadiene styrene (ABS). These devices feature channels designed to have width and height dimensions ≈ 100 [micro]m and are semitransparent to allow visualization of the solution-filled channels. Electrochemical measurements are conducted in 3D-printed channels by incorporating threaded access ports into which a fitting equipped with electrodes is inserted. We demonstrate that FFF can be used to prepare simple, inexpensive 3D-printed microfluidic devices with integrated electrodes to serve as protein biosensors.

Abstract Text

Preterm birth (PTB) is a pregnancy complication that involves delivery before 37 weeks of pregnancy. PTB causes many neonatal deaths and illnesses worldwide. Unfortunately, current clinical methods lack the ability to diagnose PTB at an early stage. Hence, therapeutic interventions are often initiated too late to prevent PTB. Several serum PTB biomarkers have recently been identified,¹ including three peptides and six proteins. We are designing microfluidic-based platforms that integrate immunoaffinity extraction, sample enrichment, on-chip labeling, and microchip electrophoresis for rapid analysis of PTB biomarkers. To date, we have developed a microchip electrophoresis protocol to separate four PTB biomarkers, including three peptides and one protein. Moreover, we have designed a multi-layer integrated microfluidic system consisting of polydimethylsiloxane valves with a peristaltic pump, and a porous polymer monolith in a thermoplastic layer. The valves and pump are fabricated using soft lithography to enable pressure-based sample actuation, as an alternative to electrokinetic operation. We have verified the operation of these pumps and valves. We are presently working to optimize on-chip extraction, enrichment, and labeling in these microdevices. In the future, solid-phase extraction and separation will be integrated to enable rapid, on-chip analysis of PTB biomarkers.

Abstract Text

Interactions of soluble proteins with the cell membrane and membrane-bound proteins are critical in regulating the blood coagulation cascade. Among other influences, the membrane lipid composition can greatly effect protein binding and activation; however, a deeper understanding of these effects could lead to new insights that suggest better treatments for bleeding-related conditions such as hemophilia. We have developed a powerful multiplexed assay platform to directly monitor complex protein-lipid interactions by spatially immobilizing phospholipid bilayer Nanodiscs onto silicon photonic microring resonator arrays. Nanodiscs are discrete lipid bilayer mimics that are well-defined by an amphipathic protein belt. They are easily fabricated, offer a high degree of control over lipid composition, and allow for the reliable incorporation of integral membrane proteins. Silicon photonic microring resonators are a label-free and modularly multiplexable sensor technology capable of monitoring binding interactions in real time without the use of enzymatic or fluorescent tags. Nanodiscs containing varying ratios of different lipids (phosphatidylcholine, phosphatidylserine, and phosphatidic acid) were arrayed onto sensor chips. Kinetic rate constants that govern binding and unbinding were then determined for important blood clotting proteins such as activated Factor VII (FVIIa), Factor IX (FIX), Factor X (FX), and Prothrombin. The effects of lipid composition on the kinetic rates of FX and FIX binding to the Tissue Factor (TF)-FVIIa complex were also determined, providing unique insights into a key multi-protein interaction of the blood clotting cascade.

Abstract Text

Non-invasive molecular tests are extremely appealing for cancer diagnosis and treatment where tissue biopsy is highly invasive and costly. Exosomes are cell-derived small membrane vesicles, which are enriched with a subset of molecular components from the origin cells, such as miRNA, mRNA and proteins. Exosomes have been implicated in many biological functions and disease development. However, biology and clinical value of exosomes remain largely unknown, due in part to current technical challenges in rapid isolation, molecular classification and comprehensive analysis of exosomes. Here we have developed a new microfluidics-based approach to improve the isolation and molecular analysis of circulating exosome directly from plasma samples. Our microfluidic technique integrates immunomagnetic isolation and in situ multiplexed immunofluorescence quantification of biomarker expression on exosome surface. Using this method, we demonstrated efficient isolation of CD9+ exosomes directly from plasma of ovarian cancer patients and on-chip quantitative measurement of three tumor biomarkers, CA125, EpCAM and HE4, all streamlined in a rapid assay (<1 hour). Because of the simple design and high performance, this technology holds the potential to accelerate translational investigation and clinical use of exosomes as a non-invasive biomarker for cancer diagnosis.

Abstract Text

Many groups have studied organ-level functionality on an in vitro platform by combining microsystem engineering with cell/tissue biology. By creating in vitro models of human tissue (both healthy and diseased) with drug delivery/metabolism, this technique has shown potential to revolutionize human healthcare. 3D printing of such platforms has enabled our group to fabricate bioanalytical systems that are high-throughput, rigid, reusable, reproducible and amenable to automated instruments. In this study, 3D printing was used to fabricate an in vitro platform for studying communication between the endocrine and circulatory systems. Specifically, a pancreatic beta cell mimic (INS-1 cells) was applied to secrete such hormones as insulin and C-peptide into a circulating blood stream, which elicited responses from red blood cells (RBCs) that, in turn, exerted a downstream impact on the vessel barrier mimicked by integrated endothelial cells. It was found that stimulated endocrine release (using 12 mM glucose) increased the release of ATP from 173 ± 13 nM to 323 ± 19 nM ($n=5$, error=SEM); downstream on the same device, the RBC-derived ATP stimulated increases in endothelium-derived nitric oxide production from 0.77 ± 0.10 μ M to 1.40 ± 0.16 μ M ($n=5$, error=SEM). Positive and negative controls can be performed, in parallel, on the same 3D-printed device. Calibration sets are measured in static wells (on the same device) by a plate reader. Importantly, studies of inter-system communication that include a circulation mimic will help create realistic versions of physiological processes using controlled, in vitro platforms.

Abstract Text

A microfluidic diffusion diluter was used to create a stable concentration gradient for dose responses studies. A new calibration method was developed to correct optical artifact effects on the linear gradient. The calibration method was used to find unknown concentrations with 12 % error. Flow rate dependant studies showed that changing the flow rates generated different gradient patterns. Mathematical simulations using COMSOL multiphysics were performed to validate experimental data. Experimental data obtained for the flow rate studies agreed with simulation results. Microfluidic diffusion diluter used in this study consisted of 128 culture chambers on each side of the main fluidic channel. Cells can be loaded into culture chambers using vacuum actuation and cultured for long times under low shear stress. Decreasing the size of the culture chambers resulted in faster gradient formation (20 min). Mass transport into side channels of the microfluidic diffusion diluter used in this study is an important factor in creating the gradient using diffusional mixing as a function of the distance. To demonstrate the devices' utility a H₂O₂ gradient was generated while culturing Ramos cells. Cell viability was assayed at 256 culture chambers, each at a discrete H₂O₂ concentration. As expected the cell viability for upper side channels increased (inject H₂O₂) whereas cell viability in lower side channels (inject medium) decreased along the chip due to diffusional mixing as a function of distance. COMSOL simulations were used to identify the effective concentration of H₂O₂ for cell viability in each side chamber at 45 min. Development of the microfluidic device used in this study will lead to a new direction generating concentration gradients that could be used to study hundreds of concentrations of a drug in a single experiment. In addition, with modification to chip design concentration gradients can be generated on different types of cells in a single chip.

Abstract Text

Parathyroid hormone-related peptide (PTHrP) is a paraneoplastic protein normally expressed in many tissues and recognized as the major causative agent of humoral hypercalcemia of malignancy (HHM). Independent of hypercalcemia, PTHrP has also been implicated in tumor progression and metastasis of a variety of human cancers and its expression mechanistically linked to the development of both skeletal and extra-skeletal metastases. Conventional PTHrP detection methods such as immunoradiometric assay (IRMA) lack the sensitivity required to measure its levels prior to the development of hypercalcemia and pose a health hazard due to the use of reagents labeled with radioactive isotopes. Therefore, there is need to develop ultrasensitive, low-cost assay for PTHrP that can aid in prognosis, diagnosis and therapeutic assessment of cancer patients at earlier stages of the disease and prior to the development of HHM. Here we describe a simple, ultrasensitive modular microfluidic system for on-line capture and detection of different fragments of PTHrP consisting of N-terminal, mid-region and C-terminal peptides. The system features a small microfluidic chamber for on-line capture of the peptides from serum by magnetic beads labeled with many copies of peptide-specific antibodies and signal-transducing enzyme labels. The magnetic bead-peptide conjugate is then washed and directed to a second microfluidic detection chamber housing an 8-electrode array. To reduce the assay cost, gold immunoarrays fabricated by ink-jet printing of 4 nm alkylthiol gold nanoparticles (\$0.2) were employed as sensor arrays. Ultralow detection limit of 3 fg/mL (≈ 1000 fold lower than the commercially available IRMAs) was achieved for simultaneous detection of PTHrP fragments within a short time (30 minutes). Accuracy and diagnostic utility of the assays was demonstrated by good correlation of the immunoarray level of PTHrP in serum and plasma from cancer patients with results from IRMA.

Abstract Title **Measurement of Total Antioxidant Capacity (TAC) on Microfluidic Paper-Based Analytical Devices (μ PADs)**

Primary Author Meng Sun
University of Kansas

Date: Wednesday, March 11, 2015 - After

Time: 04:05 PM

Room: 270

Co-Author(s) Michael A. Johnson

Abstract Text

Mounting evidence has implicated the excessive production of reactive oxygen species, and its resulting cellular damage, as a key contributor to the development of specific disease states, such as Huntington's disease and Lou Gehrig's disease. It is apparent, therefore, that the total antioxidant capacity (TAC), which is directly related to the ability of an organism to combat oxidative stress, is an important parameter to measure in these disorders as well as other conditions. Thus, it is essential to establish a quick, simple, low cost, and sensitive diagnostic method to monitor antioxidant capacity on a regular basis. Microfluidic paper-based analytical devices (μ PADs) provide all of these advantages in obtaining such measurements: they are low-cost, easy to use, provide rapid on-site diagnosis, and require low sample volume. In this work, we developed a colorimetric assay on μ PADs to measure TAC in blood plasma samples. To run this assay, less than 1- μ L of blood is required with subsequent plasma isolation in a unique, flowing plug separation device. Our studies indicate that this method provides good limits of detection of TAC in diluted blood samples. As proof of concept, we measured TAC in blood samples collected from R6/2 Huntington's disease model mice and their age-matched, wild-type littermates. Our measurements revealed that TAC was significantly greater in the R6/2 sample compared to WT, consistent with the concept that R6/2 mice produce an enhanced capacity to deal with increased oxidative stress. In future studies, this method should allow for rapid diagnosis of biomarkers in blood or other bodily fluids in which only small sample sizes may be available, e.g. cerebral spinal fluid (CSF) or tears.

Abstract Text

The correspondence of chemical bond energy levels (10-100 KCal/mol) with UV/visible frequencies (10^{14} - 10^{15} cps) results in a robust spectral resonance that provides a new spectrophotometric technique for the qualitative and quantitative analysis of complex organic substances such as crude oils. Friedel-Crafts (FC) electrophilic alkylations exhibit particularly robust spectral signals in this region while the produced chromophores are adsorbed to the active Lewis acid catalyst, Aluminum Chloride. This strong spectral energy is related to the electronic population inversion achieved in the course of these exothermic chemical reactions as expressed in the definition of a chemical laser as, "a laser operating on a population inversion produced-directly or indirectly-in the course of an exothermic chemical reaction". (Gross, R.W., (1976) "Handbook of Chemical Lasers", John Wiley and Sons. The significance of this new technique lies in the enhancement of the signal-to-noise ratio (SNR) resulting from the strong spectral signals produced when aromatics present in the crude oils (3-30%) undergo the FC reactions forming the chromophores. Thus, a relatively few "marker compounds" present in a complex substance provide definitive identification of the substance. The broadband spectra of these marker compounds undergo multivariate analysis that generates a reference library of standards to which samples are compared. A discussion of the qualitative analysis (curve shape) and quantitative (area under the curve) is presented.

The utility of this new chemical reaction/spectrophotometric technique is apparent for the analysis of petroleum hydrocarbons in the oil services industry as well as in environmental applications.

Abstract Text

Control and optimization of refinery process units, from distillation, conversion and upgrading units through to final product blending and release, has always been a major concern and objective for refinery operations, critical as it is for effective and economic operation. Process optical spectroscopy analyzers are attractive tools for stream quality measurement. However analytical technologies of this type depend on calibration modelling, correct sample conditioning, suitable installation environment and a dedicated and effective team-work approach to project execution and on-going operational use. This paper will explore these aspects in more detail, and look also at recent technical innovations within process spectroscopy, including simpler more robust process FT-NIR analysers with minimum footprint, utility requirement and significantly extended maintenance intervals, which mitigate some of these costs and allow for low-risk and robust project execution.

Date: Wednesday, March 11, 2015 - After

Time: 02:10 PM

Room: 271

Co-Author(s) Jonathan Comeaux

Abstract Text

The room temperature fluorescence (RTF) quenching of two model PAH compounds was investigated to evaluate the influence of residual water on the interactions between a heavy atom salt (NaI) and the PAH compounds within the novel solid matrix sugar glasses. These interactions have not been thoroughly investigated. Sugar glasses were prepared with a constant analyte concentration and at various quencher concentrations (0.047-0.56 M). The fluorescence intensity was measured with an Agilent Cary Eclipse spectrophotometer. The solvents used to prepare the glasses were mixtures of methanol and water (50/50 and 60/40 respectively). Stern-Volmer plots showed positive deviations indicating a complex type of quenching with glasses prepared with 50/50. Attempts to reduce the static and dynamic quenching components were unsuccessful. However, the quenching sphere of action model of Perrin fit the data; the radiuses of the quenching sphere for both compounds were determined with values of 10.62 Å for pyrene and 10.12 Å for naphthalene. Reducing the amount of water in the preparation changed the mechanism of quenching to a static ground-state complex type of quenching which was indicated by a linear Stern-Volmer plot with an equilibrium constant of $5.38 \pm 0.188 \text{ M}^{-1}$ for pyrene. Residual water left in the sugar glass after preparation influences the interactions of the heavy atom with the fluorophore and could have a significant influence on phosphorescence emission measurements. Reduction of water indicated a more rigid environment by the change in quenching mechanism.

Abstract Text

Industry today is actively seeking methods of performing more efficiently and using waste streams as alternative sources of income. In many industries the reclaimed food, plant fiber and animal fats are used in a transesterification process to produce glycerol and methyl esters. The fatty acid methyl esters (FAME) produced in the process are commonly used as either a pure biofuel source (B100) or as an additive in diesel fuel. Diesel fuels for automotive applications are commonly blended with FAME and contain biofuel from 2 to 30% (B2-B30). Biofuels are typically transported using various multi-product distribution sources such as pipe lines, tanker trucks, and marine barges that can pose a contamination risk for other fuel sources. For most high performance fuel applications, FAME is a contaminant detrimental to engine performance. As a result of contamination, the issue of FAME in fuels has become a major concern. To analyze FAME in fuels, PerkinElmer has developed an easy to use analysis package containing pre-calibrated quantitation methods for testing of FAME. This analysis technique is based on the European EN 14078 method which uses a liquid transmission cell and Beer's Law quantitation of the methyl ester carbonyl peak for the analysis of low to high concentrations of FAME. This analysis package has been used to test various fuel samples acquired from commercial distribution sources to determine the FAME content. The results of this testing using pre-calibrated quantitation methods and a portable FTIR spectrometer are presented.

Time: 03:05 PM

Room: 271

Co-Author(s)

Abstract Text

The combination of photoionization spectroscopy and time of flight mass spectrometry has been applied to perform real time studies of tobacco product smoke delivery. The photoionization events come from vacuum ultraviolet photoionization detectors (PID, krypton, 10.8 eV) and a dual-lamp design is implemented to enhance the detection sensitivity. Both the PID lamps and the molecular beam are run in continuous modes while the photo-ions are extracted at 80 KHz into the mass spectrometer. The instrument development enables high detection sensitivity and sub-second time resolution for a puff event, making it possible for the real time measurements of important species produced from smoking, such as glycerin, menthol and nicotine. The measured intra-puff and inter-puff profiles reveal the dynamic evolution of chemicals during smoking.

Abstract Text

Infrared and near infrared are useful techniques for QA/QC activities in the pharmaceutical, chemical, petrochemical and food industries. Current FTIR and FTNIRs are highly sensitive, stable and reproducible leading to little or no maintenance for the analysis calibrations. However, deployment of FTIR has been hindered by cumbersome sampling requirements and FTNIR by complicated calibration requirements. In this paper we present a novel disposable sampling methodology suitable for the mid IR that enables easy to calibrate and easy to use QA/QC applications with FTIR.

Abstract Text

Antioxidants react with the CUPRAC reagent (cupric neocuproine) to produce the Cu(I)-neocuproine (Nc) chromophore measured spectrophotometrically [1]. The method was successfully applied in our laboratory to various food extracts and human serum [2,3]. Lipophilic and hydrophilic antioxidants could be simultaneously assayed in acetone-water as their inclusion complexes with methyl- β -cyclodextrin. A low-cost optical antioxidant sensor (CUPRAC sensor) was developed by immobilizing the Cu(II)-Nc reagent onto a perfluorosulfonate cation-exchange polymer membrane (Nafion®). A novel on-line HPLC-CUPRAC method was developed for the selective determination of polyphenols in complex plant matrices. Reactive oxygen species such as hydroxyl and superoxide (SO) anion radicals can be detected and their scavenging actions measured by indirect CUPRAC methods, where either the initial probe or its oxidation products showed CUPRAC reactivity. A modified CUPRAC method for measuring the SO scavenging activity of plasma antioxidants (including thiols) utilized a tert-butylhydroquinone (TBHQ) probe with PMS-NADH non-enzymic SO generation system [4]. Recently electroanalytical, QUENCHER, and catalase activity measurement versions of the CUPRAC methodology have been developed. The current direction of CUPRAC methodology can be best described as an integrated train of measurements providing a useful "antioxidant and antiradical assay package" in biochemistry and food chemistry comprising many assays, and the results are in general accordance with those of established reference methods.

Abstract Text

UV excitation can provide advantages for Raman measurements because of larger Raman cross sections at short wavelengths, the possibility of resonance enhancement, and the ability to spectrally discriminate fluorescence which occurs at longer wavelengths. We are investigating the use of a spatial heterodyne Raman spectrometer (SHRS) for UV Raman measurements. The SHRS design offers advantages over dispersive Raman systems, especially in the UV, including up to 100 times larger acceptance angle and subsequently a larger field of view, very high light throughput, and high UV spectral resolution in a very small package for a UV spectrometer. The large acceptance angle allows large laser spots to be used on the sample, especially important in the UV to minimize laser-induced sample degradation. In previous work we showed the potential of SHRS for standoff Raman measurements, using 532 nm and 244 nm lasers at 5 meter standoff distance. In recent work, standoff UV Raman measurements were made using an SHRS with a 266-nm pulsed laser and a gated detector at standoff distances of ~20 meters, in bright ambient light conditions. In this paper a brief description of both benchtop and standoff UV-SHRS systems will be given and the overall system performance will be discussed. Key performance issues will be highlighted and applications described with emphasis on space exploration and planetary measurements.

Abstract Text

Nonpolar phase synthesized hydrophobic nanocrystals show attractive properties and have demonstrated prominent potential in biomedical applications. However, the preparation of biocompatible nanocrystal is made difficult by the presence of hydrophobic surfactant stabilizer on their surface. To address this obstacle, we have developed a facile, high efficiency, single-phase and low-cost method to convert hydrophobic magnetic nanoparticles (MNPs) to an aqueous phase using tetrahydrofuran, NaOH and 3, 4-dihydroxyhydrocinnamic acid without any complicated organic synthesis. The as-transferred hydrophilic MNPs are water soluble over a wide pH range (pH=3 to 12), and the solubility is pH-controllable. Furthermore, the as-transferred MNPs with carboxylate can be readily adapted with further surface functionalization, varying from small molecule dyes to oligonucleotides and even enzymes. Finally, the strategy developed here can easily be extended to other types of hydrophobic nanoparticles to facilitate biomedical applications of nanomaterials.

Abstract Text

To date, quantification of inorganic nanoparticles in cells has been limited to bulk analysis of homogenized cell samples typically by elemental analysis methods such as inductively coupled plasma mass spectrometry (ICP-MS). These methods provide an average concentration per cell; not ideal for understanding the heterogeneity of the nanoparticle concentration per cell within cell populations. This study investigates synchrotron X-ray fluorescence (SXRF) microscopy, a promising tool to quantify elements in cells, to quantify and characterize the distribution of titanium dioxide nanosphere uptake across cell population. For this study, individual cells were scanned using a dwell time of 5 seconds per pixel and spectral summing in the area around the cell was used to get counts of Ti within the cells. These counts were used with NIST standard 1833 for titanium to quantify the Ti concentration per cell. These results were compared with average nanoparticle concentrations per cell obtained by widely used ICP-MS. The results show that nanoparticle concentrations per cell quantified by SXRF were of one to two orders of magnitude greater compared with ICP-MS. The SXRF results from 112 cells also indicate a Gaussian distribution of the nanoparticle concentration per cell with internalized nanoparticle concentrations from 773–1751 pmol. The results suggest that quantification of nanoparticles in cell populations is subject to limitations of bulk analysis methods including potentially misleading information from taking large population averages to determine physical parameters and the lack of any information about the cellular heterogeneity.

Abstract Text

Single nanoparticle collision based electrochemical methods have demonstrated significant promise for detection and quantification of nanoparticles. In this presentation, we describe development of an electrochemical collision technique to characterize the fundamental surface properties, functionalization and reactivity of metal and metal oxide nanoparticles by nano-impact electrochemistry as the particle collide with a microelectrode. We will demonstrate several applications of this method for assessment of redox active nanoparticles, for monitoring biorecognition events at single particle surfaces for applications in sensing, and as a method enabling rapid quantification of the extent of surface attachment of bioreagents on individual nanoparticles. We will discuss the potential of this approach to complement or replace costly characterization techniques and enable routine study of nanoparticles and their reactivity.

Abstract Text

Cells in the human body are constantly receiving and integrating biomolecular and mechanical cues in a spatially defined manner. Establishing the correlation between these signals and the resulting cellular responses is a driving force in biomaterial design; however, it remains a challenge to orthogonally control mechanical and biomolecular cues. This study presents an approach for spatially controlled, overlapping growth factor immobilization using benzophenone photolithography on collagen-glycosaminoglycan membranes. Controlled material stiffness independent of biomolecule immobilization was achieved using carbodiimide crosslinking. We examined the influence of mechanical and biochemical properties on adipose-derived mesenchymal stem cell bioactivity and lineage-specific gene expression. Results revealed that bone morphogenic protein (BMP-2) and platelet derived growth factor (PDGF-BB) significantly influenced stem cell fate on softer materials, while mechanical properties dominated lineage commitment on the stiffest materials. The described approach enables us to more closely mimic the native extracellular matrix as a means of systematically investigating cell behavior. Further efforts are focused on strategies for dynamic tuning of chemical properties to enable spatial and temporal manipulation of cellular microenvironments.

Abstract Text

Identification of proteins at low abundance or with post-translational modifications is important in the biomedical and clinical research. We propose the microfluidic chips or mesoporous materials as bioreactors for highly efficient and controllable analysis of low-abundant proteins, phosphoproteins, glycoproteins and membrane proteins. A droplet-based microreactor is developed for on-line proteolysis reaction and also acts as an interface to fractionate proteins separated by liquid chromatography and identification by ESI-MS/MS or MALDI-MS. A facile online enrichment protocol is proposed based on microfluidic droplets, and low-abundance biological species are successfully concentrated and analyzed in such a system via the droplet shrinkage. Additionally, the surface interaction or surface charge controlled reaction exhibits highly proteolytic efficiency due to the in situ adsorption of different proteins from bulk solutions into the nanopores or microchannels, where the target biomolecules and enzymes are selectively confined in the microspace to realize a quick biological reaction. The ordered mesoporous matrices tailored by different pore size, surface charge and functional group modifications have been used as nanoreactors to favor the rapid protein digestion and analysis, where the reaction kinetics is simulated.

Abstract Text

Appropriate physical-chemical characterization to determine product quality is vitally important during pre-clinical testing of drug products containing nanomaterials. As a case study, gold, silver, and silica nanoparticles with different physical-chemical attributes and stability considerations were followed through an 8 week repeat dosing study. Particle size and size distribution, morphology and agglomeration, zeta potential, pH, concentration, purity, chemical composition, endotoxin burden, and particle stability in the dosing solution and rodent serum were determined for the stock solutions at the initiation of the study. Particle size and size distribution, pH, agglomeration status, and concentration were then evaluated each week after formulation and post animal dosing. Instrumentation used for the characterization included dynamic light scattering, transmission electron microscopy, UV-vis spectroscopy, and neutron activation analysis.

The silica and gold nanoparticles did not have appreciable stability issues over the dosing timeframe. Silver nanoparticles showed particle instability as well as sensitivity to the formulation and dosing environment as evidenced by agglomeration within the formulation containers and syringes. Interestingly, when reporting the simple numerical results such as Zave or average Feret diameter, there was no evidence of instability, even when the agglomeration and plating was so extensive that it could be observed visually. Histograms obtained by dynamic light scattering as well as morphological analysis of transmission electron micrographs indicated the instability of the formulation. This result highlights the importance of understanding the critical quality attributes of the nanoparticle formulation, the correct methodology to measure these attributes, and the correct ways to analyze the data arising from the methods. By having a solid understanding of these issues, the quality of the product is more likely to be ensured.

Abstract Title **Improving the Sensitivity of Nanohole Arrays and Design of a 96-Well Plate Reader for Plasmonic Sensing**

Primary Author Maxime Couture
Universite de Montreal

Date: Wednesday, March 11, 2015 - After

Time: 03:45 PM

Room: 272

Co-Author(s) Hugo-Pierre Poirier Richard, Jean-François Masson

Abstract Text

This research aims at developing a high throughput biosensor for protein detection based on the nanohole array technology and a custom-made 96-well plate reader. Gold nanohole arrays exhibit distinct plasmonics properties depending on the excitation mode of the surface plasmon polaritons (SPPs). Excitation of such plasmonic material requires simple optical setup working in transmission spectroscopy, benefit from the availability of low-cost manufacturing technologies and exhibit high sensitivity. Gold nanohole arrays can be excited in SPR with the Kretschmann or by grating coupled attenuated transmission (GCAT) configuration. Kretschmann configuration leads to higher sensitivity in nanohole arrays. Tuning the excitation conditions in GCAT can narrow this gap in sensitivity for nanohole arrays between both modes of excitation. Thereby, the optimization of the excitation angle of gold nanohole arrays in GCAT mode leads to an improvement of the sensitivity to binding events. To prove this, we performed a study of the surface and bulk sensitivity of the (1,0) Bloch-Wave SPPs mode for gold nanohole arrays 1000 nm of periodicity for an excitation angle range from 0° to 30° from the normal. At an optimal angle, the wave length shift, in comparison to direct transmission analysis, for the detection of IgG (limit of detection of 1 nM) was improved by a factor of 3. Optimization of the excitation angle of nanohole arrays affect the confinement of the plasmonic field which can lead to applications with techniques such as surface enhanced Raman spectroscopy (SERS) and metal enhanced fluorescence (MEF). Thus, a 96-well plate reader was designed to analyze nanohole arrays at different angles. In conclusion, gold nanohole arrays hold great promise for the development of a future multiplexed plasmonic transducer.

Abstract Text

Measuring proteomic biomarkers which are shed into the bloodstream during disease progression serve as non-invasive mode for clinical diagnostic. However, the greatest challenge in their detection is their rarity in the blood (10^{-18} to 10^{-12} M). In the present work, a technology platform is introduced that integrates Surface Plasmon Resonance imaging (SPRi) and aptamer technology with nanomaterials and microwave-assisted surface functionalization. This unique combination and integration makes it possible for the SPRi biosensor to detect C-reactive protein (biomarker) in spiked human serum at attomolar (10^{-18} Molar) level (zeptomole or fg/ml). The results are encouraging and show promise in extending the platform to detect an array of biomarkers in complex biological fluids that are indicative and even predictive, of disease onset and disease progression.

Abstract Text

While one of the most basic steps in chromatography, proper column installation can make or break chromatographic system performance and productivity. Forming and maintaining leak free connections is critical in achieving low background noise, sharp peaks, optimal column resolution and lifetime. Small leaks, excess void volume and flow path activity take their toll on chromatographic results regardless of the mobile phase being used.

Chromatographers working with HPLC and UHPLC are often challenged by problems such as peak tailing, peak broadening, split peaks, carryover, etc. One common cause for these problems that is often overlooked, and time consuming for troubleshooting, is bad tubing connections. Dead volume or micro-leakage in tubing connections can strongly affect the performance and reproducibility of HPLC and UHPLC analysis, especially with ultra-high pressures and small column dimensions.

Chromatographers working with GC and GC/MS systems often need to retighten fittings as the materials in some ferrules shrink with repeated heat cycling. A new innovative self-tightening column nut eliminates the need to retighten these fittings that chromatographers have learned to live with over the years. These new fittings coupled with a suite of deactivated connectors for gas phase applications make forming and maintaining gas tight connections easy and reliable.

Abstract Text

Comprehensive two-dimensional gas chromatography (GCxGC) is the most effective technique for the analysis of complex volatile and semi-volatile mixtures. A single-stage thermal modulator for GCxGC that requires no consumables for operation has been developed that traps, focuses and reinjects analytes into the second column using a specially prepared coated stainless steel capillary trap. Desorption is completed using a capacitive discharge power supply to resistively heat the trap, while rapid cooling is accomplished by compressing the steel capillary between two passively or actively cooled ceramic pads. An evaluation has been completed that focuses on the repeatability and reproducibility of the results obtained with the device. Investigated samples included diesel fuel, a fragrance mixture, and environmental pollutants including polychlorinated biphenyls, organochlorine pesticides and chlorobenzenes. Replicate analyses of these samples have been performed and within-day repeatability, day-to-day reproducibility, as well as between-trap reproducibility were assessed. The results are very encouraging as negligible shifts in retention times were observed for both within-day and day-to-day comparisons of the studied samples. Eliminating retention time shifts vastly simplifies the advanced statistical analysis of data without the need for alignment procedures. Routine analysis and quality control applications will also benefit from improved retention time reproducibility. An overview of the device operation and the results from this study will be presented.

Abstract Text

Structure determination of proteins of various origins is focus of studies by numerous instrumental methods. Specific behavior of these macromolecules consisting of amino acid residues under mass spectrometry conditions can be interpreted on the basis of established fragmentation pathways of the initial amino acids. A systematic study of alkyl and/or perfluoroacyl derivatives of amino acids and their [²H-], [¹³C-], [¹⁵N]-analogs by GCMS has been carried out for the first time in this research. Mass spectra of L-glycine, L-alanine and L-phenylalanine derivatives will be used for establishing general fragmentation patterns under electron ionization conditions. Among specific dissociation directions the following topics will be discussed: (a) diagnostically important cations useful for structure determination of L-valine, L-leucine and L-isoleucine derivatives, (b) competing fragmentation processes in the molecules of substituted L-serine, L-threonine, L-cysteine, L-methionine, L-aspartic and L-glutamic acids, and (c) charge localization under electron ionization dissociation of substituted L-lysines as well as L-prolines and L-tyrosines. These specific fragmentation pathways for most amino acid derivatives can be useful for their structure determination within peptides and proteins. A special attention will be paid to the formation of nitrilium cations containing 2-C and amino N-atoms, and to ions due to oxygen and hydrogen rearrangements; the mechanisms will be discussed.

Abstract Text

The US Environmental Protection Agency (US EPA) is currently revising Methods 8260 and 8270, which are commonly used gas chromatography/mass spectrometry reference methods for analysis of volatile and semi-volatile organic chemicals in environmental matrices. These methods are part of the SW-846 compendium of Test Methods for Evaluating Solid Waste which provides test procedures and guidance for use in conducting the evaluations and measurements needed to comply with the Resource Conservation and Recovery Act (RCRA) [superscript 1]. This presentation will address the major changes to each of these methods, including the addition of the lower limit of quantitation (LLOQ) verification, updates to the performance data and appropriate preparation techniques, expansion of the analyte lists (to include those frequently found in Superfund sites), addition of advanced mass spectrometry techniques (Tandem Mass Spectrometry, Time-of-Flight), guidance for using hydrogen carrier gas, and clarification of requirements for some quality control elements. This presentation will also discuss the harmonization of these methods with each other, and where possible, harmonization with waste water Methods 624 and 625. This presentation will provide an opportunity for attendees to see the revisions to the methods. These validated methods are expected to be posted on the RCRA Methods website [superscript 2] for comments and use in 2015, with finalization to follow.

Abstract Title **Encouraging Results for Some Challenging Industrial Applications Using a Stationary Phase**

Primary Author Ken Lynam
Agilent Technologies

Date: Wednesday, March 11, 2015 - After

Time: 03:45 PM

Room: 277

Co-Author(s) Gary Lee, J Luong, K Gras, Ronda Gras

Abstract Text

In addition to traditional applications performed by the classical 624 type stationary phase, the DB-624UI was found suitable for use in a number of difficult and challenging chromatographic applications like the characterization of oxygenated compounds in waste water, phenol and alkylated phenols used as anti-oxidant in fuels and lubricants, furans analysis for cellulose degradation monitoring, and sulfur compounds in hydrocarbons to name a few. Example chromatograms highlighting these promising results will be shown.

The stationary phase demonstrated a high degree of inertness with low bleed characteristics with a maximum operating temperature of up to 260oC and a unique selectivity. The column is available in different dimensions and was found to be compatible with different GC techniques such as single or multi-dimensional gas chromatography, comprehensive two-dimensional gas chromatography and hyphenated techniques like GC-MS.

Abstract Text

We combined an Open Probe inlet with a low thermal mass (LTM) ultra fast gas chromatograph (GC) and a mass spectrometer (MS) of GC-MS, forming a new method and device for obtaining real time analysis with separation. The Open Probe is based on a vaporization oven that is open to ambient pressure while having helium purge flow protection to eliminate air leakage into the oven and MS ion source.

Sample introduction into the Open Probe is as simple as: touch the sample, insert the sample holder into the open probe oven for its thermal vaporization and have the mass chromatogram data in 20-30 s.

The Open Probe is mounted onto the LTM fast GC that is coupled either with the Aviv Analytical 5975-SMB GC-MS with Cold EI, or with the Agilent 5975/5977 MSD for obtaining in-vacuum electron ionization, followed by quadrupole-based mass analysis. Open Probe fast GC-MS provides real time analysis in combination with GC separation, library identification, absence of ion suppression effects and uniform electron ionization response for improved quantitation. Furthermore, it employs the simple and low cost mass spectrometer of GC-MS.

The operation of the Open Probe fast GC-MS will be demonstrated with forensic application including:

- 30 s full analysis cycle time of heroin in its street drug powder.
- Fast THC and CBD analysis in Cannabis.
- Cockroach repeller liquid residue on tomato analysis in 30 s.
- Trace TNT on human hand that was analyzed in 40 s with NIST library identification of TNT.

Abstract Text

Fire investigation is always a challenging task for forensic chemists. Recently, we have demonstrated the application of chemometric tools to the automated identification of gasoline in casework arson samples. In order to expand these methods to a wider library of ignitable liquids (ILs), a method to simulate fire debris would be ideal. However, established simulation methods have been shown to be inadequate for the purposes of training a model to classify casework arson samples.

Here, we present the results of a study into the effects of pyrolysis conditions on the pattern of observed pyrolysates when analysed by GC in order to have a better understanding of pyrolysis and to ultimately enable the rapid generation of fire debris suitable for training chemometric models for casework samples. A variety of substrates were pyrolysed individually and in various combinations. Parameters tested for the pyrolysis include the pyrolysis temperature, the heating profile for the samples, and the composition of the atmosphere in the pyrolysis tube.

Abstract Text

Synthetic cathinones are a class of psychoactive compounds marketed as alternatives to drugs like methamphetamine and ecstasy. Cathinones are addictive and their use has been linked to overdoses and deaths. Although legislation has attempted to restrict these compounds, only a few specific compounds are legislated while others have indeterminate legal status. With new derivatives of cathinones continually surfacing, controlling these substances is challenging.

Ambient MS methods increase throughput of analyses as well as provide more detailed structural information of unknowns. DART-MS is an ambient technique where an unknown white powder can be ionized directly without extraction or chromatography, greatly reducing analysis time. As a preliminary screening tool, DART-TOF-MS has the potential to reduce backlogs and streamline analysis.

DART-MS was used to characterize individual cathinones and mixtures of cathinones and various cutting agents. Simple spectra can provide parent $[M+H]^+$ peaks indicative of the number of compounds present, with high mass accuracy key in predicting formula weights. Cathinones were also fragmented by in-source collision induced dissociation (CID) to produce fragment patterns for structural characterization, used to differentiate isobaric cathinones based on characteristic fragments. Furthermore, a mixture of cathinones shows that individual components can be distinguished within a mixture. The process allows for rapid identification of common cutting agents, providing a means to simplify more complex mixtures. With no sample preparation needed, spectra were obtained in seconds, and the DART-MS is ideal for structural characterization of unknowns.

Finally, DART-MS data is suitable for statistical analysis. Any differences in samples due to degradation or many other factors can be the basis of statistical differentiation against several statistical models and programs, allowing the reporting of results with a higher level of confidence.

Abstract Text

Morphologically Directed Raman Spectroscopy (MDRS) can be applied to a variety of forensic evidence types, such as illicit drugs, counterfeit pharmaceuticals, hoax powders, soils and gunshot residues. It is a novel and reliable tool that would enable criminalists to obtain more information from forensic samples than is currently employed for investigations and adjudications. MDRS combines automated particle imaging and Raman spectroscopy in one instrument. Particle imaging is performed to determine particle size and shape distributions of components in a blended sample. Particle size is an important physical property of particulate samples because it has a direct influence on a variety of material properties such as reactivity or dissolution rate, suspension stability, efficacy of delivery, texture, feel, appearance, flowability, handling, viscosity, packing density and porosity. Although measurement of particle size distributions is routinely carried out across a wide range of industries and is often a critical parameter in the manufacture and analysis of many products and substances, it is not widely used in the forensic sciences. Raman spectroscopy is a useful technique in forensic science for determining molecular chemistry because it is rapid, reliable, does not require contact with the sample, and is non-destructive. Combining these two analytical techniques allows the individual components present within a blend or mixture to be independently characterized and compared. This presentation will demonstrate how such a tool can be used to gain a better understanding of mixtures across many areas of forensic science, as it is applicable to a range of Raman active samples.

Abstract Text

Methamphetamine is a highly addictive drug and its manufacture, distribution, and abuse are issues of international importance. Enforcement agencies continue to develop methods to characterize methamphetamine samples. In particular, significant efforts have been directed to investigation of the chemical signatures that are characteristic of the starting material and methods used for its synthesis, which can be used to track the activities of clandestine laboratories, distribution networks, and trafficking patterns. These chemical signatures include trace impurities such as residual starting materials and/or by-products from the synthetic method. Methamphetamine was prepared from five different synthetic routes and characterized using direct analysis in real time mass spectrometry (DART-MS). DART-MS is an ambient ionization method that was used to characterize samples in their native form without any preparation. In addition to methamphetamine, dozens of different impurities were identified by accurate mass measurements. These impurities included residual starting material, intermediate products, route-specific identifiers, and other synthetic by-products. Together, these various impurities serve as a specific chemical signature for methamphetamine that is related to the synthetic method and starting materials employed. The DART-MS method used here demonstrates the utility of the technique to rapidly characterize methamphetamine samples in a manner different, yet complementary to current standard methods.

Abstract Text

Blood stains, which are among the traces encountered most frequently at crime scenes, are important for potential extraction and amplification of DNA for suspect identification, as well as for spatter pattern analysis to reveal a sequence of events. Determination of blood stain age can contribute to verify witness' statements, limit the number of suspects and confirm alibis. As a result, estimate the age of blood stains with good accuracy and precision has been an elusive goal for forensic investigations.

Attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) was used in forensic detection of blood stains and age estimation because of signature absorbances in the mid-infrared region at 3300 cm^{-1} (Amide A), 2800 cm^{-1} to 3000 cm^{-1} (Amide B), $\sim 1650\text{ cm}^{-1}$ (Amide I), $\sim 1540\text{ cm}^{-1}$ (Amide II), and 1200 cm^{-1} to 1350 cm^{-1} (Amide III). Peak position and intensity shifts of blood spectra due to aging changes occurring as a result of the denaturation of blood proteins and water absorption/desorption were observed with FTIR. Principal component analysis (PCA) and partial least square regression (PLS) were used in this work to combine these changes in a multivariate calibration that reveals correlations between the amide peak changes and blood age. Calibration experiments over several months at 30 degree Celsius under a variety of humidity and substrate conditions enable prediction of blood stain age under different environmental conditions.

The results contribute to the understanding of mechanisms of blood aging and provide a nondestructive approach for predicting blood age under a variety of environmental conditions.

Time: 03:45 PM

Room: 273

Co-Author(s) Jarrod B. Bechard, Mark D. Boatwright

Abstract Text

This report reveals the potential of enhancing forensic fingerprint evidence by adding a qualitative chemical dimension. The chemical residue on the skin of the person leaving the fingerprint on a reflective surface may potentially be identified by infrared microspectroscopic techniques. Various commercial skin lotions and hair preparations have an organic component in their formulation that enables differentiation according to the brand. A partial library of spectra from a clean reflective substrate surface is used for comparison of the incidental fingerprint residue deposited on an everyday reflective item. Using the background obtained from an organic coating in proximity of the fingerprint, the spectrum of the surface deposition is obtained.

Abstract Text

A compact, rugged wide-field electronically tunable wavelength filter has been developed for hyperspectral imaging applications in the visible and near-infrared region. The filter employs surface plasmon coupling in metal films separated by a tunable dielectric layer. The advantages of the surface plasmon-coupled filter (SPCF) are its large spurious free spectral range (450nm-1000nm), high throughput (>50%), and compact design. The rugged optical assembly, ease of operation, and small size make it suitable for hand-held hyperspectral imagers as well as for incorporation into existing optical assemblies. Unlike conventional electronically tunable widefield imaging filters such as the acousto-optic tunable filter and liquid crystal tunable filters, the SPCF provides a straight-through optical path without the need for intermediate polarizers or complex electronic control circuits. The underlying theory and SPCF design are presented. In addition, widefield hyperspectral imaging using the SPCF is demonstrated for the first time on both model substrates and real-world samples.

Co-Author(s)

Abstract Text

Previously, we demonstrated a side illuminated optical fiber for non-simultaneous measurement of multiple samples. In this paper, we adapted the previous set up with sources of non-overlapping spectral distributions to probe three samples simultaneously.

We used:

A 20 cm long tapered optical fiber: diameter between 1 and 2 mm.

Three LEDs of non-overlapping spectral distributions: peak wavelengths at 470, 570 and 645 nm.

An LED driver to power the LEDs.

Red, green and blue food dyes for calibration purposes: used to emulate commercially available colorimetric tests and

An Ocean Optics USB-2000 spectrometer.

The procedure used was the following:

1. We prepared six calibrating solutions with the food dyes: concentrations between 0 to 5 drops/0.5 L of water.
2. The solutions were placed into cuvettes which were sandwiched between their corresponding LEDs and the optical fiber.
3. To maximize light absorption, the cuvettes with red, green and blue solutions were simultaneously illuminated with the blue, green and red LEDs, respectively.
4. The spectral distribution of the samples were obtained.

Light from each LED is absorbed by their respective samples, coupled into the fiber and transmitted to the spectrometer at the fiber tip. A total of six spectra, obtained from the different concentrations, were collected. Each spectrum has three different peak wavelengths which correspond to the three simultaneous measurements (see Figure). Accordingly, the intensity decreases with dye concentration. We plotted the calibration curves, fit them with an exponential function and obtained very high correlation coefficients: this confirms the data obeys Beer-Lambert's Law. The confidence levels, CL, were 100%>CL>99.9999%, 99.999%<CL<99.99% and 99.99%>CL>99.9% for the red, blue and green LEDs, respectively.

In conclusion, we demonstrated a rather inexpensive setup for simultaneous absorption measurements from multiple samples. We are now using this proof of concept for fluorescence, scattering and index of refraction measurements.

This work was supported by a Phase II grant from the SBIR Program of the US Department of Agriculture, Award No. 2011-33610-31155, National Program Leader William Goldner.

Primary Author Alexander Scheeline
SpectroClick

Date: Wednesday, March 11, 2015 - After

Time: 02:10 PM

Room: 274

Co-Author(s)

Abstract Text

Conventional absorption spectrometers are designed with detectors whose dynamic range is inherently sufficient for the desired measurement, and typically observe only one or two diffraction orders. We describe an instrument with an inexpensive rectangular array CMOS detector using multiple orders to provide dynamic range that is the product of the dynamic range of the grating and of the camera. Such spectrometers require sophisticated software to generate a spectrum, but can be produced simply. They can observe spectra with a range of throughput/resolution tradeoffs simultaneously. We contrast the throughput, resolution, precision, and calibration of multi-order instruments with more conventional approaches, and critically evaluate what situations may benefit from this instrument geometry. The limitations of using consumer cameras optimized for snapshots and video recording as spectrometric detectors are also described, as are plausible means of overcoming the limitations. The spectrometer is mated with software to synchronize user actions, spectral measurements, and determination-specific data interpretation. Method examples will be presented, including visible reflectance and absorption. Human interfaces that hide the spectroscopy and chemometrics from the unskilled user, yet allow for “drill-down” to understand measurement complexity are also discussed.

Abstract Text

The introduction of recent legislation, such as the EU Environmental Liabilities Directive 2004/35/EC, has encouraged the development of precise and robust analytical systems for identifying pollutants. However, the sheer number of toxic compounds which may require monitoring at any given time makes this a challenging prospect.

Quadrupole GC-MS methods often employ selective ion monitoring (SIM) for trace-level detection of target compounds. However, this protocol prevents retrospective searching of data for the latest contaminants of emerging concern. The use of time-of-flight mass spectrometry (TOF MS) can overcome this issue by providing highly sensitive detection whilst acquiring full range mass spectra, to allow both target and unknown identification in a single, rapid analysis.

This poster will illustrate the advantages of TOF MS by comparison with a modern quadrupole system operating in a regulated commercial environment. The reproducibility of quantitation and qualifier ion peak areas using this system will be shown, along with the ability to generate spectra that are a close match for those in the NIST library.

Abstract Text

For years, 1301-type stationary phases for capillary chromatography have provided an effective solution for the separation of many common volatile organic compounds. Although these cyanopropylphenyl polymers are well-suited for volatiles, they have historically suffered from poor thermal stability, resulting in higher bleed and low maximum operating temperatures. The poor thermal stability of these columns has also precluded their wide use in GCs using MS detection due to interference from bleed ions and source contamination from high bleed.

The new Rxi-1301Sil MS contains a more thermally-stable cyanopropylphenyl stationary phase that allows for low bleed at temperatures up to 320°C. This makes this column usable in MS instruments without the problems mentioned above. Additionally, the broader temperature range of this column allows for the analysis of less-volatile compounds that still benefit from cyano-type selectivity, such as the analysis of glycol ethers.

An evaluation of the performance parameters for the Rxi-1301Sil MS was performed. Evaluation criteria included MS bleed, selectivity, and lot-to-lot reproducibility. The Rxi-1301Sil MS exhibited less MS bleed than traditional 1301-type columns at a higher maximum temperature, while still exhibiting selectivity very close to that of traditional 1301 phases. Lot-to-lot reproducibility of several lots of columns was found to be excellent. This poster will present results of the column evaluation, as well as analysis of amyl alcohols in alcoholic beverages and MS analysis of glycol ethers.

Abstract Text

Polymers and additives are used in a variety of subcutaneous and intravascular medical devices, such as sutures and drug delivery systems. These devices typically can be classified as being either absorbable or non-absorbable by the human body.

Natural materials, such as silk and catgut, are largely being replaced by synthetic materials. So, the reliability of these devices relies on the quality and proper application of these synthetic compounds. But regardless of their composition, the materials used are foreign to human tissue and will elicit a foreign body reaction to a greater or lesser degree.

This poster will demonstrate the analysis of several types of implanted medical devices from different manufacturers using pyrolysis-GCMS. Traditionally, pyrolysis has been used as a technique to identify polymers, which will be shown. But in addition,

one or more "pre-pyrolysis" steps will be programmed first so that we can analyze for residual monomers, solvents, additives and contaminants, if present. These unwanted non-polymeric compounds or the incorrect quantity of an additive can often lead to product failure or worse.

Abstract Text

Dinitrotoluene (DNT) is a common compound of interest for the instrumental detection of explosives. Several structural isomers of DNT are by-products or decomposition products of TNT while other isomers are commonly used as internal standards, particularly when performing gas chromatography / electron capture detection (GC-ECD) analysis of nitro-aromatic explosives. Despite direct analytical confirmation that aliquots of commercially-obtained, purified solid DNT consist of only single DNT isomers (~99% purity), the headspace vapor above these solids has been observed to consistently contain multiple DNT isomers.

In this work, the headspace of purified DNT isomers, including 2,4-DNT, 2,6-DNT, and 2,3-DNT, were sampled by whole-air sampling via an online cryogenically-cooled injection system and solid phase micro-extraction (SPME). Samples were analyzed by gas chromatography / mass spectrometry (GC-MS) and compared to analyses of solutions made from the corresponding purified solid DNT isomers. Several sources of DNT were compared. This work demonstrated ratios of DNT isomers in the headspace that were inconsistent with those in the source material and were not attributable to impurities in the initial DNT stock or to differences in vapor pressure among different isomers. This evidence suggests a vapor-phase rearrangement as the source of the isomerization.

Abstract Text

The predominant mechanism by which liquid hydrocarbon fuels undergo degradation in storage or when thermally stressed, is free-radical autoxidation. Alkyl hydroperoxides are produced during autoxidation and can accumulate in the fuel. Thus the presence of hydroperoxides can serve as an indication that a fuel has undergone oxidation. Hydroperoxides have also been known to degrade fuel system elastomers and can serve as an oxygen source for further oxidative degradation. Traditionally, the standard test method for hydroperoxides in fuels is ASTM D3703, which is an indirect iodometric titration. This method requires up to 40 mL of fuel, is time consuming and is resource intensive. In addition, iodometry results in significant waste materials. Thus, an instrumental method for accurate determination of hydroperoxides in fuels was sought. An instrumental method has been published¹, based on derivitization of hydroperoxides in aviation fuels with triphenylphosphene (TPP) and detection by gas chromatography with flame ionization (GC-FID) detection. The method measures hydroperoxides in fuels by quantifying the amount of triphenylphosphine oxide (TPPO) formed in reaction of TPP with measured hydroperoxides. However, it was found that this method was not applicable to hydroperoxides produced in diesel and marine gas oil fuels. We describe here how the TPP method was successfully modified and transitioned to an automated GC-MS-MS instrument, and extended to provide reliable measurements in a wider range of fuel types. The results of the automated GC-MS-MS method will be compared to the iodometric titration.

Abstract Text

The hydrocarbon isomer distribution in petrochemicals contributes to many commercially important petrochemical characteristics such as boiling and melting points, octane number, combustion efficiency, flash point, viscosity, lubricity, solubility, and solvation power.

Electron Ionization Gas Chromatography / Mass Spectrometry (EI GC/MS) is a powerful and information-rich technique for qualitative characterization and quantitative analysis of the compounds in a petrochemical mixture. One of its most valuable functions is to provide the molecular weight of a compound. However, for high molecular weight or highly branched compounds this important ion may be small or absent because of energetic instability relative to its fragment ions. In that case analyte confirmation is more dependent upon measured retention time and comparison with established standards.

In contrast, Cold Electron Ionization GC/MS (Cold EI GC/MS) can improve petroleum isomer distribution analysis by substantially increasing the molecular ion peak intensity of a compound while retaining the EI fragmentation pattern for spectral library searching without modification to established GC methodologies. Enhanced molecular ion abundance allows plotting the molecular ion chromatogram for easy determination of isomer distribution, even for isomers with a high degree of branching and small or no molecular ion in conventional EI.

When used in a novel q-TOF configuration the enhanced molecular ion in Cold EI provides enhanced selectivity and valuable information on the isomeric content and distribution of petrochemical fluids.

Abstract Text

Several plants are used in folk medicine to treat infections that cause male infertility. *Carpolobia lutea* (G. Don) (Polygalaceae) is a plant used by practitioners of alternative medicine in South West Nigeria for the management of infertility gonorrhoea, gingivitis, infertility, ulcer and malaria. This study is to extract and analyze essential oil from the roots of *Carpolobia lutea*. The fresh roots were air-dried, pulverized and the essential oil extracted into hexane by hydro-distillation over 4hr period. The hexane in the extract was evaporated off and dried with anhydrous sodium sulphate. The essential oil obtained was analysed with GC model 7890 A and MS model 5975C of capillary column size 30m x 250µm x 0.25µm film thickness which was packed with HP-5MS 5% Phenyl methyl siloxane. Helium was the carrier gas at a flow rate of 1ml/min. The mass spectrometer (MS) was fitted with Chem.-Station software for processing the data. The temperature program of the column was initially 50[degree]C held at same temperature for 17 minutes, gradually increased to 200[degree]C at 40[degree]C /minute and finally increased to 240[degree]C at 15[degree]C /minute. Mass spectra were recorded using ionization energy of 70 eV. The molecular ions detected were identified by the MS library. Some of the compounds identified in the extract are dodecanoic acid, n-hexadecanoic acid, 13-octadecenal and oleic acid. The presence of fatty acids in the essential oil may be useful for the management of bacterial and fungal infections which may be implicated in male infertility factor. Thus the plant extract may be useful in the management of male infertility factor arising from bacterial/microbial infection .

Abstract Text

The Volatile Organic Compounds (VOCs) are a class of organic chemicals having high vapor pressures at room temperature (low boiling points), which cause a large number of molecules to evaporate or sublime, into the gas phase.

In the recent years, the presence in Air of Toxic Organic Compounds such as pesticides, pharmaceuticals, explosives, chlorine disinfection byproducts, petroleum hydrocarbon and chlorinated solvents have been continuously increasing.

In accordance to EPA Compendium Method TO-17 for the determination of Volatile Organic Compounds in Ambient Air Using Active Sampling onto Sorbent Tubes, this work investigate the analytical performance of a Thermal Desorber coupled with a Gas Chromatograph/Time of Flight Mass Spectrometer System (TD-GC-TOF MS). The emissions are collected into a sorbent material filled tube. After sampling, the absorption tube is placed in the Thermal Desorber where it is heated. The Volatile Compounds are then desorbed by a flow of inert gas and transferred to a narrow-bore packed trap. This last one is filled with one or more sorbent material and is kept at a low temperature. Once the refocusing step is completed, the trap is instantaneously heated providing a rapid analyte transfer into the GC-TOF MS system.

Abstract Text

The Ganges River (India) is a highly socially and economically significant river, being an important focus for religious activity as well as a main water source for the agricultural, industrial, and waste removal needs of 400 million people. Increasing utilization of the river's water by these practices may potentially affect religious activities and customs that have existed for several millennia.

□

In this pilot study, we surveyed 150 individuals at six sites of religious significance along the length of the river, from December 2012 to February 2013, during the Maha Kumbh Mela. Water samples were concurrently taken and analyzed for polychlorinated biphenyls (PCBs), organochlorinated pesticides (OCPs), and polycyclic aromatic hydrocarbons (PAHs), using micro-electron capture or mass spectrometric methods. These data were spatially matched with our survey data that examined how and why religious activity and perception of the sacredness of Ganges River Water (GRW) was changing. Results suggest that while the religious entity of GRW is seen as pure and untaintable, the sacredness of GRW is reduced by a perception of high levels of visual and chemical pollutants. While previous research has demonstrated high levels of visual pollutants, we observed relatively low levels of the aforementioned chemical pollutants at sites surveyed.

Abstract Text

Exposure to air pollutants has long been recognised as a cause of health problems. Historically, pollutants from vehicle exhaust and the burning of fuels were of primary concern, but as urban air quality has generally improved, attention has shifted to vehicle interior air quality (VIAQ). Emissions of volatile and semi-volatile organic compounds from car interiors can have an adverse effect on VIAQ, raising concerns for passenger health & safety. As a result of these concerns, VIAQ is of growing importance to the automotive industry, culminating in the development of harmonised methods to quantitate chemical release from materials used in cars. Methods generally specify the use of environmental chambers, vapour sampling onto sorbent tubes and analysis by thermal desorption (TD) with GC-MS. However, the broad range of sample types and the presence of target compounds at ultra-trace levels, often within complex matrices, provide a challenge to analytical chemists. Comprehensive 2D gas chromatography coupled with time-of-flight mass spectrometry (GCxGC-TOF MS) offers a potential solution by combining enhanced chromatographic separation with exceptional sensitivity. Select-eV ion-source technology extends this capability by enabling both hard and soft electron ionisation with no loss in sensitivity. The availability of full-fragmentation spectra for confident library matching is complemented by the ability of Select-eV to enhance diagnostic ions and distinguish between similar compounds. Fragment ions that ordinarily dominate high matrix samples become greatly reduced, enhancing selectivity and further improving detection levels. This holistic approach to material emissions profiling, combining TD-GCxGC-TOF MS with Select-eV ionisation technology, provides both enhanced separation and extended limits of detection for confident identification of a wide range of target compounds in a single analysis.

Abstract Text

Dietary supplements are made from naturally derived ingredients (e.g. botanical) and may contain environmental xenobiotic contaminants. Persistent organic pollutants (POPs) in dietary supplements can be a source of xenobiotic toxins in the human body and cause detrimental impacts on human health. However, few methods exist for the extraction and quantitative determination of POPs in dietary supplements. Development of an efficient and precise method to extract and analyze POPs in dietary supplements is of significant importance to the regulation of dietary supplements.

In this research, a method was developed for organic toxins listed in EPA Method 625 and the Stockholm Convention. Samples were spiked with isotopically enriched analogues of the analytes into the preferred extraction solvent. Stir-bar Sorptive Extraction (SBSE) method optimization and Isotope Dilution were conducted and the optimized SBSE method was validated for gas chromatography–mass spectrometry (GC-MS) by analyzing blank-subtracted dietary supplements accurately spiked with EPA 625 analytes and enriched isotopic standards.

Desorption of the analytes was accomplished using thermal desorption–gas chromatography–mass spectrometry (TD-GC-MS) and quantification was made by isotope dilution mass spectrometry (IDMS). Following validation, the SBSE-TD-GC-MS method was used to analyze commercially available dietary supplements from U.S. and Chinese manufacturers. Specific patterns of organic contamination were found among the different manufacturers and varying points of botanical origin.

Abstract Text

DNA and cells of the human body are constantly exposed to attacks of oxidative environment. These attacks can be divided into two categories as exogenous and endogenous. Exogenous sources of oxidation relate to specific exposures of the organism to ionizing radiations Endogenous attacks correspond to natural origin such as through cellular signaling and metabolic processes. During these attacks, although not in all cases, the primary damage is being induced by reactive oxygen species (ROS) and reactive nitrogen species (RNS). Two of the most common endogenous DNA base modifications are 8-oxo-7,8-dihydroguanine (8-oxoGua) and 2,6-diamino-4-hydroxy-5-formamidopyrimidine. We investigated the levels of modified bases in calf thymus DNA by gas chromatography-mass-mass spectrometry (GC-MS/MS). Methodologies using GC-MS/MS have been developed to accurately measure the oxidation products of DNA with excellent sensitivity and selectivity in vitro. This work reports the effect of resveratrol, carvacrol and cyanidin-3-glucoside antioxidants on the endogenous levels of modified DNA bases in vitro. The levels of some modified bases increased, whereas those of others decreased. Measuring only 8-OH-Gua or 8-OH-dGuo would not have revealed contrasting changes in product levels by antioxidants. The results show that the types and yields of modified bases depended on the experimental conditions on the type of DNA damaging agent or oxidizing agents.

Abstract Text

Gas chromatography tandem mass spectrometry has enjoyed resurgence especially in applied markets in recent years. A critical part of this technique is the development of robust SRM methods. This can be challenging due to the sheer number of precursor ion options for some compounds and at the same time, the lack of precursor ions for other compounds. In addition, the potential of matrix interferences corrupting SRM transitions requires that additional transitions be optimized. Choosing and optimizing SRM transitions is time-consuming and there is little written guidance.

This work summarizes the challenges and makes recommendations for choosing and optimizing SRM transitions specifically for pesticides. Transitions for over 200 pesticides were optimized and from that guidelines have been developed to help shortcut the process of SRM method development. Intensity and selectivity are weighed for choosing the best transitions and candidate transitions were vetting in food matrices.

Abstract Text

Introduction:

The ability to profile volatile and semi-volatile components present in grains without the use of solvent extractions has several advantages including improving sample throughput, reducing the chance of a volatile component being "lost" in the extraction process and eliminating the need for solvent disposal. This study utilizes the advantages of direct thermal extraction GC/MS to profile whole grains of wheat, rye & barley as harvested and after being homogenized into a dry powder form. Direct Thermal Extraction GC/MS provides for fast analysis with no carryover problems that can be associated with other GC/MS techniques.

Method:

A small sample of each grain was analyzed by placing approximately 10 mg in a 4 mm id thermal desorption tube. The tube was then placed in a commercial thermal desorption system coupled to a GC/MS and desorbed. During the desorption process a cryotrap was cooled to -60C to trap and cryofocus the components. After desorption is complete the trap is ballistically heated to release the volatiles and start the GC/MS method. This process was repeated after the grains were dry homogenized to compare the volatile & semi-volatile profiles.

Preliminary Data:

A variety of small grains were analyzed by Direct Thermal Extraction GC/MS. The Direct Thermal Extraction GC/MS was able to detect the volatile and semi-volatile components of each sample. We were able to detect a complete profile of volatile and semi-volatile components from wheat, barley and rye grains both whole grains as well as in the dry homogenized state. The Direct Thermal Extraction GC/MS provided a quick way to evaluate the sample profiles, eliminating the need for solvent extractions.

Abstract Text

Dang Gui root (*Angelica sinensis*), is widely used in traditional Chinese medicine to treat a wide range of ailments. Extracts of the root contain numerous constituents associated with the biological activity of this plant including several alkylphthalides (butylphthalide Z-ligustilide and Z-butylidenephthalide), and ferulic acid. Extraction, purification, and analysis of these constituents has been achieved using a wide variety of techniques including sonication or Soxhlet extraction with aliphatic solvents followed by TLC or HPLC both as analysis and purification techniques.

As an alternative strategy, Dang Gui root pieces were first extracted using supercritical fluid extraction (SFE). Extracts were analyzed and components identified using Ultra Performance Convergence Chromatography (UPC2) combined with mass spectrometry. Identified components were then isolated and purified using preparative scale supercritical fluid chromatography (SFC). Following purification, identity and purity of the isolated components were confirmed using UPC2.

Abstract Text

Capillary electrophoresis is a powerful separation technique that can achieve high efficiency separations of charged analytes. However, one limitation of capillary electrophoresis is the adsorption of cationic proteins and peptides onto the inner surface of the capillary wall, due to the negatively charged silanol groups on the bare fused silica capillaries. This can lead to poor separation efficiencies and band broadening. Gold nanoparticles have been known to exhibit unique interactions with biomolecules, which has led to an increased interest in these particles for pharmaceutical applications and separation science. Our group is attempting to investigate two different approaches for the separation of a number of opioid peptides using gold nanoparticles. Approach 1: Using a recently reported method for the preparation of a gold nanoparticle modified capillaries⁽¹⁾. These capillaries produced by treating the inner surface of fused silica capillaries with 3-triethoxysilylpropylamine, followed by the introduction of freshly prepared citrate stabilized gold nanoparticles (particle size 25nm). Approach 2: We are also attempting to separate opioid peptides using the same citrate stabilized gold nanoparticles using capillaries treated with a layer of a positively charged poly(diallyldimethylammonium) chloride, that would adsorb the negatively charged gold nanoparticles⁽²⁾. The electroosmotic flow, apparent electrophoretic mobilities, resolution and plate numbers for the opioid peptides under both approaches are compared to those obtained by conventional capillary zone electrophoresis on bare silica.

Abstract Text

Recent reports demonstrate a large sensitivity increase in CZE-ESI-MS systems that employ etched capillaries, potentially due to changes in spray density. Ion distribution in electrospray generated from an electrokinetically driven sheath flow CZE-ESI-MS interface was mapped. The sheathing and separation buffers contained either a 25 [micro]g/mL solution of dimethylated bradykinin or a 25 [micro]g/mL solution of isotopically labeled dimethylated bradykinin (+6 Da deuterium), respectively or vice versa. The ratio of peptides during constant infusion was monitored while rastering the electrospray emitter across the MS inlet orifice, effectively highlighting the density of ions entering through the capillary as well as any spatial inhomogeneity in the spray. Ion distribution was also monitored by infusing the fluorescent dye Rhodamine 6G into the spray, exciting with a 532 nm green laser, and rastering in a similar manner as before. Mapping was completed using either a standard capillary (150 [micro]m o.d.) or a capillary where the outer diameter had been etched with HF (60 [micro]m o.d.). Our results may suggest a more focused beam of peptides present while using an etched capillary, leading to a greater number of ions entering the mass spectrometer, and hence a more sensitive measurement.

Abstract Text

Reversed phase liquid chromatography (RPLC)-electrospray ionization (ESI)- MS/MS is the usual analytical technique for bottom-up proteomics because of its good compatibility with ESI-MS/MS and high resolving power for peptide separation. However, the bias of RPLC-MS against small and hydrophilic peptides makes it essential to have a method with orthogonal separation mechanism providing complementary information. Capillary electrophoresis (CE) is a potential alternative. Capillary zone electrophoresis (CZE), which is the simplest model of CE, employs very simple instrumentation. With the development of an improved CZE-MS interface, CZE-MS/MS has recently attracted increasing attention for MS-based proteomics.

CZE has two primary advantages. First, it provides fast and efficient separation than RPLC. The flat flow profile of CZE leads to narrower peaks and better resolution. Second, the orthogonal separation mechanisms of CZE and RPLC could produce complementary information of the analytes. Nevertheless, the significant disadvantage of CZE is limited loading capacity, 1-3 orders of magnitude smaller than RPLC, which causes difficulty in identifying complex samples.

Sample prefractionation before CZE-MS/MS analysis can improve the peptide and protein identifications, so I developed a C18-capillary RPLC (cRPLC) based peptide fractionation method for CZE-MS/MS based bottom-up proteomics.

Around 50 µg E. coli peptides were loaded to the cRPLC column, and 61 fractions were obtained. Through the automated CZE-ESI-MS/MS system, 1,200 protein groups and 6,563 peptides were identified from the 50 µg E.coli digest. This result largely increased peptide and protein group IDs from the previous report, demonstrating the potentiality of CZE-MS in bottom-up proteomics. With the further improvement in CZE-ESI-MS/MS setup and prefractionation method, CZE-ESI-MS/MS may lead to better application in proteomics.

Abstract Text

Micelles formed from bile salt aggregates are capable of resolving chiral isomers of binaphthyl compounds through micellar electrokinetic capillary chromatography (MEKC). Optimal resolution depends on a number of factors including the identity and concentration (10.0 to 100 mM) of the bile salt as well as the concentration of analyte enantiomer (0.10 to 3.00 mM). Here, the chiral isomers of model compounds such as 1,1'-binaphthyl-2,2'-diyl hydrogen phosphate (BNDHP) were separated with MEKC using various concentrations of the bile salts cholate (CA), deoxycholate (DC) or taurodeoxycholate (TDC). The best resolution and efficiency were observed with TDC-mediated MEKC, and solutions of TDC were analyzed with NMR to further investigate the TDC micelle. Relatively low bile salt concentrations (10.0 to 20.0 mM) and the lowest analyte concentrations (0.10 mM) provided the best MEKC resolution for all three bile salts. The critical micelle concentration (cmc) for each bile salt, demonstrated by the onset of chiral separation, differed across the three bile salts with the lowest cmc observed using TDC. TDC solutions were analyzed via 1D [¹H] NMR without analyte present, with R-BNDHP in solution and with S-BNDHP in solution at six different cholate concentrations (3.00 mM, 10.0 mM, 20.0 mM, 30.0 mM, 60.0 mM and 80.0 mM). Data from both MEKC and NMR experiments will be presented with the goal of developing an overall understanding of the factors that give rise to micelle formation and chiral separation.

Co-Author(s) Hadir Maher, Haya Joharc, Maha Sultand, Mona Alshehria

Abstract Text

A novel method based on microemulsionelectrokinetic chromatography (MEEKC) with reversed electrode polarity stacking mode (REPSM) was developed and validated for the simultaneous determination of dexamethasone sodium phosphate (DEX-SP) and the active drug dexamethasone (DEX) in rabbit plasma. The optimum separation was achieved when using a microemulsion background electrolyte consisting of 30 mM boratebuffer(pH9.2), 20 mM sodium dodecyl sulfate (SDS), 0.8 % ethyl acetate and 2% 1-butanol. Electrophoretic separation was carried out at 24°C and at +23 KV. For the purpose of sample stacking, the following program was applied: + 23 KV (0-0.6 min) then -23 KV (0.6-1.5 min) and finally +23 KV for the rest of the run. The analytes were base-line resolved within 12 min. Using hydrochlorothiazide (HCT) as internal standard, the peak area ratios were found to be linear in the concentration range (0.1-2.0µg/ml, DEX-SP and 0.05-2.0µg/ml, DEX). The applied stacking mode increased the detectability of the method by about 40-fold with limit of detection and quantitation of (0.03, 0.1 µg/ml, DEX-SP) and (0.02, 0.05 µg/ml, DEX). The developed method was fully validated according to the ICH guidelines. This optimized method was applied for the determination of DEX-SP and DEX in rabbit plasma samples previously treated with I.V. injection of DEX-SP. The in-vivo results thus obtained were used to study the pharmacokinetics of the cited drugs in rabbit plasma.

Abstract Text

Capillary zone electrophoresis (CZE) separates ions by their mass to charge ratio rather than hydrophobicity, which is more efficient for proteins. CZE also has an advantage over liquid chromatography in separation speed. These two features of CZE make CZE-ESI-MS/MS a high throughput screening method for quality control of monoclonal antibodies. Top-down analysis of intact antibody requires ultra-high resolution mass analyzer (i.e. FTICR) due to its high molecular weight (~150 000 Da). By reducing intact antibody, it breaks into light chains and heavy chains which are 50 000 Da and 25 000 Da, respectively, so more accessible mass analyzer such as Orbitrap can be applied for antibody analysis. In this work, capillary zone electrophoresis was coupled to LTQ Orbitrap Velos to analyze reduced monoclonal antibodies. Antibody was first denatured, reduced and alkylated. During desalting with ziptip, sample was eluted in 50% acetonitrile and 35% acetic acid in water to prevent it from precipitation. Sample can be preserved in solution longer than 1 month compare to dozens of minutes with only 50% acetonitrile. LPA-coated capillary was first directed infused with standard protein solution to further block the inner capillary wall. Total analysis time was 15 min with a separation window of ~5 min. Heavy chain and light chain were baseline separated for single monoclonal antibody. The mass of heavy chain and light chain were calculated by MagTran. For a mixture with two antibodies, light chains were baseline separated, while heavy chains were partially separated.

This work was funded by the National Institutes of Health (R01GM096767) and Eli Lilly Company through the Lilly Research Award Program.

Abstract Text

Aptamers are short, synthetic oligonucleotide sequences that can selectively bind to targets with high affinity. Selection of aptamers is accomplished by the Systematic Evolution of Ligands by EXponential enrichment (SELEX). The target is incubated with a random sequence oligonucleotide library and target-bound sequences are separated from the unbound pool to generate a higher affinity library for use in subsequent selection rounds. Capillary electrophoresis (CE) has been used for the selection of large protein targets and requires fewer rounds of selection than conventional SELEX methods. Unlike large targets, small molecule targets bound to DNA sequences show little to no change in electrophoretic mobility, resulting in poor separation from the unbound sequences. To solve this problem, quantum dots (QDs) with covalently bound target molecules can be employed to effectively increase the size of small molecular targets and allow efficient separation based on the QDs mobility. As proof of concept for the use of QDs in CE-SELEX we used commercially available QDs conjugated with streptavidin to show that QD-target-DNA complexes can be separated from unbound DNA sequences. Laser-induced fluorescence-CE and fluorescently labeled DNA allowed for real-time identification of DNA-target binding by fluorescence resonance energy transfer between the DNA fluorophore and the QDs, increasing the latter's fluorescent intensity. The dissociation constant of target-bound libraries was found to decrease throughout selection rounds until a minimum was reached.

This project was funded by Eastern Michigan University.

Abstract Text

A capillary electrophoresis with laser induced fluorescence (CE-LIF) instrument was constructed with a low limit of detection. A calibration curve for this instrument was created using the product of the AttoPhos substrate system. Single enzyme molecules will be examined through CE-LIF to determine their individual activity. The calf intestinal alkaline phosphatase (ciAP) enzyme will be studied first in these experiments; a single enzyme molecule will be injected into a capillary filled with substrate, and several incubations will be performed at different points along the capillary. Each of these incubations with the AttoPhos substrate produced a pool of highly fluorogenic product known as AttoFluor, which will migrate through a highly sensitive laser-induced fluorescence detection system. The areas of the peaks produced will be used to create a kinetic plot to determine the activity of the enzyme with high precision. These experiments will be adapted for use with mass spectrometry and different enzymes in the future.

Abstract Text

DNA damage is the underlying cause for mutations leading to cancer. It can be caused by a number of different agents ranging from chemical compounds to radiation sources. Detection of these different types of damages is important for understanding the mechanisms by which DNA damage is caused and propagated, particularly under real-world conditions of exposure to multiple sources. DNA damage from ultraviolet radiation (UVR) is caused by the formation reactive oxygen species and free radicals that result in the formation of two main damages; cyclobutane-pyrimidine dimers (CPDs) and 6-4 photoproducts (6-4PPs). CPDs are generally the most common and most toxic form of DNA damage that results from UVR; however, 6-4PPs are more likely to cause serious damage and induce potentially lethal mutations. The objective of this work was to develop a method to simultaneously detect CPDs and 6-4PPs in genomic DNA irradiated with UVB or natural sunlight using using capillary electrophoresis with laser-induced fluorescence (CE-LIF). Human cells were first exposed to varying amounts of UVB or natural sunlight to induce DNA damage. Genomic DNA was extracted and incubated with anti-CPD and anti-6-4PP primary antibodies attached to secondary antibodies with a fluorescent quantum dot reporter that emitted either red or yellow fluorescence. CE was used to separate the unbound antibodies from those bound to the photoproducts, and LIF with appropriate optical filters was used to separate the fluorescent signals from each QD to individual photomultiplier tubes for simultaneous photoproduct detection. Using this strategy, photoproducts were detected from ~6 ng of DNA under a low UVB fluence of 65 J m^{-2} for CPDs or 195 J m^{-2} for 6-4PPs. This assay was also the first to demonstrate the detection of CPDs in human cells after only 15 minutes of irradiation under natural sunlight.

Abstract Text

The determination of creatinine, a marker for renal failure, is a common clinical analysis. Here we explore the use of an eletrophoretically mediated microanalysis (EMMA) assay for creatinine. The EMMA analysis requires low volumes of biofluids and generates minimal waste, but suffers from relatively low sensitivity. One way to improve EMMA sensitivity is to concentrate the assay product (aka Jaffe product) within the capillary. Here, discreet plugs of highly mobile hydroxide ions are used to affect dynamic stacking of the anionic product of this in-capillary assay. Creatinine reacts with anionic picrate forming the Jaffe product, a red ($\lambda_{max} = 485 \text{ nm}$), highly mobile anion. The goal of this project is to use hydroxide, an even more mobile ion, as the leading anion to perform dynamic transient isotachophoretic (tITP) stacking of the in-line generated product. Discreet plugs of sodium hydroxide have been successfully employed with the EMMA assay to determine creatinine concentrations in both "elevated" (> 2.0 mM) and "normal" (as low as 0.05 mM) clinical ranges. Moreover, samples of creatinine in various matrices including 18 M \square m water, 125 mM sodium chloride, and deproteinized artificial serum were analyzed to see how ionic strength and various ionic content affect the in-line assay. Using a 33.5 cm, 50 μ m i.d. capillary, the Jaffe stacking system was systematically investigated using pH 9.0 background electrolyte (60.0 mM borate), and discreet hydrodynamic injections of (i) hydroxide (0.1 to 0.6 M for 50 to 400 mbar•s), (ii) 150mbar•s of picrate (47 mM, pH 12.3), and (iii) creatinine (0.05 to 10 mM in various matrixes). In general, stacking improved with hydroxide concentration and relatively long plug lengths (300 mbar•s). Importantly, the assay also showed good linearity over the clinical range of creatinine concentrations.

Abstract Text

We present a flexible and low-cost fraction collector for preparative capillary zone electrophoresis. We have demonstrated its application to the isolation of putative aptamers against thrombin and aim to further expand upon the capabilities of the instrument. We incorporate a novel two-dimensional CE interface into the instrument. This interface houses two capillaries separated by an incubation cell. This system will result in a fully automated two-dimensional CE instrument capable of generating high-affinity aptamers in a high-throughput fashion.

Abstract Text

Electrophoretically Mediated Microanalysis (EMMA) is applied to the measurement of creatinine through the Jaffe reaction to efficiently perform this clinically significant assay on the nano-liter scale. In addition, transient isotachopheresis (tITP) is used to stack the Jaffe product produced during the in-line reaction; the tITP step is initiated by a plug of highly mobile hydroxide ions. Simul, a computer simulation program, is used to visualize the dynamics of the overlap and stacking processes, allowing a detailed understanding of this complex tITP and EMMA-based reaction system. Through simulations, the dynamic stacking throughout the entire duration of the reaction can be "seen" and can give a deeper understanding of the overall reaction dynamics. Recent results pointing to optimal conditions for the analysis in Borate buffers of various concentration and pH in addition to altering the concentrations and lengths of the hydroxide plug will be presented. Ultimately the careful characterization of this system may lead to a more general understanding of tITP and EMMA dynamics to allow for prediction of optimal conditions for in-line electrophoretic analyses.

Abstract Text

Neutral oligosaccharides have proven to be a difficult class of compounds to analyze by capillary zone electrophoresis (CZE) coupled to electrospray ionization-mass spectrometry (ESI-MS). Capillary electrochromatography (CEC), a hybrid of CZE and liquid chromatography, offers a solution by using electroosmosis to drive separations through a packed capillary, generating chromatographic separations of neutral analytes. Monoliths are an attractive alternative to traditional stationary phases, as they have high stability and permeability and are easily adaptable to current needs. We present results from a hydrophilic monolithic capillary column for CEC-ESI-MS of a neutral oligosaccharide mixture. Preliminary work with maltose oligomers indicates that the columns couple well with our sheath-flow interface but further column modifications are necessary. After system optimizations, we will explore a more complex sample: the nested fragments of the human high mannose 11mer.

Abstract Text

The analysis of airborne aldehydes and ketones first involves collection of the analytes by passing air through a cartridge containing 2,4-dinitrophenylhydrazine (DNPH). As the air passes through the cartridge, the analytes react with the DNPH to form hydrazones which are immobilized on the cartridge. The cartridges are then eluted with solvent and the DNPH derivatives can be analyzed using HPLC with UV detection.

Using a robotic sampler with a special tray to hold DNPH cartridges, the entire process of desorbing the analytes and injection of the samples into the LC-UV system can be easily controlled. Automating the desorption of these cartridges can result in significant improvement in accuracy and reproducibility as well as reducing potential experimental errors by the operator. The intuitive software includes tools that allow the desorption of a cartridge to take place during the chromatographic separation of a previously injected sample to ensure maximum sample throughput.

In this report, the automation of the online desorption and analysis of airborne DNPH derivatives by the robotic autosampler is discussed. Examination and calibration for a variety of aldehyde- and ketone-DNPH derivatives is described. Finally, DNPH cartridges collected from representative matrices are desorbed and analyzed online and the resulting precision data are provided.

Abstract Text

Sandalwood (*Santalum album* L.) is a desired wooden base note for many fragrances in perfume and other scented products including Japanese incense. Typically the tree is grown for 12 years before the total harvest of trunk, branch and root. There are many related species giving rise to counterfeiting and confusion among consumers. The greatest component in distilled oil is alpha santalol which is usually present in a concentration of approximately 50%. The alpha santalol is a weak odor compound with beta santalol being the stronger odor compound more associated with sandalwood oil.

The yield of the wood will change over time with a transition from beta to alpha santalol reported. There are more than 234 compounds that have been identified in sandalwood extract to add to the overall experience with ongoing research still identifying others. Not all compounds have an odor that contributes to the overall scent and it is possible to identify tree source by the ratio of compounds present. There is also a synthetic iso bornyl cyclohexanol that is available and present in commercial fragrances.

Three oil samples were obtained from a commercial aromatic oil source and analysed using Gas Chromatography Olfactometry (GCO) with simultaneous mass spectrometry detection, alongside samples of cedar wood oil and frankincense. The analysis showed the distinct differences in sandalwood oil from Indian and Western Australian sources and a synthetic sandalwood oil sample.

Abstract Text

Silver engineered nanoparticles (AgNPs) are frequently used in consumer products from socks to washing machines, primarily due to their antimicrobial action. However, AgNPs are known find their way into environmental waste streams and to have toxic effects on human health as well as aquatic life.

To better understand the impact of nanoparticles in the environment, several key characteristics need to be assed, such as concentration, particle size, and size distribution. The recent development and advancement of single particle inductively coupled plasma mass spectrometry (SP-ICP-MS) provides very high sensitivity, the differentiation between dissolved and particles, particle size (if shape is known or assumed) and size distribution or agglomeration.

This presentation will discuss the application of SP-ICP-MS to a real world consumer product analysis. The hardware requirements that allow for very fast continuous data acquisition (100,000 points/sec at 10 us dwell time) as well as the commercially available software application which processes this large amount of data into usable particle analysis data will be discussed.

Abstract Text

Air fresheners are commonly used in households to mask unpleasant odors. Many types of fragrances are commercially available. The fragrance can be a complex mix of many components. The effectiveness of the freshener to mask the off odors over time can be directly related to the air concentration of the fragrance components. Therefore, an important aspect in product development is airborne concentration of the fragrance components.

This study describes the use of the GERSTEL GSS-FP sampler for the collection of fragrance compounds in air. The GSS-FP is a 28 position active sorbent tube gas/air sampling system designed to collect sample onto sorbent tubes. The sampler can collect multiple samples on a pre-programmed schedule or on demand from the user interface.

Air fresheners were dispersed in a room and samples collected using the GSS-FP. The sorbent tubes were analyzed by thermal desorption GC/MS. Several fragrance components contained in the dispersed products were monitored and quantified over time. The study also shows validation of an air sampling method for the compounds.

This type of experiment can be used to show the rate at which compounds decay in the room air as a function of time as well as identifying which compounds are important contributors to the perceived odor in the room.

Abstract Text

Niacinamide, a water soluble vitamin, is often used as a whitening agent in lotions. Niacinamide containing lotions have been shown to lighten the skin and give a more even complexion. Many of these lotions list niacinamide in the ingredients but do not give the concentration present. In this study, niacinamide was extracted from six different Olay products using liquid-liquid extraction. HPLC was then used to determine the concentration of the extracted niacin in each product. A spiked sample of an Olay lotion that did not contain niacin was used to determine the percent recovery for the extraction method. The percent recovery for the method was 99.22% with a percent relative standard deviation of 1.87%.

To test the method's ruggedness, the experiment was performed by undergraduate students in a quantitative analysis course and also by students in an honors general chemistry course. The students' results show that the experiment was simple to follow and the procedures were clearly written and gave consistently good results.

Abstract Text

Liquid chromatography mass spectrometry (LC-MS) is the best choice for the accurate measurement of vitamin D in clinical samples. Indeed, LC-MS/MS has been coined the “gold standard method” for vitamin D analysis. LC-MS methods often encounter ion suppression and reduced sensitivity of the compound. The major metabolite of vitamin D is 25-OH vitamin D that circulates in blood plasma with extended half-life. In this report, we studied the increase of sensitivity of the two major metabolites: 25-OH vitamin D2 (m/z 413) and 25-OH vitamin D3 (m/z 401) utilizing selected ion monitoring (SIM) in positive mode ionization.

We performed the LC-MS analysis of 25-OH vitamin D by using different mobile phase formulations. The mobile phases were a combination of additives such as volatile organic acids, low salt or the mobile phase without any additives. A small variation in pH and ionic strength introduced a substantial change in the SIM response of both 25-OH vitamin D2 and D3. Response comparisons were performed using both electro spray ionization and jet stream ionization mechanisms. Jet stream ionization showed significant increase in sensitivity compared to ESI when the mobile phase was used without any additive. Superior response was observed for low pH mobile phase in ESI. Trace amount of vitamin D could be detected by fine tuning a low pH mobile phase composition together with instrument operating parameters. To our knowledge, this is the first report of a comparative study of mobile phase effects on vitamin D sensitivity by LC-MS.

Abstract Text

Corrosion costs the petroleum industry an estimated \$1.3 billion in non-productive time, materials and labor annually. Imidazolines prepared from fatty acids and amines are a widely-used class of chemical corrosion inhibitor, due to excellent performance and ease of handling. However, imidazolines actually comprise a mixture of several different chemical compounds, and the relative proportions of these species can have a large impact on both corrosion inhibition and product physical properties. The absence of gold standard analytical methods to characterize the active ingredients in imidazolines limit the understanding of the chemistry of these materials. It is for this reason that an SPE-LC-MS method was developed to supplement the chemical information afforded by bulk testing / wet chemistry methods (e.g. titrations etc). A high resolution time-of-flight (TOF) mass spectrometer was selected based on the fast scanning platform. This feature allows for low level sample interrogation in non-targeted analysis. Preliminary method development work was completed at the Biotage US Applications Lab (Charlotte, NC). The optimized sample preparation parameters were transferred to MWV (Charleston, SC). It is anticipated that this method will have significant impact in the formulation of new corrosion inhibitors for oil pipeline field applications as well as the quality control of finished products in manufacturing.

Abstract Text

1-[2'-chloro-5'-sulphophenyl]-3-methyl -4-azo – [2''-carboxy-5''-sulphonic acid]-5-pyrazolone was prepared by diazotization of 4-sulphoanthranilic acid and then coupling with 1-[2'-Chloro-5'-Sulphophenyl]-3-Methyl-5-Pyrazolone in alkaline medium. It was characterized by elemental analysis and spectrophotometry studies. The transition metal chelates of the same were prepared with Cu²⁺, Ni²⁺, Co²⁺, Mn²⁺ and Fe³⁺ and characterized by Infra red spectral studies and physico chemical studies.

The PH of Ni(II)- [CSMACSP] was found 9.0. The molar absorptivity calculated was found 1.14x10³ lit/mole.cm . The Beer's law obey up to 14.26 ppm. and the ratio of M:L was found 1:2 using mole- ratio and Job's method. The stability constant of the chelate were found 3.99x10⁹ .The Gibb's free energy was also calculated.The antimicrobial activity of ligand and its metal chelates were screened against various gram-positive (+) and gram-negative (□)organism. The results show that all these samples are more or less active agents against various organisms. The reagent were also studied % of Ni(II) in German silver. Thermal Analysis spectra and ,BOD/COD were also studied. DFT calculation was also done for its stability.

Abstract Title **A New Method for Continuous Detection of Trace Ions in Pure Water**

Primary Author Hiroto Masunaga
Nichiri Manufacturing Co., Ltd.

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Hideki Igai, Mizuo Ishii

Abstract Text

Herein, we report a new method for continuous detection of trace ions contained in pure water. The system consists of two mechanisms (a device that continuously removes either cations or anions selectively among the trace ions, and a virtually maintenance-free detector).

The container used for the ion removal device is made out of PEEK (PolyEtherEtherKetone). The container has three compartments that are isolated from each other by an ion exchange membrane. At both end of container, an electrode is installed.

Those three compartments are filled with either cation exchange resins or anion exchange resins. The continuous and selective removal of ions is accomplished by migration of trace ions from a central compartment toward either electrodes (cathode or anode) based on an electro kinetic phenomenon generated on surfaces of ion-exchange resins and membranes under the electrical field.

The measurement of trace ion amount is carried out with a contactless conductivity detector. The detector has a detection cell composed of PEEK tubing and three electrodes which are connected to the tubing. The cell has low void volume. Because electrodes have no contact with solutions passing through, an elution of metal ions due to electrolysis is prevented.

H⁺ and OH⁻ concentration in a closed vessel of the pure water production process is calculated according to a change in electrical conductivity measurement of pure water upon removal of either cations or anions respectively.

The pH value of pure water is determined from an ion concentration difference between H⁺ and OH⁻

AS a detection limit of H⁺ and OH⁻ with this proposed method is lower than 0.1 μM, the pH value of solution, which is lower than 100 μS/cm (mS/m), can be measured accurately.

Electrical conductivity detection of KCl solution that is pretreated with this removal device is shown in Figure 1 attached hereto.

Abstract Title **Fast and On-Site Natural Gas Odorants Analysis Using Micro Gas Chromatography**

Primary Author Remko van Loon
Agilent Technologies

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Coen Duvekot

Abstract Text

Natural gas is a widely used source of energy; it's a colorless, odorless, flammable gas and therefore odorized for safety reasons. The actual location where the gas is odorized is country dependent. This can be done during production, at the country border or at different stages in the distribution network. Multiple, relative costly components can be used to odorize the natural gas. Preventing both 'under' and 'over' odorization there is a demand for a fast and accurate method to quantify odorant levels.

The natural gas suppliers association for an European-based country uses a Micro Gas Chromatograph for on-site analysis of both tetrahydrothiophene (THT) and tert-butyl mercaptan (TBM). This association is responsible for periodic odorant characterization and quantification for over 350 distribution points across the country's entire natural gas network. Instead of taking a sample and bring it to the lab, which can take up to a few days before the result is known, the natural gas is directly analyzed using a Micro GC mounted in an off-road vehicle.

The Micro GC's shoe-box size dimensions and low carrier gas consumption enables easy implementation in process applications and mobile laboratories. Direct, on-site analyses secures the integrity of the sample. Moreover, it leads to fast availability of the odorant's concentration levels. In case of the Micro GC analysis, results are known within 90 to 120 seconds run time. Out-of-spec values can directly be communicated and corrective actions can be taken accordingly.

Abstract Text

Process control is a major challenge for the chemical and petrochemical industries and in the field of energy. A better process monitoring ensures quality product, cost control, better maintaining of productivity and risk control. Direct analysis in the heart of the process is the most efficient way, but the market suffers from a lack of solution that could cover a wide range of applications. In this context, a collaboration between IDEEL and SRA Instruments companies was set up to develop solutions for on-line analysis answering to industrial needs.

A new generation of miniaturized gas chromatograph has been developed for the rapid analysis of liquid components. The analyzer is equipped with an on-line sampling valve developed and commercialized by SRA Instruments. This injection device uses a piston with a micro machined groove at its lower extremity, designed to contain the pressurized sample to be analyzed. The corresponding volume of liquid will be vaporized during the injection step thanks to the very fast and very powerful heating of the groove. Sample can be then injected directly in a short capillary column without saturation before detection by a μ FID. This miniaturized flame ionization detector presents a strong interest for the micro analyzer, because of its low gas consumption, low power requirements for operation. It brings also similar sensitivity compared to conventional ones. Results obtained of all the technological building blocks are encouraging, this is the reason why a first prototype is presently being evaluated in IDEEL's Laboratory of Industrial Analysis and tested on hydrocarbon mixtures.

Experimental evaluations are intended to measure performances of the instrument in terms of separation, repeatability and detection limit.

This new generation of micro-analyzer should extend the possibilities of in-situ process control. It represents a powerful tool to monitor complex liquid matrices.

Abstract Text

Honey is a valuable food commodity that gains a lot of attention due to its potential health benefits and usage to sweeten foods and beverages. To save on manufacturing costs, honey is susceptible to deliberate adulteration with sugar syrups such as corn syrup. Honey adulteration does not pose significant health problems, but it negatively influences market growth and consumer confidence. Fourier transform infrared spectroscopy (FTIR) with attenuated total reflectance (ATR) was used to collect absorption spectra of various commercial honey samples. Partial least-squares (PLS) was used to process FTIR spectra to determine the potential adulteration of the honey samples. The techniques presented in this work provide an alternative method to determine the purity and authenticity of foods, such as honey, and other natural products.

Abstract Text

The verification of provenance is of vital important in establishing food authenticity. For high value foods, the country of origin has a dramatic effect on the price, as such; falsifying the provenance of foods is an attractive proposition to fraudsters. A prime example is olive oil, being marked incorrectly from desirable countries or regions, such as North African Olive being identified as Italian or Spanish. Whilst various techniques such as trace metal analysis or isotopic ratios have been shown to separate different geographical classes, other factors such as year on year crop variations and changing weather conditions have caused these separations to be less conclusive. Using more than one technique and/or chemometric analysis to differentiate can be more conclusive. This work uses advanced analytics and visualization software with in built principle component analysis function or PCA to separate the geographical origin of olive oil utilizing GCMS data, Wine using ICPMS data and Whisky using ICPMS and LCMS data combined.

Co-Author(s)

Abstract Text

A multi-residue method, based on programmed temperature vaporization gas chromatography triple quadrupole tandem mass spectrometry (PTV-GC-MS/MS), was developed for rapid determination of 54 kinds of pesticide residues in vegetables and fruits. We injected extracts of spinach, cucumber, apple, tomatoes, pepper, cabbage, cowpea, Chinese chives from the updated QuEChERS sample preparation method. Average recoveries were 70~130% for 54 of the pesticides in 3 different matrix. Also, detection limits were $<5 \mu\text{g}/\text{kg}$ for all but a few pesticides, depending on the matrix. LODs were determined as 3.3 times S/N. LODs were in the range $2.0\text{-}10.0 \mu\text{g}/\text{kg}$. The quantification of pesticide residues was performed by GC-MS/MS equipped with a programmed temperature vaporizer (PTV) inlet, which can remarkably reduce the background noise and column burden by selective transfer of target analytes onto column. It was demonstrated to be a simple, sensible, reproducible and environment friendly method for the determination of pesticide residues in vegetables and fruits.

Abstract Text

A fast method was developed for the simultaneous analysis of 174 pesticides in grape using gas chromatography tandem mass spectrometry (GC-MS/MS) in multiple reaction monitoring (MRM) acquisition mode. The samples were extracted by acetonitrile, and separated with liquid-liquid partitioning from water in the sample by salting out with sodium acetate and magnesium sulfate (MgSO₄). The supernatant liquid was purified by C18 and primary-secondary amine (PSA) to remove most of the fats and pigments in samples. The treated samples were then subjected to MRM analysis for 174 pesticides using GC-MS/MS, every compound has 2 MRM transitions (primary for quantification, secondary for qualification), totally 348 transitions in 15 minutes. The result showed that the linear relation between peak area and concentration of target were good from 5 ng/mL to 100 ng/mL ($r^2 > 0.99$). The limits of quantitation (LOQs) of all the pesticides studied were 0.1 µg/kg. The average recoveries were 70%~130% of target compounds and the relative standard deviations (n = 6) were below 10% in grape spiked levels at 10 µg/kg. The results show that this method can be used to simultaneous analysis of 174 pesticide residues in grape.

Abstract Title **Examination of Dietary Supplements for PDE-5 Inhibitor Adulteration by PLM and FTIR Microscopy**

Primary Author Chester M. Talbott
Shimadzu Scientific Instruments

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Anton N. Bzhelyansky, Jeffrey R. Head, John M. Kinyanjui

Abstract Text

Significant concern has arisen over the widespread adulteration of dietary supplements with synthetic phosphodiesterase type-5 (PDE-5) inhibitors sildenafil (Viagra®), tadalafil (Cialis®) and vardenafil (Levitra®) and their numerous structural analogs. Although mass spectrometry is being successfully employed by advanced investigators, regulatory agencies, and, increasingly, contract testing facilities, cheaper, and more accessible alternatives are desirable to enable mid-range QC laboratories to perform effective screening. Typical physiologically relevant dosages for the PDE-5 inhibitors start at single-digit milligram amounts; adulteration at lower amounts renders such remedies inefficient. However, presence of 50-100 mg offending substances is not uncommon. Dietary supplement matrices add additional degree of complexity to sample preparation, and limited solubility of these molecules in typical solvents could be problematic. Therefore, analysis of the solid matter without relying on elaborate sample preparation procedures, and complex analytical techniques, is desirable. The crystal morphology of the PDE-5 inhibitors may offer a rapid means of identifying their presence in dietary supplement matrices. Polarized Light Microscopy can be used to screen for the presence of PDE-5 inhibitor contamination, and FTIR Microscopy can then be used to further verify the identity of suspect crystalline inclusions, or at least, suggest their structural category. This combined microscopy approach is utilized to examine a number of dietary supplements purchased online and in US retail locations, to demonstrate feasibility of this methodology in erecting a barrier to adulteration, and permit rapid screening of potentially tainted dietary supplements.

Abstract Text

Phthalate esters (PAEs) are a group of commercial chemicals widely used to make plastics more malleable and help lotions penetrate skin. A number of phthalate esters are known to cause birth defects or reproductive harm. As we all known, alcoholic drinks have always been popular around the world. In alcoholic drinks production, plastic containers are typically used in the storage and transportation process, which could make some phthalate esters leak easily from PVC tubes or vessels as well as plastic caps. The aim of this study is to determine the level of phthalate esters migration in alcoholic drinks by fast liquid chromatography-electrospray tandem mass spectrometry. This method is simple and rapid with acceptable sensitivity to meet the requirements for the analysis of PAEs in alcoholic drinks.

Abstract Title **Wool Packing or No Wool Packing in a Splitless GC Inlet Liner—What is Better for Pesticide Analysis? A Case Study with a QuEChERS Strawberry Extract**

Primary Author Jack Cochran
Restek

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Jaap de Zeeuw, Linx Waclaski, Rebecca Stevens

Abstract Text

Pesticide chemists usually avoid glass wool packing for splitless injection GC because, sometimes, lower responses are seen for active or thermally unstable pesticides (e.g., Carbaryl, DDT, Iprodione, etc.). But, properly deactivated quartz wool can not only be a valuable protector of the GC column from nonvolatile “dirt,” but also offers increased responses for pesticides because it stops them from hitting the bottom seal in a typical GC inlet, where they can be lost or degraded.

This study compared GC-MS response factors for a group of volatile to involatile pesticides from organochlorine, organonitrogen, organophosphorus, carbamate, and pyrethroids classes spiked into a QuEChERS strawberry extract, which was then splitless injected into single taper liners with wool and without wool. Not surprisingly to me, since I had seen it before with tobacco extracts (EPRW 2012), initial response factors were higher for the wool-packed inlet liner versus the liner with no wool. After 60 analyses of strawberry extract on each liner, some of the more difficult pesticides showed lower response factors on both liner types, but overall, the wool-packed liner still showed higher response factors versus the unpacked liner.

A final part of the study compared response factors for deactivated quartz wool liner packing to deactivated borosilicate wool liner packing. Deactivated quartz wool was significantly better for analyzing Dimethoate, Chlorothalonil, Carbaryl, Methiocarb, Dicofol, and Deltamethrin.

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) François Béland, Genevieve Gingras, Vincent Bédard, Yvan Chouinard

Abstract Text

The QuEChERS method was developed in 2003 by scientists at the USDA to speed up and simplify food sample preparations for multiclass, multiresidue pesticide analysis. Over the years, many modifications have been brought.

This poster describes the use of the original extraction method and the AOAC approach for clean-up of 13 different pesticides, among those mostly used by Canadian apple producers.

The method involves 1) an initial extraction in an aqueous/acetonitrile system using magnesium sulfate (MgSO_4) and sodium chloride (NaCl); followed by 2) a dispersive solid phase extraction (dSPE) as a clean-up step using primary-secondary amine (PSA), MgSO_4 and C18.

Target pesticides in the apple extract have then been detected and analysed by liquid chromatography coupled to electrospray ionization tandem mass spectrometer (LC-ESI-MS/MS).

This method has been validated in terms of recovery and reproducibility, and a limit of quantitation (LOQ) was also determined.

This work employed SiliCycle[®] SiliaQuick[®] extraction packets QE-0001-100P and SiliaQuick dSPE tubes QD-2006-15T.

Abstract Title **Antimicrobial Agents in Bovine Milk: Screening to Confirmatory Analysis by Liquid Chromatography Mass Spectrometry**

Primary Author Kenneth Rosnack
Waters Corporation

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Danny Chan, Dominic Roberts, Eimear McCall, Joe Romano, Sara Stead

Abstract Text

An important aspect relating to the use of veterinary medicines in cattle is the presence of residues in milk. Antimicrobials constitute the largest class of compounds administered to livestock globally. This widespread use together with stringent food safety legislation necessitates the availability of rapid and sensitive analytical techniques for residue detection. Cost-effective, robust and broad-scope platforms, which can be easily implemented in routine control laboratories are of importance. Other considerations are the flexibility of analytical scope and the extent of compliance with internationally recognised validation criteria.

The workflow from screening to confirmatory analysis of antimicrobial residues, as required by European Union (EU) Regulation 2002/657/EC will be discussed. A simple dispersive solid phase extraction (d-SPE) procedure provided effective and simple sample clean up, where average recoveries were > 90 % for all multi class analytes.

Liquid chromatography separation, coupled with an accessible single quadrupole mass detector provided robust analysis and high sample throughput, where the screening target concentrations (STC) were less than the EU MRLs for each analyte. Suspect positive results identified by this screening method were directed for quantitative confirmatory analysis on a compact and high performance tandem quadrupole mass spectrometer.

The method was found to be fit for purpose, thus allowing for the qualitative and quantitative analysis of commonly administered antibiotics below EU regulatory limits in bovine milk.

Abstract Title **Analysis of Kenyan Honey for Essential and Heavy Metals by Atomic Absorption and Atomic Emission Spectroscopy**

Primary Author Onditi O. Anam
Jomo Kenyatta University of Agriculture and Technology

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Anne Mbiri

Abstract Text

Analysis of honey is important due to its nutritive and medicinal value. High concentration of essential metals and heavy metals can be toxic to both man and animals. Due to rapid increase in industrialisation in Kenya, there is corresponding increase in environmental pollution, hence increase in these metals in honey. Honey samples were collected from different geographical regions in Kenya. These included Nairobi, various parts of Rift Valley Province and Eastern Province. The selected Heavy metals (Pb, Cd, Zn) were determined by Flame Atomic Absorption Spectroscopy, while arsenic was determined by Hydride Generation-Atomic Absorption Spectroscopy. Essential elements (Na, K, Ca and Mg) were determined by Flame Atomic Emission Spectroscopy. The concentration of K, Na, Ca and Mg were found to range from 172.83 \pm 0.02 to 781.52 \pm 0.09 ppm, 98.04 \pm 0.03 to 269.10 ppm, 19.33 \pm 4.07 to 70.17 \pm 3.90 ppm and 12.64 \pm 0.43 to 41.88 \pm 0.92 ppm respectively. The results obtained showed that most of the samples had a high concentration level of Zn with mean value of 0.19 \pm 0.06 ppm followed by Pb with mean concentration of 0.16 \pm 0.10 ppm and then Cu with mean concentration of 0.03 \pm 0.01 ppm followed by Cd with mean value of 0.02 \pm 0.01 ppm and finally As with mean value of 0.01 \pm 0.01 ppm. The mean concentration level of Pb was found to be higher than 0.1 ppm which was above standards set by the World Health Organization (WHO) and Kenya Bureau of Standards (KEBS) for food products.

Xylem/OI Analytical

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Jonathan Howerton

Abstract Text

Most continuous flow analyzers are designed to perform either Segmented Flow Analysis (SFA) or Flow Injection Analysis (FIA). Neither technique addresses the full range of reaction chemistries and analyses laboratories are called on to perform. Segmented flow analyzers require complex air injection and wetted solutions, while flow injection analyzers are less effective with chemistries requiring long reaction times. This poster will report results of a performance study on a new continuous flow analyzer that combines SFA and FIA techniques on a single instrument platform. Design and performance characteristics such as reduced detector noise and expanded calibration range of the new automated chemistry analyzer will be presented.

Abstract Text

Generally, inductively coupled plasma - Optical emission spectroscopy (ICP-OES) is used to analyze gasification slags. However, tedious sample preparation process and availability of small amount of slags sample is of great concern. In order to overcome these problems, we propose the use of Laser induced breakdown spectroscopy (LIBS) for analysis of small quantities of slag samples. It is advantageous to use LIBS because it permits a rapid [i]in situ[/i] sample analysis with little or no sample preparation. In this work, synthetic slags with chemistry falling within coal-petcoke mixed feedstock slags were prepared for the investigation. A small amount of synthetic slag sample placed on a double sided adhesive tape was used in LIBS experiments. Optimization of energy, gate width, and gate delay for well resolved spectra with good SNR and SBR was carried out. Careful selections of spectral lines of Al, Ca, Fe, Si, V which do not suffer from potential self-absorption were considered for LIBS analysis. Intensity ratios to reduce shot to shot fluctuations were used to develop calibration curves and result was compared to those obtained using ICP-OES. Furthermore, multivariate statistics and data analysis methods were used to ascertain the results.

Abstract Text

In order to gauge the environmental effects of titanium dioxide, an abundantly produced nanomaterial, it is important to characterize its binding affinity to biological substances in aquatic ecosystems. Estradiol and ethinyl estradiol are of interest as these chemicals are common endocrine disruptors. The subsequent health defects associated with endocrine disruption are further complicated by estrogen-titanium dioxide complexes. To understand the extent of these effects, it is crucial to determine the binding constants of titanium dioxide to estrogens in different mediums. Bound estradiol is quantified using pH-mediated stacking in capillary electrophoresis. This method concentrates the analyte of interest, requiring microliter sample volumes and improving the limit of detection to the nanomolar range. Furthermore, the technique utilizes a mixture of cyclodextrins and lauryl sulfate (SDS) micelles to allow the partitioning and separation of neutral steroid hormones.

Initial studies involve the binding affinity of titanium dioxide to estradiol in a pure water medium, followed by the more complex matrices of albumin and aquatic biome mediums. Results of albumin-facilitated binding give insight into the effect of protein adsorption on nanoparticle-small molecule complex formation. The result of the binding study in aquatic biome enhances understanding of contaminant binding in river water and wastewater. This study also allows a better understanding of the toxicity of titanium dioxide with regards to reproduction and circulating steroid hormone levels in the blood.

Abstract Text

Fast analysis used to be limited to chromatographers with access to expensive UPHLC systems. The re-introduction of superficially porous particle (SPP) liquid chromatography columns to the marketplace has given everyone access to the increased efficiency and peak capacity to decrease their analysis times. The high amount of hydrophobic retention of a traditional C18 phase is well established and every chromatographer includes one in their cache. This new SPP C18 is an endcapped Octadecylsilane phase for fast, rugged, consistent, and reliable reverse phase chromatography. The particles provides higher efficiency for faster analysis and increased sample throughput on typical LC systems. With them we achieve UHPLC like speed and performance with the 2.7 μ m SPP and higher efficiency per unit backpressure than traditional fully porous silica supports with the 5 μ m SPP. The versatility of these columns makes them ideal for separations in bioanalytical, CMC testing, food safety, environmental, and other testing areas. Example separations on these particles will be shown to illustrate their contributions to efficiency and overall sample throughput.

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Annu Suoniemi-Kähärä, Mari Klemm, Sari Hartikainen

Abstract Text

In this study, a rapid method is described for detecting L-Ascorbic acid (Vitamin C, L-Ascorbate) concentrations from milk powder and other samples in the dairy industry. This method is adapted for use with an automated discrete analyzer which is capable of simultaneously analyzing multiple parameters using enzymatic, colorimetric or electrochemical (ECM) method principles. The automated L-Ascorbic acid method is based on the capability of tetrazolium salt MTT [3-(4,5-dimethylthiazolyl-2)-2,5-diphenyltetrazolium bromide] to reduce L-Ascorbic acid and other substances by means of the electron carrier PMS (phenazinium methosulfate) to form colored formazan.

For determination of L-Ascorbate, the assay was specifically designed to use a sample blank, where L-Ascorbate is oxidatively removed by Ascorbate Oxidase. Ascorbate Oxidase was available in a ready-to-use liquid format and the process to add the reagent was fully automated. The difference in absorbance at 575 nm between the sample and the sample blank was equivalent to the amount of L-Ascorbate in the sample. All results were calculated automatically. Samples requiring pretreatment were dissolved in 1.5% metaphosphoric acid (pH 3.5-4). Turbid samples were filtered prior to analysis.

This test can be used for a sample concentration range from 50-2500 mg/L. The method is very fast, requiring approximately 75 minutes for analysis of 100 samples without the need for any additional hands-on time. In method correlation studies, the same samples were measured by both HPLC analysis and the automated discrete analyzer method. Very good correlation was shown in the results.

Abstract Text

The development and application of new ion chromatographic columns packed with ion exchangers of smaller particle sizes (e.g., 4 μm or smaller) have gained increasing interests in recent years since these columns bring out new opportunities to perform fast and high-resolution separations of ionic analytes. The new smaller-particle-size columns typically yield pressures higher than 3000 psi, which is the maximum operating pressure of the current generation of the Reagent-Free Ion Chromatography (RFIC) systems using electrolytic eluent generators. Therefore, there is a need to develop new RFIC systems and electrolytic eluent generators capable of operating at higher pressures.

In this presentation, we will report our recent efforts in developing new generation of electrolytic eluent generation devices for producing high-purity potassium carbonate and bicarbonate eluents using only deionized water as the carrier stream at pressures up to 5000 psi. We will describe the principle and operation of the new electrolytic eluent generators. We will demonstrate the advantages of using the high-pressure RFIC systems to achieve fast and high resolution ion chromatographic separations of target analytes in different samples.

Abstract Text

Superficially porous particles (SPP) offer improved efficiency and performance over similarly sized traditional totally porous particles, with similar performance to sub-2 μ m materials but without many of the drawbacks encountered with those materials. This is primarily due to a shorter mass transfer distance and substantially narrower particle size distribution of the particles in the column. Higher efficiency leads to improved resolution and possible time savings with SPP, hence their growing popularity for HPLC analyses. Columns using superficially porous particles are currently available in a wide variety of particle sizes, pore sizes and stationary phase chemistries to meet most analysts' needs.

Often methods using totally porous particle columns can be directly transferred to SPP columns without adjustment. This is particularly true when similar or identical bonding chemistries are available on both types of particles. Method scalability is also facilitated by the increase in choices of particle sizes. Together, these qualities allow for quick and reliable method scaling or transfer, ranging from method development for preparative laboratories to methods for high throughput analyses, while also catering to the use of a wide range of instruments and pressure limitations. For those analysts looking to speed up analyses, SPP columns can offer shorter analysis times, and improved sample throughput. However, analysts must pay attention to the instrument configuration and connections for maximum performance. This work will address method transfer and scalability from totally porous particles, as well as among different varieties of SPP, and overcoming some common barriers of method transfer.

Abstract Text

GPC is an important technique for determining the molecular weight distribution of a polymer and for comparing batch-to-batch polymer quality. In common with other liquid chromatographers, GPC users are making more demands on the technique both in terms of speed of analysis and quality of results. These additional demands have to be balanced with the need to control costs, and the purchase of new specialized instrumentation to achieve performance gains may not be justified. The combined requirements for faster size-based separations and the use of conventional instrumentation could be achieved through the use of novel GPC column technology.

Columns packed with particles that have a very high pore volume deliver significantly increased resolution compared to a conventional GPC/SEC column set – this allows run times to be decreased, through the use of shorter column lengths and higher linear velocities, without sacrificing separation quality. Using industry standard, highly cross linked polystyrene/divinylbenzene (PS/DVB) particles with a diameter $\geq 3 \mu\text{m}$ maintains compatibility with conventional GPC instruments.

In this work, the results for the analysis of polymer samples run on an Agilent 1260 Infinity GPC/SEC system and conventional column set are compared to results obtained from analysis on the same instrument using columns packed with high pore volume particles. The comparison demonstrates that significant reductions in analysis time can be achieved while maintaining acceptable results quality, without the need for specialized instrumentation.

Abstract Text

Temperature affects chromatography. This fact is well known and this is why every good chromatographer will implement some form of temperature control in his/her experiments. With UHPLC, operating temperatures have risen to values very close to or even above the boiling points of typical solvents. Consequently, column ovens have evolved from simple units with fixed temperatures, to high-tech devices capable of heating up a mobile phase to the actual column temperature prior to entering the column, as well as the ability to cool mobile phases prior to entering the detector. In addition, viscous heating is a much discussed topic in UHPLC. When pressures increase to values above 400 bar the friction between the column and the mobile phase can generate additional temperature increases inside the column. Adiabatic heating is typically applied to remedy this situation. However, although it will generate a more uniform temperature increase across the column, the adiabatic approach does not prevent viscous heating. In this work we critically evaluate the various elements of the column oven to accurately determine the effects of different setting on chromatographic performance. Furthermore, we measured the degree of viscous heating that takes place inside the column and discuss how adjustment of chromatographic parameters can be used to maintain or even improve separation.

Abstract Text

Evaluating the efficacy of psychotropic pharmaceuticals often involves in-vivo animal experiments with repeated sampling of brain extracellular fluids for their neurochemical content. By using a microdialysis probe, any changes in levels of biogenic amines and major metabolites can be monitored over time. This offers insights into the psychoactive nature of the drug candidate. Therefore, experimental samples must be repeatedly and accurately analyzed so that any possible changes of major neuroactive chemicals can be observed with reasonable temporal resolution. Rapid analytical techniques such as UHPLC with sensitive electrochemical detection provide advantages over traditional HPLC assays since the sampling rates can be increased due to shorter run times involved with analysis.

The analysis of biogenic amines and major metabolites in these samples is challenging since these compounds are labile and their levels in extracellular fluids from various brain regions are quite low due to active reuptake systems and catabolism. Transport of these compounds by diffusion processes across the microdialysis probe is limited, so only partial recovery of these chemicals from the extracellular fluid actually occurs. These issues present significant assay sensitivity challenges. Combining low microliter sample volumes with short collection periods means the assay must be capable of detecting picomolar levels of analytes. By using a specialized LCEC system, capable of handling the elevated pressures related to UHPLC operation while maintaining the full sensitivity requirements of the electrochemical detection to femtogram levels of detection, assay requirements can be fully satisfied. This work describes the analytical conditions for the successful measurement of biogenic amines and major metabolites in microdialysis samples.

Abstract Text

Sample preparation is one of the most important processes to achieve a good analytical separation. In order to develop more appropriate sample preparation techniques, simplification, automation and miniaturization have been studied widely in the field of analytical chemistry, along with the development of alternative methods.

In this study, an online sample preparation/separation system for aqueous sample was developed with polymer-coated fiber-packed capillary. The system has been developed using an extraction capillary and two trap capillaries packed with a bundle of polymer-coated filaments. As a coating polymer onto the surface of the filaments, a silicone polymer, which is a conventional liquid stationary phase for capillary columns in gas chromatography (GC) was employed. Packed longitudinally with a bundle of polymer-coated filaments into a stainless-steel capillary (0.8 mm i.d., 150 mm length), the polymer-coated fiber-packed extraction capillary was prepared. Aqueous sample solution was pumped through the extraction capillary and the solutes were extracted therein. Taking advantage of the heat-resistant property of the polymer-coated fiber, the extracted analytes were sequentially eluted and roughly separated in the extraction capillary with a temperature-programmed run. Introducing two trap capillaries packed with a bundle of polymer-coated filaments (0.5 mm i.d., 100 mm length) as the interface, the developed extraction system was on-line coupled to micro column LC. The system allowed highly selective and sensitive analysis of benzoates in aqueous solution.

Abstract Text

Multi-angle light scattering (MALS) detection has become an indispensable tool for polymer characterization. The coupling of MALS with high-performance size exclusion chromatography has provided a unique and attractive technique for obtaining absolute molecular weight information and molecular size information about macromolecular systems including both natural and synthetic materials.

We have successfully developed new size exclusion polymer packing material for a column suitable for MALS analysis. Our new column allows for detection of polymers with a molecular weight range of approximately 10,000-100,000 daltons. This molecular weight range was particularly difficult for estimation by MALS due to interference from noise due to the packing material. Thus, our new column with low noise will allow MALS detection for a greater number of compounds with lower molecular weight.

We will introduce the feature of reduced noise as well as several basic features using MALS detection on our newly developed column with several applications.

Abstract Text

Although levamisole is sometimes used as an anthelmintic therapeutic treatment for horses, there has been some concern that because it metabolizes to aminorex, an amphetamine-like drug, it has the potential for abuse, and so its therapeutic use has been banned in some countries. Moreover, it is thought to play a role in the in-vivo production of a significant performance enhancing drug, pemoline. Levamisole is also used as an adulterant in cocaine, its addition likely to extend the effect of cocaine by metabolising to aminorex just as the effect of cocaine diminishes.

Chiral analysis may play a significant role in understanding whether detected levamisole and/or aminorex are due to legal administration of drug products or illicit use for performance enhancement. The project employed several cyclodextrin-based chiral stationary phases and covers the method development and optimization processes. The resulting method may be used to differentiate enantiomers of tetramisole (levamisole and dexamisole) for drug product analysis and performance-enhancing activities in horse-racing. In addition, the method has been shown to provide separation of aminorex and cocaine from the tetramisole enantiomers and thus may be useful in cocaine related studies.

Abstract Text

An ultraviolet (UV) absorbance detector for HPLC has been widely used in many fields. However, the UV detector is hardly used to detect sugar because of its almost non-existent UV absorption. Also, the UV detector is frequently used to detect peptides, but its sensitivity is low because the peptide bond has weak UV absorption at around 210 nm. It is well-known that most organic substances have strong light absorption in the far-ultraviolet (FUV) region below 190 nm. Therefore, if the detectable wavelength of the absorbance detector could be extended to a wavelength region below 190 nm, it could detect not only sugar but also peptides with high sensitivity.

In this study, we modified the UV detector for the wavelength region down to 175 nm for sugar and peptide analysis. The results reveal that the absorption peak of sugar lies at around 178 nm. The detection limit ($S/N = 3$) of fructose and glucose were 50 and 177 pmol, respectively (Fig.1). Also, the results clearly show that the peptide bond has a strong absorption peak at around 190 nm. The peptides (Met-Enkephalin and Gly-Gly) were separated by using a gradient elution method with water/acetonitrile at 190 nm and showed a detection limit ($S/N = 3$) of 2.4 and 2.7 pmol, respectively, which were five times larger than those at 210 nm. In addition, significant changes in the baseline due to the gradient elution were corrected with a newly developed gradient monitor based on near-infrared absorptiometry (Fig.2).

Abstract Text

Herein, we report a new Non-Pneumatic (without vacuum) Membrane Gas Removal System that selectively removes CO₂ (H₂CO₃) gas dissolved in a solution. The system consists of two mechanisms (Cation removal mechanism and CO₂ removal mechanism).

Cation removal mechanism, which is often referred to as an ion suppressor in Ion Chromatography for anion analysis, removes cationic ions from the solution and converts HCO₃⁻ (CO₃²⁻) dissolved in the solution to CO₂. CO₂ converted from HCO₃⁻ (CO₃²⁻) is then removed from the solution by CO₂ removal mechanism.

CO₂ removal mechanism consists of an airtight seal vessel that encloses a gas permeable tubular membrane module and a disposal packet of CO₂ adsorber. In this mechanism, the dissolved CO₂ (H₂CO₃) starts to migrate out of the solution in accordance with a concentration diffusion theory based on a difference of CO₂ concentration between inside and outside of the tubular membrane. The temperature in the vessel is controlled at 37°C. The pressure in the vessel is controlled at 100 kPa.

The gas permeable tubular membrane is 4m long Teflon AF2400 (U-VIX Corp., Tokyo, Japan). The CO₂ adsorber is a tea bag like packet of commercially available polypropylene-nonwoven fabrics and is packed with very well dried OH type AE resin (Amberlite IRA402BL, Dow Chemical).

The vessel has two ports which are used to reduce pressure in the vessel.

The CO₂ concentration contained in the solution was decreased down to a level similar to the one of pure water by the system. The result is shown on Figure 1 attached hereto.

Abstract Text

The increasing need for renewable fuel sources has led to the investigation of different methods that can maximize the bioethanol production from the fermentation of carbohydrate-rich biomass. Two most commonly used pretreatment methods for carbohydrate-rich biomass are enzymatic hydrolysis and mineral acid hydrolysis. However, enzymatic hydrolysis is a slow process and mineral acid hydrolysis requires neutralization and generates a waste stream. In this study, high temperature water and carbonic acid were used as an alternative to the conventional dilute mineral acid hydrolysis. Unlike mineral acids, carbonic acid generated from dissolved CO₂ does not require post-neutralization and reduces the waste stream. A high pressure continuous flow reactor with pressurized carbon dioxide was employed for the hydrolysis of wet microalgae and other biomass. The reaction conditions such as pressure, temperature and residence time were optimized by monitoring the formation of simple sugars and degradation byproducts with HPLC. The yield of simple sugars from the direct treatment of whole microalgal biomass for 5 minutes at 210°C using 7 MPa CO₂ was very low, but increased to levels similar to the dilute mineral acid hydrolysis when a small amount (0.05%) of sulfuric acid was added. The amount of thermal degradation byproducts such as 5-HMF and furfural was approximately one order higher, however, no inhibition was observed during the subsequent fermentation of hydrolysis substrates to ethanol.

Abstract Text

Gold-coated iron oxide core-shell nanoparticles (IO-Au NPs) are of interest due to their potential uses in numerous biomedical applications including capture and detection of circulating tumor cells for early cancer diagnosis, enhancement of MRI and near-infrared photothermal therapies. In order for a nanoparticle to exhibit optical properties that are advantageous for a specific application, there are several significant components including shell thickness and particle size, but the largest contributing factor is the shape of the nanoparticle. Core-shell IO-Au-NPs have been synthesized in various shapes including, spheres, pins and stars, however, the mechanisms determining the final shape of the nanoparticles are not well understood. A systematic study of nanoparticle growth through the use of Transmission Electron Microscopy (TEM) will assist with future synthesis of nanoparticles tailored for specific methods. For this investigation, we have developed a TEM method for time-resolution of Au-shell formation and growth processes to form core-shell IO-Au NPs. Information regarding the Au-shell growth process may allow for the improvement of current synthesis methods to form more monodisperse anisotropic IO-Au NP samples with desired optical-plasmonic properties.

Abstract Text

The hydrogel-liposome bi-compartmental structures (lipobeads or lipogels) combine biocompatible surface properties of lipid bilayer with the polymer network's mechanical stability, loading capacity, and ability to release drugs controllably. Giant lipobeads (GLB, 3-500 [micro]m) are convenient objects for direct observation by optical microscopy and modeling their properties as drug delivery systems. We have prepared GLBs using two methods: polymerization within liposomal reactor and microgel-liposome mixing. In the first method, hydrogel forming solution was incorporated inside giant unilamellar vesicles (GUV) and exposed to UV light to provide polymerization within the GUV microreactors. In the second method, microgel beads prepared by means of inverse suspension polymerization were mixed with liposomes prepared by means of extrusion. The experimental steps, optimal parameters and conditions were justified for both methods. To distinguish between the lipid bilayer envelope and the hydrogel core using fluorescence and confocal laser scanning microscopy, red image of a phospholipid layer was originated from rhodamine B (555 nm excitation) covalently attached to the heads of phospholipids, whereas green image of inner portions of the lipobeads was originated from fluorescein-o-acrylate (488 nm excitation) covalently attached to the polymeric network. Two mechanisms of controlled load release are discussed for temperature sensitive hydrogel cores with lower and upper volume transition temperatures, respectively. Possible procedures for loading of curcumin or doxorubicin are proposed to develop versatile delivery systems of these curing agents.

Abstract Text

Understanding the interfacial phenomenon, especially molecular transport, e.g., adsorption/desorption, diffusion and migration near a solid surface, is important since it is involved in both fundamental science and advanced applications. In chromatography, a plenty of surface modifications have been applied to change the interactions between samples and stationary phase to optimize the retention time to achieve the best separation. As a high temporal resolution technique, Fluorescence Correlation Microscopy (FCS) has provided an approach to study the particles/molecules dynamics in solution and near surface. However, due to the spatial resolution limit, it is challenging to differentiate diffusion within a small area from adsorption. Thus, a super-resolution technique, Stimulated Emission Depletion Microscopy (STED), has been used in combination with epi- and confocal fluorescence microscopy to study how particles/molecules retained in a C18 modified porous structure. In experiments, we found that the retention time of the particles in the pores does not correlate with the adsorption time of the particle on C18 surface. To fully understanding this phenomenon, different fractions of C18 and modifications have been studies. This study provides a new view to understand how particle-surface interaction affects molecular retention in porous media.

Abstract Text

The extracellular matrix is composed of a complex mesh of matrix protein and glycosaminoglycans heterogeneously decorated with sequestered biomolecular cues, which together with soluble cues, control cell fate and function. It has long been appreciated that traditional 2D cell culture plates poorly model native cell environments, which in turn can lead to unnatural cellular behavior. We have developed a suite of techniques to modify collagen-based 3D cell culture scaffolds to more accurately mimic the native mechanical and biomolecular complexity of the ECM. Using benzophenone (BP) mediated photoimmobilization we demonstrated functional patterning of vascular endothelial growth factor (VEGF), which induced spatial induction of endothelial cells towards a vascular fate and an overall increase in penetration into the scaffold. This photochemical approach to factor immobilization is limited in the depth of patterning by the opacity of collagen scaffolds. To alleviate this limitation, we have implemented a layering-based approach to create scaffolds that have biomolecular cue variation in all three spatial dimensions. We have utilized these layered scaffolds to controllably differentiate mesenchymal stem cells towards both a tendon and bone phenotype with an interfacial region in the middle mimicking the native tendon-bone interface—a challenging and important target for regenerative medicine. Overall, we have developed a generalizable toolbox to rationally modulate both the mechanical and biomolecular presentation of cues that more accurately recapitulate native environments for a range of advanced cell culture and tissue engineering applications.

Abstract Text

Total holographic characterization uses holographic video microscopy to measure the size, refractive index and three-dimensional position of individual colloidal particles moving freely through their fluid medium. The detailed information derived from these measurements have applications in product development, quality assurance and manufacturing process control in industries as diverse as consumer products, food, cosmetics, medical diagnostics, pharmaceutical manufacturing, petrochemicals, among others. Based on the Lorenz-Mie theory of light scattering, holographic characterization yields a particle's size to within a nanometer and its refractive index to within a part per thousand. These data are available for each particle in the microscope's field of view and for each snapshot in the holographic video stream. No other particle characterization technique provides such a wealth of information. The analysis is fast enough that population statistics on tens of thousands of particles can be amassed in minutes. Holographic characterization therefore yields insights into the composition of inhomogeneous and multicomponent colloidal dispersions that cannot be obtained in any other way. Holographic tracking data, obtained at the same time, yields insights into individual colloidal particles' responses to external forces, their interactions with bounding surfaces and their interactions with each other. In combination with optical micromanipulation, these measurements provide an unprecedented view into the stability and dynamics of colloidal dispersions.

Abstract Text

Currently, many lab-on-a-chip devices are fabricated in fused silica, which has a homogenous distribution of surface functional groups; however, fabrication of glass-based devices is costly and time-consuming. Whereas thermoplastics offer low cost, simple and scalable fabrication, and ease of functionalization via surface oxidation (UV/O₃ and O₂ plasma). Activation and characterization of thermoplastic surfaces is essential for many lab-on-a-chip applications, especially for electrophoretic separations in nanometer scale columns. We have previously characterized surface-confined carboxylic acids (COOHs) present on UV/O₃ modified cyclic olefin co-polymer (COC) and poly(methylmethacrylate) (PMMA). However, due to analytical limits, the density and spatial distribution of COOHs could not be determined, which is essential for evaluating non-plug like flow that may be generated with high surface charge heterogeneity. We have developed a new approach to characterize activated surfaces utilizing super resolution microscopy, specifically Stochastic Optical Reconstruction Microscopy (STORM). Surface COOH groups were generated via UV/O₃ or O₂ plasma treatment with the COOHs aminated and covalently labelled with a fluorescent marker and imaged by STORM. Both COC and PMMA were analyzed via STORM as a function of activation dosage. Results indicated a higher COOH density on COC substrates compared to PMMA with an optimal activation dosage. Also, high surface heterogeneity was noted. Furthermore, using COMSOL, the STORM images were mapped onto surfaces in three dimensions across nanochannels to simulate electroosmotic flow (EOF) for different functional group densities and uniformities. The results indicated that low density surface charges and non-uniform distributions introduced a non-plug like EOF. The effects of this non-plug like EOF profile will be discussed in the context of nanoscale electrophoresis.

Abstract Text

One of the most common traditional methods for moisture specific analysis is Karl Fischer (KF) titration, in which iodine is reacted with water molecules to create an electrical current that can be measured. This has shown to be a reliable method of moisture-specific analysis, but it requires and consumes hazardous wet chemical reagents and delicate glassware and so is not a practical choice for many applications, industries and environments.

The Computrac® Vapor Pro® moisture specific Relative Humidity (RH) analyzer is an ideal replacement for a KF titrator. This technology thermally vaporizes water from a sample and sweeps it over a dry RH sensor using a dry carrier gas. Although other volatiles may also be present in the gas, the RH sensor is specific to only water molecules and will accurately and reliably detect moisture in virtually any type of product. No wet chemical reagents are required for this RH sensor method, making it safer, less prone to interferences, and cost-effective. In this paper, we demonstrate equivalency between RH and KF methods in plastics, food and pharmaceutical products while weighing the positive and negative aspects of each method.

Abstract Text

The integration of optics and fluidics at the microscale is a powerful tool and can be used for many biological applications. Amongst the ones being studied at present are single or multiple cell sensing [1,2], sorting [3], study of intra- and extracellular forces [4, 5] and spectroscopy (SERS) [6]. Although some of these techniques are quite mature, a major bottleneck is the complexity of system fabrication and assembly. Optofluidics is at present performed in large part with samples that are cumbersome to fabricate, expensive and require complex alignment procedures [7]. We here describe the fabrication procedure of an injection molded TOPAS polymer chip for optofluidic applications. Such chip allows simple assembly with commercially available waveguides, precise alignment and is suitable for fabrication in large batches [8]. Further advantages lie in the chemical and thermal resistance as well as optical transparency of TOPAS that allow on-chip processing and optical detection. Fabrication details as well as first optofluidic tests of both single and multiple cell manipulation will be shown.

Abstract Text

Polyolefins are an important class of polymer that are used in common plastic materials. The most common polyolefins, polyethylene (PE) and polypropylene (PP) are often characterized from their pyrolysis products by Py-MS [1]. Nowadays the development of direct probe atmospheric pressure sources allow the direct analysis of these polymers [2]. The polymer deposited on a glass tip is desorbed with a hot nitrogen flux and ionized by nitrogen or helium plasma. These sources operate at atmospheric pressure, which imply a limited control of the ionization conditions. It was shown that side reactions could occur with species present in air such as O_2 that may lead to the formation of oxidized compounds [3].

In this work ion mobility - mass spectrometry (IM-MS) and Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR) was used for the exhaustive characterization of the PP and PE pyrolysis ions produced using plasma-based atmospheric pressure ion sources. Both PP and PE yielded distribution of pyrolysis products presenting different number of unsaturation as shown by Lattimer but also different number of oxygen atoms. PP yielded mostly species presenting one and two oxygen atoms while PE yielded species presenting 0 to 7 oxygen atoms (Figure 1). From the FTMS data is was possible to obtain elemental composition of each ion allowing to examine extensively the different ion distributions whereas IM-MS yielded information on collision cross section allowing the differentiation of isomeric ions (Figure 2). In particular the ions produced from PP presented a lower CCS than those produced from PE.

Abstract Text

The Laser Flash or Light Flash Technique (LFA) is a well-known method for the determination of thermophysical properties of, for example, carbon materials and metals from below room temperature up to high-temperatures (e.g. -125[degree]C to 2800[degree]C). In this technique, the front surface of a plane-parallel, disk-shaped sample is heated by a short, high-energy pulse. The resulting temperature rise on the rear surface is measured versus time using an IR sensor. The advantages of the LFA technique are its short measuring times, easy sample preparation and high measuring accuracy. It is also a contactless and non-destructive measuring method. Simultaneous determination of the thermal diffusivity and the specific heat are possible. With knowledge of the material's density, direct determination of the thermal conductivity is possible. Until recently, the LFA technique has mainly been used for well-conducting materials like carbon materials and metals. This poster will describe the newest developments and special sample holders which allow measurement of low-conducting materials such as polymers, composites, and liquids / powders. This poster will detail a new sample holder for low-viscosity liquids such as water, oils and resins (e.g. during curing). The newly designed sample holder consists of parts made of stainless steel combined with a PEEK ring which allows faster, less costly thermal conductivity measurements with high precision.

Abstract Text

Some lignin derivatives as methylated lignin, thioglignin and lignosulphonate were prepared and evaluated as reinforcing filler for rubber. They were incorporated with rubber and its ingredients through mixing process of rubber industry. The mixing was done on two roller with 460 mm in diameter, working distance 250mm, speed of slow roll 16 rev./min. and gear ratio 2. The rheometric characteristics of the compounded rubber were measured using Monsanto oscillating Disc rheometer. The mechanical properties were tested according to the standard methods. The analytical data obtained from the tested properties were evaluated. It was found that, methylated lignin and thioglignin increase the optimum cure time and slightly decrease the rate of vulcanization. Lignosulphonate increases the rate of vulcanization as confirmed from the cure rate index. The physico mechanical properties illustrated that the presence of 10 phr from methylated lignin or thioglignin in the vulcanizates increases tensile strength and modulus at 200% of strain. The crosslinking densities were increased as indicated from the percentage of equilibrium swelling. The thermal stability of the investigated vulcanizates were determined by measuring the mechanical properties after thermal oxidative aging at 90 degree. The vulcanizates tolerated aging up to 7 days, also, resist the ultra violet light up to 10 days after subjecting to UV lamp of 200-300nm.

Abstract Text

The chemical composition of rigid polyurethane foams was studied using FTIR microscopy. Due to temperature gradients during the processing of rigid polyurethane (PU) foams, chemical gradients are observed across the radial axis creating a chemically heterogeneous composite. Furthermore, as you traverse across the cell micro-structure of these cellular materials, the chemical composition of the cell wall becomes distinct from the chemical composition of the gas filled cell nucleus. FTIR microscopy offers an ideal tool for studying variations in chemical composition at these microscopic levels. The chemical gradients in cross-link functional groups across the radial axis of a rigid PU foam in addition to residual starting materials such as isocyanate present in the foam is analyzed and presented.

Abstract Text

Polymer materials and films impact our daily lives. Many characteristics of these materials have been enhanced by the addition of nanoparticles to provide unique solutions we see and touch every day. Weight reduction, safety, cost control and appearance in the automotive industry being only one application where polymers are an important materials. The determination of color and haze, (clarity) in automotive finishes and components such as windshields and other transparent or semi-transparent materials and polymer films impacts both appearance as well as safety and needs to be fully characterized. UV/Vis/NIR spectrophotometers equipped with a correctly designed 150 mm integrating sphere are a critical analytical platform necessary for the characterization of color and haze for both development as well as Quality Assurance testing needed for these materials as they become more complex.

Abstract Text

Contaminants of are an important issue for plastic recycling activity. The control of incoming material and washing process is necessary to minimize this risk. Heracles system can be used to quantified very rapidly the residual solvents, such as benzene and toluene, and odorous compounds such as limonene in the incoming material and the finish product. The AroChemBase software can also be used to investigate the nature and odor threshold of unexpected contaminants. Plastic such as Polyethylene (PE), polypropylene (PP), High Density Polyethylene (HDPE) and polyethylene terephthalate (PET) are increasingly recycled. Recycled plastics face a higher risk of contamination and unwanted off-odors that could affect the organoleptic properties of the food they protect.

In this study, HERACLES fast gas chromatograph as used to detect the main contaminants of recycled plastics. This instrument features two metal columns of different polarities (non polar RXT-5 and slightly polar RXT-1701, length = 10m, diameter = 180µm, Restek) mounted in parallel and coupled to 2 Flame Ionization Detectors (FID). It allows headspace or liquid injection mode and also integrates a solid adsorbent trap thermo-regulated by Peltier cooler (0-260°C) fort pre-concentration of light volatiles. Recycled HDPE resin was analyzed with or without standard additions. A standard mixture of n-alkanes (n-hexane to n-hexadecane) was analyzed to allow retention time conversion.

Calibrations were conducted using a mixture of chloroform, benzene, toluene, 4-vinyl-1-cyclohexene, trichloroethylene, limonene, methyl salicylate and benzophenone in methanol. The detection limits of the analytical method in plastic ranges from 0.5 µg/kg to 2 mg/kg depending on the compound and the potential contaminant molecules of plastic can be isolated in a chromatogram in less than 2 minutes.

Abstract Text

Diethyl 4,6-dichloro-1,3,5-triazin-2-ylphosphonate and dimethyl (4,6-dichloro-1,3,5-triazin-2-yloxy)methylphosphonate are known to be very effective flame retardant (FR) additives for cotton fabrics. To understand their mechanism of action, an investigation of their thermal degradation on twill fabric was carried out in three steps: a) using the attenuated total reflection infrared (ATR-IR) spectroscopy to characterize the control and treated fabrics; b) employing the thermogravimetric analysis coupled with fourier transform infrared (TGA-FTIR) to study the evolved gases produced thermally; and c) applying the bond dissociation energy (BDE) to measure the strength of bonds in both FRs. Several novel features observed in the infrared spectra of materials include characteristic absorption peaks of phosphonate in the solid samples and of the methanol and ethanol in the released gases. Furthermore, the change in the enthalpy favors the cleavage of the phosphonate groups and chloride which lead to the possibility of the formation of cyanuric acid. These results reveal some distinctive details in the thermal degradation of the two compounds and they manifest their flame retardant nature on the substrate.

Abstract Text

Passive microrheology based on Diffusing Wave Spectroscopy is a new innovative technique for the study of the viscoelastic properties and the gel point transition of polymers and hydrogels. Passive microrheology consists of using micron sized particles to measure the local deformation of a sample resulting from the thermal energy, that is to say the Brownian motion.

DWS is an extension of the DLS technique to opaque media. The determination of the Mean Square Displacement (MSD) curve enables the complete characterization of the viscoelastic properties of a sample. The technique allows to measure particles displacement in a spatial range between 0.1 and 100 nm and a time scale between 10⁻³ and 10⁵ seconds.

Biopolymers have been introduced to a large scale of formulation not only in the food sector. Their unique properties in stabilization, structuration as well as texturation made them to extensively used components. Especially the gel formation capacity is of outmost interest.

This work presents a rescaling data processing known in rheology as time curing superposition [1-4], to determine precisely the gel point transition and gel strength parameters according to the Winter-Chabon-Criterion. Results will show the determination of the gel point versus time for carrageenan, gel point versus concentration for xanthan polymer, cross-linker concentration effect on the gel point.

Abstract Text

The analysis of flavonoids in citrus species is often used for quality control and product authenticity because of their remarkable taste properties and variation in flavonoid profiles in different species and varieties of citrus(1,2). The most common technique is RPLC with UV/Vis detection or PDA detection. The challenge in this analysis is that flavonoids consist of dozens of structurally similar compounds, typically differing only in the degree of ring substitution, the type of substitution, and the type and degree of glycosylation. PDA detection lacks the selectivity in distinguishing the subtle structural difference in flavonoids. Mass spectrometry (MS) can provide better selectivity and better sensitivity for flavonoids analysis than the PDA does. However, the cost and the ease of use of MS instrument has always been a concern, especially for QC labs in manufacturing plants. The ACQUITY QDa Detector can provide mass spectral data with minimal tuning at affordable cost. It not only extends the sample detection to compounds with no UV or fluorescence chromophore but also improves the selectivity, which leads to a simpler and faster liquid chromatographic methods.

Here we report a fast and simple LC analysis of flavonoids (Narirutin, diosmin, hesperidin, didymin, sinensetin, nobiletin, tetramethoxycutellarein, and tangeretin) with a Waters ACQUITY UPLC HSS T3 column (2.1x100 mm, 1.8 μ m) using an ACQUITY UPLC H Class system and an ACQUITY PDA and an ACQUITY DQa detector. The chromatography run time, including the column equilibration, is 13 min. The analytical performance is comparable to the existing QC method.

Abstract Text

The laboratory in which instruments are installed and the office in which operators perform day-to-day operations are usually far apart from each other. Consequently, analysts spend a great deal of time moving between both locations.

Interactive communication with instrument improves productivity and promotes an advanced laboratory environment with operation capabilities from the built in touch panel and a smart device, thereby enabling a PC-free laboratory.

This feature enables operators to perform minimal operations to start an analysis via the instrument while the data acquisition is synchronized with Chromatography Data System. In addition, smart device such as a smartphone and a tablet PC spreads and is inflected as a simple multi-functional terminal. These information terminals create a new paradigm to start analysis and remotely monitoring system status and chromatograms without using any special software.

The interactive communication with instrument allows easy access to a system regardless of the operating environment, such as the operation of a system installed under a hood, in order to analyze highly active pharmaceutical ingredients.

The operations in the laboratory are minimized and performed free of errors. More efficient use of laboratory is realized.

In this study, the improvement of the usability and workflow to reduce the laboratory work and space by this new concept is demonstrated.

Abstract Title **Best Practices for the Use of Micropipettes**

Primary Author A Bjoern Carle
Artel

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Doreen Rumery, George W. Rodrigues

Abstract Text

Mechanical action micropipettes are ubiquitous in laboratories and are used for many routine tasks, including the quantitative measurement and dispensing of analytical samples and reagents. Concentrations of biological and chemical components in the prepared samples for assays and tests are volume-dependent and incorrectly performed pipetting steps will directly impact the transferred volumes, and hence, the test results. The design and construction of these pipettes render their performance susceptible to the technique and skills used by the operator of such devices.

This poster describes the basic principles related to an operator's pipetting technique, and quantifies the errors induced by using improper techniques. For example, not pre-wetting the pipette tip may induce up to 1.5% error in the dispensed volume, which may be added to another 1.5% variation induced by the length of the pause before removing the pipette tip from the sample solution. Adding to the cumulative error in pipetting are inconsistencies in aspiration and dispense speeds and applied pressure on the plunger (up to 0.5%), heat transfer from the hands (up to 1.8%), improper immersion depth of the pipette tip into the sample (up to 1.3%), and the choice of the pipetting mode (up to 2.5%).

For obtaining reliable laboratory test results it is imperative that all pipette operators are consistently using the proper pipetting technique. Training pipette operators on using the correct pipetting technique ensures confidence in test results, and is equally critical in assay transfer situations or whenever results from different operators and laboratories need to be compared to each other.

Abstract Title **Controlling Vapor Pressure the Key to Improved Loss-On-Drying Moisture Analysis**

Primary Author Brady P. Carter
Decagon Devices, Inc

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Wendy Ortman

Abstract Text

Moisture content provides valuable information about yield and quantity, making it an important measurement from a financial standpoint. The most common method for determining moisture content is loss-on-drying where a sample is weighed, dried, and weighed again to determine the water loss. Unfortunately, this methodology is plagued by multiple sources of variation such as: weighing errors, recording errors, lack of a dry reference, and error introduced by varying ambient conditions. Automation can eliminate many of these sources of variation, especially weighing and recording errors, while facilitating the simultaneous analysis of multiple samples. However, to address the issues of defining dryness and varying ambient conditions requires controlling the vapor pressure in the oven such that all samples are dried to a common endpoint, regardless of ambient conditions. Since evaporation ends when the vapor pressure of the sample is equal to the vapor pressure of the oven, it follows that the way to eliminate the variation that results from changing vapor pressure in the oven is to always control the vapor pressure to a pre-defined value. Then, dryness could be defined as the point when the sample equilibrates to the controlled vapor pressure in the oven, as indicated by constant weight. For this study, the moisture content of flour was determined under varying relative humidities (vapor pressures) with and without vapor pressure control to determine if controlling vapor pressure eliminated variation due to changing ambient humidities. It was determined that the samples analyzed while controlling vapor pressure did not significantly vary while those analyzed without vapor pressure control decreased as relative humidity increased. The results indicate that an automated loss-on-drying moisture content system that controls vapor pressure improves the reproducibility of moisture content analysis while providing a consistent “dry” reference.

Abstract Title **Monitoring Noise and Vibration in Sensitive Facilities to Control End Results**

Primary Author Gladys Unger
Acentech

Date: Wednesday, March 11, 2015 - After
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Steven Africk

Abstract Text

Facilities often quantify noise and vibration during fit-out, comparing the levels with established criteria and making modifications to conform. This approach, while laudable, presumes that the noise and vibration remains constant over time, or that the processing equipment, itself, will not add noise or vibration.

In recent years monitoring systems for vibration and noise – portable packages incorporating accelerometers, microphones, analysis software and communications hardware -- have become increasingly available, providing real-time information that can be correlated with laboratory activities. For example, one manufacturer measured vibration signatures at several locations on his apparatus in an effort to explain an intermittent degradation in performance. At another facility a researcher found that acoustic noise, generated by his system, already well vibration isolated, generated small vibrations that compromised his results. With continuous, real time monitoring correlations can quickly be established.

Monitoring systems have become increasingly sophisticated, providing real-time information that can be posted to the internet and accessed from a variety of locations. Alarm levels can be implemented, both in terms of amplitude and spectral range. Warning lights, sirens, video monitoring, and email alerts can be incorporated to warn of exceedances, limit damage, and uncover faults.

Vibration and noise monitoring systems require knowledge of the appropriate sensors to employ, the problematic levels of vibration and noise, and the spectral range of importance to the specific process. Bringing this knowledge together with a flexible system architecture can, in a reasonably short time and at surprising low cost, provide quality control for environmental conditions often ignored.

Abstract Text

Odors are produced from a variety of natural and artificial sources. In this regard, odors can be considered characteristic of the emission source. Thus odors can be exploited as markers for identification. As such, odor recognition has become an attractive field, with numerous applications in environmental monitoring, biomedical diagnostics, quality control, and public safety. Incidentally, odors, which are constituted by complex mixtures of volatile organic compounds, can prove challenging targets for accurate identification using conventional techniques. In observance of this limitation, the development of novel gas sensing systems and materials, for identification of complex mixtures has garnered much interest in recent years. Herein we describe a simple method of odor recognition based on the use of QCM virtual sensor arrays. Each array consists of a single ionic liquid thin film immobilized onto the surface of the QCM-D transducer. Upon exposure to 10 different odors both closely related and distinct, measurements of frequency shift (Δf) were recorded at multiple harmonics to obtain odor specific sensing patterns. The multiple harmonic data were then evaluated using principal component analysis and discriminant analysis, which revealed that each of the virtual sensor arrays allowed odor recognition with extremely high accuracy.

Abstract Text

High resolution and high specificity methods are desirable for quality control of herbal supplements and plant material in order to identify purity and origin. In this study, a laboratory-built sheath liquid capillary electrophoresis mass spectrometry (CE-MS) interface was fabricated using a small dimension CE capillary inserted through a mixing-tee to analyze 14 naturally occurring flavones, flavonols, flavonones, and their glycosides. Electrospray ionization was performed in negative ion mode and daughter ion scans were used to characterize the flavonoids of interest. The CE separation was carried out using a borate based buffer, which is commonly considered incompatible for CE-MS applications. The migration order was dependent on the extent of B-ring hydroxylation, conjugation of the aromatic rings, number of glycosidic functionalities, and ability of the flavonoid to form stable borate complexes. Parent ion scans yielded $[M-H]^-$, except for cis-diol containing flavonoids, which were also detected as borate adducts. Daughter ion scans of these adducts and flavonoid glycosides typically produced deprotonated aglycone fragments, which are instrumental in flavonoid identification. This method was used to identify flavonoids from the ethanolic extracts of Ginkgo biloba herbal supplements.

Abstract Text

All measurements are performed with a goal, ranging from the assessment of the compliance of a product with a specification to the characterization of a new material. The adequate fulfilment of this goal depends on the fitness of measurement uncertainty (MU) for its intended use. The assessment of the compliance of a gold alloy with a specification for gold content must be performed with a low uncertainty due to the price of this component. The characterisation of a meteorite must be performed with an uncertainty small enough to distinguish their composition from other minerals. Therefore in setting the measurement requirements, in addition to specifying performance parameters such as recovery, repeatability and bias, it is also necessary to set a target value for the MU. The International Vocabulary of Metrology [<http://www.bipm.org/vim>], defines the “target uncertainty” as the “MU specified as an upper limit and decided on the basis of the intended use of measurement results”. Unfortunately only in a few cases does the specification and/or the legislation define the target measurement uncertainty required for compliance assessment. This communication will describe how to set the target MU to achieve the goals of the measurement.

Abstract Text

Many pharmaceutical and biotech companies are moving towards an Electronic Laboratory Environment. These systems greatly improve the scientist's ability to locate specific data compared to traditional paper notebooks. The ability to quickly locate past experiments shortens turnaround time for addressing regulatory questions, provides evidence to protect intellectual property, and allows for improved compliance through software engineering. These systems can also allow users to access their experimental information remotely, and provides a framework for data sharing and collaboration across departments. Implementation of these systems is an interdisciplinary challenge requiring strong relationships between scientists, software engineers, and project management. Discussions must range from high-level system information to granular details of both science and code. In this presentation, a case study of a team's planning and implementation of a flexible, sustainable, and efficient electronic laboratory environment for an Analytical Development department is described. In addition, some of the challenges faced and lessons learned will be presented.

Abstract Text

In this study the quantity of Aspirin (acetylsalicylic acid), acetaminophen (4'-hydroxyacetanilide) and caffeine (3,7-dihydro-1,3,7-trimethyl-1 H-purine-2,6dione) active ingredients in pain relieving drugs commonly dispensed in Kenya were determined using Gas-Chromatography-Mass spectrometry (GC-MS) coupled system. The results obtained in this work showed that acetaminophen in Panadol drug is comparable to the amount in Neladol and Elymol drugs (455-560 mg/tablet) while Hedex drug had the least value (24mg/tablet). The highest amount of Aspirin was found in Maramoja (937mg/tablet) followed by Hedex drug (790mg/tablet). The Aspirin content in Panadol, Elymol and Neladol drugs were below the limits of detection. Maramoja drug had the highest amount of caffeine (93mg/tablet) while Action drug had amount of caffeine of 80mg/tablet. The amount of caffeine in Panadol was 0.1 mg/tablet which was significantly different from those obtained for Maramoja and Action drugs. The difference between the experimental values obtained from this study and the amount indicated on the labels for each tablet by the manufacturers was highest for acetaminophen in P500(212mg/tablet) and lowest in Panadol (26mg/tablet).

Abstract Text

Simultaneous analysis of fat-soluble vitamins in foods is challenging due to their different properties and concentrations. A typical method involves extraction and saponification of fat, followed by a high performance liquid chromatography (HPLC) with UV/Vis detection. After saponification the extracts can be analysed for vitamin A directly, but for vitamin D3, the extracts have to be cleaned on a semi-preparative chromatograph and concentrated. For this reason the vitamins A and D3 were analysed separately. The HPLC of these compounds suffers from a long runtime, slow equilibration and poor reproducibility.

As the extraction and saponification of separate vitamin A and D3 methods are identical, we investigated whether it is possible to apply Ultra-Performance Convergence Chromatography (UPC2) to analyse the extract for vitamin A and D3 in one chromatographic run.

UPC2 is a separation technique that uses supercritical carbon dioxide as the primary mobile phase. It takes advantage of sub-two micron particle chromatography columns, low viscosity of the CO₂ and an advanced chromatography system. This offers an alternative chromatography method to traditional HPLC methods and improves the selectivity of this assay¹. It also generates much lower solvent wastes compared to conventional liquid chromatography². In this work, we report a method for analysis of vitamin A and D3 in vitamin premixes and concentrates in one analytical run without purification or dilution. The metrological properties of the UPC2 and advantages of the method compared to the HPLC are also discussed.

Abstract Text

Mobile phase, buffer and chemical solutions are prepared for analytical techniques such as HPLC, UV-VIS, LCMS, spectrophotometry and other analytical techniques. These formulations are derived from method development or various published methods. Most often they are made in-house by an instrument or analyst. Documentation points out the potential for errors with formulations made by these techniques. These formulations can result in poor quality, out of specification (OOS) results, and batch rejections. Root causes can be traced to lot to lot inconsistency, contamination and human error. A solution to many of these issues is to utilize commercially prepared formulations.

This poster will examine references to the problems of in-house blending and need for quality premixed formulations. Commercially prepared blends for use as mobile phases, buffers and other analytical work are a solution to these issues. Analytical results from various commercially prepared formulations will be presented as evidence to demonstrate quality, lot to lot consistency, and reliability over time. By utilizing prepared formulations a company can increase efficiencies and improve their analytical results. Honeywell LabReady™ Blends by Burdick & Jackson™ is an example of an available solution specifically suited to eliminate these problems and improve analysis quality.

Abstract Text

Conventional optical scanners are normally designed for dedicated or couple types of sample containers or sample holding tray. The application of those traditional optical scanners are operated without automated optical light focusing. This poster will introduce the design of an automated universal Raman scanner for 2ml and 5ml vials, drug tablets, solid powder, liquid, SERS plates, as well as 96 and 384 microtiter plates. The system features patented laser self-focusing technique for reproducibly obtaining the maximum Raman spectra intensity for the substance scanned. The fully automated design achieved <1% RSD for 100 times measurements of sample in solid form, powder form, gel form, liquid form etc. It is an ideal Raman scanner for fast substance molecular spectra identification and sample amount quantification. Examples for the QA of lipstick, drug, tea, counterfeits will be presented.

Abstract Text

In x-ray fluorescence analysis (XRF), sample preparation is an important step in the analytical procedure. A borate fusion is frequently used for the determination of main components. At the present, there are several gas and electrical fusion systems on the market.

We have now developed a new automatic electrical furnace which overcomes the well-known problems and disadvantages of systems based on muffle furnaces.

The design consists of a lift bottom oven where the door is the bottom and it can be opened using a lift to load the sample. The crucible containing the sample and the mold are held by a rack, which is placed onto the lift by an autosampler. The homogenization of the sample inside the furnace is solved by external spinning at the bottom with a bidirectional motor.

The casting function is overtaken by the autosampler while the rack with the crucible is unloaded from the furnace.

The new system shows excellent precision and accuracy for all elements typically analyzed in oxidic materials like cements, gypsum, sands, iron ores, clays, geological samples, etc.

The closed design also helps to avoid the loss of volatile elements like sulfur, fluorine and chlorine.

Abstract Text

Brominated vegetable oil (BVO) is often used as a weighting agent, or a solubility-transmitter for citrus oils and other lipophilic compounds¹ in soft drinks and beverages. The US FDA has established a BVO limit at 15 ppm in finished beverages, while many countries in Europe, Asia, South America, and Australia, have banned its use in beverages. Analysis of BVO is rarely reported. Gas chromatography with mass spectrometry (GC-MS) has been proposed recently for the analysis of BVO in soft drinks and cocktail syrups^{2,3}. This GC-MS method requires tedious derivatization (or saponification) of BVO, and has a long run time (about 50min).

UltraPerformance Convergence ChromatographyTM (UPC2[®]) is a state-of-art supercritical fluid chromatography (SFC) that provides exceptional efficiency and speed of separation⁴. It has been applied to a wide range of compounds, including VO, and has shown great benefits in selectivity, throughput, and ease-of-use⁵. This work demonstrates a rapid and simple analysis of BVO in soft drinks and beverages using UPC2-MS. BVO was extracted and analyzed directly without any derivatization. The chromatography total run time was 9 min. The analytical method performance (limit of quantitation or LOQ, repeatability, linearity, and recovery) as well as the analysis of BVO in soft drinks and beverages are presented.

Abstract Text

The Mayo Clinic Metals Laboratory is a small, specialized lab that includes an ISO class 7 cleanroom for trace elemental analysis. The lab performs analyses for essential, heavy, and trace metals in biological samples, as well as kidney stone analysis. The Metals Laboratory currently has 9 ICP-MS, 2 ICP-MS with HPLC, 2 ICP-OES and 2 FT-IR instruments. The lab employs 26.3 FTE, and performs 49 different analyses on whole blood, serum, urine, plasma, tissues, and kidney stones. These analyses are comprised of 99 orderable tests, performed utilizing 24 different analytical SOPs. Staff utilization within the Metals Laboratory had not been previously mapped, therefore, scheduling and staffing was difficult and at times, suboptimal. A utilization model was created that allows the lab to determine current and future staffing needs based on test volumes, available FTE, days tests are performed, analytic time, and indirect time. The staff utilization model created allows the lab to balance the workload on a day to day and shift to shift basis.

Abstract Text

Gamification is the use of game thinking and game mechanics in non-game contexts to engage users in solving problems. There are various forms of games that we all are familiar with from apps on our mobile devices to TV shows. The use of games and scenarios to engage learning, thinking and problem solving is not too distant from the skills sets, we as analytical chemists want from our students, to gain during their education. However game thinking or scenario based exercises are seldom used in the teaching of analytical practices and principles. I have utilized the principles of gaming as a means to provide real-life scenario based teaching to students but also to develop transferable skills and establish competitive spirit. All traits that are essential to enhance employability. We have utilized 'The apprentice' TV show as the model for our game and activity, where we got students to look into was the scientific evaluation and marketing of a new analytical HPLC column. Our show was fully supported by Phenomenex UK and students had to pitch their project to a panel of experts just like the actual show. Students learnt the importance of scientific communication and the need to learn about how to utilize their scientific knowledge in different environments like marketing and business. This exercise is now regarded by the students as the best highlight of their course and during my presentation I will give you an overview of the benefits and pitfall of gaming exercises in education and how the educational gaming we used improved student performance and engagement.

Abstract Text

The challenges in teaching undergraduate analytical chemistry are numerous and evolving. These challenges may relate to class size and time constraints, student engagement, and fostering higher order thinking skills, among many other aspects of teaching. In this presentation, I will describe how my colleagues and I are working to address some of these challenges in our courses through the use of guided-inquiry activities. For example, we have implemented a new hands-on laboratory activity where students build their own photometers from simple and economical components. The activity reinforces key concepts from lecture and makes those concepts tangible. It also challenges the "black box" mentality that can be a byproduct of sleekly designed and user-friendly instruments, provides an introduction to LabVIEW, and gives students a strong sense of satisfaction upon completion. In addition, we have recently developed an online applet that allows students to build virtual block diagrams of instruments by arranging and connecting images of components. The applet provides on-demand feedback to students so that they can tinker with instrument designs and sort out their own misconceptions about the form and function of those instruments. Another interactive applet for analytical method development is being designed, and is styled after the popular "Choose Your Own Adventure" series of books from the 1980s and 90s. Students are given a sample to analyze for a particular analyte and are guided through a series of decisions, with stepwise feedback, to arrive at one of several possible final analysis methods. Although we are in the early stages of implementation and assessment, we anticipate gains in the teaching-learning experience and improved critical thinking from students. Ultimately, we hope that these guided-inquiry strategies will be adopted by the analytical community at large.

Abstract Text

Analogical reasoning is ubiquitous to human cognition, and the use of analogies in teaching is a well-established pedagogical tool. We have developed an analogy to gas chromatography/mass spectrometry (GC/MS) analysis in order to explain the key concepts of the emerging technology of comprehensive two-dimensional gas chromatography/mass spectrometry (GCxGC/MS). A clear understanding of the principles of GCxGC/MS is needed by a growing number of people inside and outside of the separation science fields (such as mechanical engineers or computer scientists), and the use of this analogy in introductory workshops has been very useful in bridging the concepts in a domain that is more familiar to the student (source concepts) and the concepts in the unfamiliar domain (target concepts).

In this presentation we will explain the separation and identification technique of “namography/alphabetography”. Namography, like chromatography, is capable of separating people’s names by the length of letters in their name. Alphabetography, like mass spectrometry, is capable of identifying a person’s name by providing a histogram of the letters contained in the name. We will demonstrate the basic operations in GC/MS through this analogy using a sample of the names of the 44 US presidents, and will also discuss the need to use GCxGC/MS for complex samples. We will also present software development that was conducted in conjunction with the development of this example.

Abstract Text

Our analytical chemistry laboratory is a research-based lab in which we monitor persistent organics, formaldehyde, chlorophyll, phosphate, metal ions, water hardness, chloride, and nitrate in a local wetland over the course of the term. Each method is introduced over a two-week period, with calibration in the first week and calibration and analysis in the second week. Data are compiled over the term and analyzed for trends as a culminating project of the laboratory. Our ecology laboratory simultaneously monitors ecological health of the wetland using surveys of plants, macroinvertebrates, and amphibians. Scientists in the two labs collaborate on data analysis and presentation. Undergraduate scientists are involved at every stage of the project, from sample collection through data presentation.

Abstract Text

The inverted, or “flipped”, classroom model facilitates the implementation of active-learning in the teaching space. Realigning the traditional lecture so that it is introduced outside of the classroom environment, the newly acquired time in the classroom is filled with active-learning techniques. This hands-on approach to learning replaces the passive lecture-centered method with an active, personalized learning experience where students can direct the learning process based on their needs. With a strong emphasis on quantitative skills and reasoning, the Analytical Chemistry course is a natural fit for the inverted classroom model. While the essence of the inverted classroom is simply to deliver an active-learning experience while in the classroom, the Analytical Chemistry course at Elmira College relies heavily on various technological tools in order to enhance the learning experience for the student both in and outside the classroom. Video production software, quick response codes and interactive writing surfaces, among other technologies, will be discussed within the context of enhancing the analytical chemistry experience. Additionally, assessment in terms of both student perception and performance will also be discussed.

Abstract Text

High-Throughput Automation, Analysis and Screening of complex mixtures are key capabilities offered by the Analytical Chemistry Speciality Team (ACST) to support drug discovery and development at Merck. ACST specializes in complex chemistry problem-solving through state-of-the-art innovative analytical chemistry solutions. Members of the team employ high-throughput assay development screening, definitive metabolite synthesis and elucidation, and stereochemical analysis; as well as identify process impurities via high-throughput tandem high-resolution mass spectrometry. Presentation will include discussion on novel advances in the area of high-throughput screening of 1536 nano-scale chemical reactions, development of an electrochemistry mass spectrometry technology for metabolite identification and synthesis, and macromolecule screening capability for analysis and purification. The development and implementation of these high-throughput analytical technologies has helped to ensure the highest quality of drug discovery and API development.

Abstract Text

Manipulating samples as droplets within microfluidic devices has emerged as an interesting approach for chemical analysis and screening. In segmented flow, one embodiment of this technology, nanoliter samples are manipulated in microfluidic channels as plugs separated by an immiscible fluid, such as air or fluorinated oil. These plugs serve as miniature test-tubes in which reactions can be performed at high throughput. Microfluidic tools have been developed to split, dilute, extract, and filter such plugs at rates up to 10 Hz. We have developed methods to analyze plug content by mass spectrometry (MS) and electrophoresis. Analysis rates of 5 samples/s by MS and 1 sample/s by microchip electrophoresis are possible. A natural application of this technology is high throughput screening for drug discovery. By coupling droplet manipulation with MS detection, it is possible to greatly reduce reagent consumption, to save on costs, and eliminate the need for fluorescent labels or coupled reactions, to prevent false readings. The technology and application to screens of deacetylase reactions and protein-protein interactions will be presented.

Abstract Text

Assays that utilize MS for analysis offer direct, label-free assessment of relevant probe substrates; however, these methods have traditionally required liquid chromatography systems coupled with atmospheric pressure ionization mass spectrometry and have slow cycle times that are not amenable to high throughput screening in early drug discovery. Other available high-speed methodologies are often limited because of their use of labeled substrates, which are costly to synthesize and often yield different results than those obtained with physiologically relevant substrates downstream. In an effort to provide MS-based screening support with throughput speeds approaching those of plate-readers it is necessary to evaluate multiple platforms.

Recent advances in front-end technologies have resulted in significant improvement in the speed of MS-based analysis. First of all, multiplexing several fast-gradient HPLC systems and performing staggered injections onto the same MS has reduced the per-well cycle time to as low as 15-20 seconds. Another approach completely bypasses HPLC separation and instead performs direct online SPE with very fast robotics. With these systems, it is possible to achieve cycle times of 5 seconds per well. A 3rd approach attempts to utilize the very high speed MS analysis offered by matrix-free laser desorption/ionization (LDI) techniques. However, liquid assay samples have to be deposited onto the carrier prior to MS analysis, potentially shifting the bottleneck to sample preparation. More recently, acoustic nano-dispensing technology has been leveraged to "print" liquid samples directly onto the carrier prior to LDI analysis. The coupling of acoustic dispensing and LDI makes this technology amenable to post-reaction sample cassette analysis; allowing multiple reaction samples to be transferred into the same well, resulting in even faster throughput.

Applications of these platforms will be discussed in detail during this presentation.

Abstract Text

This presentation will provide a vision of future automated testing procedures of solid oral drug product, and then discuss how current automated spectroscopic tablet analyzers enable us partially integrate and streamline final product testing process with speed and accuracy. In this study, the optical performance of an integrated tablet tester, TANDEM III that can measure tablet thickness, weight and near infra-red spectra in a sequence was evaluated against standalone spectrometers. Then, the tablet tester was connected directly to a tablet press in a pilot plant, allowing for automatic, nondestructive and real-time content uniformity analysis. Meantime, the integrated tablet tester was also connected to a data warehousing package to allow synergistic integration with other real-time process data. Two categories of development efforts, including automated equipment method development and traditional spectroscopic method development, deem necessary to enable a robust testing process. A more in depth discussion will illustrate the benefits and concerns that come with implementing Tandem from laboratory to pilot plant environments regarding:

1. the product formulation impact to the automated equipment method development;
2. the pilot plant environment influence on equipment automation;
- and 3. the utilization of 3-D printing technologies to advance spectroscopic method development.

The automatic tablet tester provides both physical and chemical characteristics of pharmaceutical tablets, allowing both timely collection of process data and control of tableting process. Its high throughput and easy integration with digital control systems have greatly avoided overloading traditional analytical laboratory and led to a paradigm shift in the capability and capacity arrangement.

Abstract Text

Is having to manually curate analytical results, make routine determinations and add comments really necessary? Are there not better things we can be doing with our time?

Parallel synthesis strategies have become a key part of our product scale-up strategies in recent years by optimizing cost of manufacture, time to decision of the best scale-up route, allowing for greener chemical synthesis routes, reducing downstream product cleanup strategies and providing new routes of product patent protection. Moving to a matrix based optimization process, by default creates many new process bottlenecks, one of which is the interpretation of the analytical data. In visiting, talking and working with scientists from different laboratories around the globe, we remain surprised that the analytical results interpretation process is often performed sequentially with manual review of each analytical result and marked by hand to produce the final summary of results into the project teams. Is this really necessary?

Our presentation focuses on recent developments in software automation that allow for data from individual or multiple instruments to be automatically processed, standard process chemistry calculations to be made, and an automated evaluation of the analytical data for common problems that are present in chromatographic types of experiments using example case studies. By automating the majority of the analytical process has led to an overall time reduction of more than 50%.

Abstract Text

Low Energy Ion Scattering (LEIS) [1] has been used for decades for the analysis of single crystals and "real world" surfaces. The latter application is, however, often hampered by the use of non-dedicated instruments which in many cases do not allow the utilization of the key feature LEIS to full extent: The quantitative elemental characterization of the outermost atomic layer.

Typically, the surface is bombarded with noble gas ions with an energy of 1 - 8 keV. By detecting the scattered ions under a well defined scattering angle and measuring their energy distribution, the composition of the surface can be derived from the peaks in the energy spectrum. The intensity is directly proportional to the surface coverage, while neutralization of the ions when penetrating the surface discriminates signal from deeper layers. This sub-surface signal can be evaluated separately to give insight into the composition a few nm below the surface.

Modern LEIS instrumentation is optimized to make these features available on many different kinds of samples, ranging from supported catalysts over self-assembled monolayers to thin films. Key for this is the dedicated energy analyzer, which is optimized for sensitivity to limit the required ion fluence and therefore avoid significant modification of the surface. It also allows choosing the optimum noble gas ion species to resolve the elements of interest. Furthermore the sample treatment after transport through air to remove atmospheric contamination has to be considered.

In this presentation, the fundamentals of the technique, the consequences for the instrumental design and the associated protocols for sample treatment will be covered. In the second part a number of applications will be shown, illustrating the importance of the outer surface of materials in many cases, as well as the benefit of the analysis using LEIS.

Abstract Text

X-ray diffraction (XRD) is a powerful technique for characterizing crystalline materials. For polycrystalline materials such as powders, metal foils, sintered samples, finished parts, coatings and films, XRD can be used not only to quickly identify a material but also to quantify its phase composition, unit cell parameters, crystallite size, microstrain, and texture. Many of these properties can be studied in situ as a function of temperature. XRD can also be made surface sensitive using grazing incidence diffraction, which enables depth profiling of distances on the order of nanometers. Performing diffraction in the plane of the sample allows those crystal planes perpendicular to the surface to be characterized.

For films and materials that are not necessarily crystalline, X-ray scattering techniques can provide useful information. X-ray reflectivity (XRR) for example can be used to determine the thickness, density, and roughness of each layer present in any film. Small angle X-ray scattering (SAXS) can be used to characterize the average size and shape of nanoparticles or macromolecules in a matrix (liquid or solid) as well as the average pore size or other meso- or nano- characteristic distances present in partially ordered systems. After a brief overview of these techniques, a few specific examples will illustrate the wide range of materials for which X-ray diffraction and scattering can be useful.

Abstract Text

Photoelectron spectroscopy (PES) has been one of the most utilized techniques for understanding of materials physics and chemistry since its development by Kai Siegbahn for which he received the 1981 Nobel Prize in Physics. In a photoelectron spectroscopy measurement, the kinetic energy of electrons emitted by the sample upon excitation by UV or X-ray photons is measured. This measured quantity is related to the binding energy of the electrons in the material and depends upon the electronic structure of the material. Using photoelectron spectroscopy, one can directly probe the valence electrons in the material, those with binding energy between approximately 0 and -25 eV. These are the electrons involved directly in chemical bonding and are the band states in solids. Measurements as a function of angle, Angle Resolved Photoelectron Spectroscopy (ARPES), allow experimenters to measure the band structure of crystalline solids for comparison with theoretical models. At higher binding energies, the core electrons are observed. These electrons are sensitive to the chemical state of the elements in the material. When the photopeaks are measured at high resolution, fitting of the spectral lines allows for the determination of the chemical bonding and oxidation state of the elements in a material. Using ARPES on the core level peaks, diffraction effects can be used to obtain the local atomic structure of elements in different chemical states. This talk will focus on using PES to elucidate problems of reaction chemistry with examples including chromatography, semiconductor devices, and the nuclear industry.

Abstract Text

Laminated polymer structures are found in wide ranging applications from food packaging to a wide variety of industrial applications across many markets. The laminates present an analytical challenge due to their complex structure and the migration of species throughout the entire construction. Of particular importance is understanding the surface chemistry of the sealant film, which can significantly impact important properties like coefficient of friction, heat seal temperature and long term performance. Interlayer adhesion is often achieved through corona treatment of the bonding polyolefin surfaces. The stability of the surface chemistry after treatment can be modeled to predict long term performance. Here, an array of surface chemistry related analyses will be presented including SIMS, XPS and surface energy.

Abstract Text

We have recently reported a series of new materials for liquid chromatography and for digital data storage. Our latest materials for liquid chromatography consist of carbon nanotube templated thin layer chromatography plates, and our new materials for digital data storage consist of nanofuses that can serve as memory elements. A variety of techniques have been applied to the characterization of these new materials. For example, X-ray photoelectron spectroscopy (XPS) has provided surface elemental analysis and oxidation state information about our new materials. Time-of-flight secondary ion mass spectrometry (ToF-SIMS) has been used to complement the information obtained by XPS, providing additional chemical information about the surfaces of our materials. ToF-SIMS is a form of surface mass spectrometry. Spectroscopic ellipsometry (SE) has provided film thicknesses, optical constants, and roughnesses. Atomic force microscopy (AFM) has provided more direct measures of film roughnesses and thicknesses. Scanning electron microscopy (SEM), transmission electron microscopy (TEM), and helium ion microscopy (HIM) have been invaluable for surface imaging. Rutherford backscattering (RBS) has provided bulk (ca. 1 micron) views of our materials. X-ray diffraction has shown their crystal structures. The combination of the results from these techniques has allowed us to develop a reasonable understanding of our materials.

Abstract Text

The desire for decreasing detection limits and the comprehensive analysis of more complex samples (all possible constituents of a sample to be determined qualitatively and quantitatively) leads to increasingly sophisticated analysis platforms. Powerful analysis methods for such problems include the comprehensive two-dimensional gas and liquid chromatography (GC x GC and LCxLC), each coupled with advanced, high-resolution mass spectrometers. But even with the combination of these two high-performance separation methods, it is often not possible to analyze a complex sample in detail (food, tissue, plasma, plant, sewage sludge, etc.).

In 2000 EB Ledford wrote about the relatively new comprehensive two-dimensional gas chromatography "GCxGC has revealed that many samples are more complex than we had realized."

We propose that the introduction of another dimension of separation will reveal an even greater complexity of the samples. Through the use of LCxLC-IMS-qTOF-MS not only isobaric substances can be separated. Because of the higher peak capacity (LCxLC and IMS) the chemical noise is reduced and the limit of detection is much more better as without IMS.

Here we present the combination and potential of LCxLC and GCxGC with IMS-qTOF-MS.

Abstract Text

Comprehensive on-line two-dimensional liquid chromatography (LCxLC) can produce considerable larger peak capacities compared to optimized one-dimensional separations in analysis times as short as 15 minutes. However, this result depends on using optimized second dimension cycle times (t_c) and achieving fractional coverages (f_{cov}) close to 1. Typically t_c is at an optimum between 12 and 21 s. We have also shown that using carbon clad columns in the second dimension ($2D$) produces f_{cov} ranging from 0.58-0.63 relatively independent of the choice of the 1D bonded reversed phase column (e.g. C18, perfluorophenyl or polar embedded type phase). In this work, we compared the use of an C18 column to a carbon clad phase in the $2D$. The sample and 1D columns were similar to those used in the prior study. The SB-C18 2D column produced f_{cov} values ranging from 0.18-0.39. In contrast, the carbon clad 2D column produced f_{cov} values ranging from 0.49-0.56. While f_{cov} values using the carbon clad column in the $2D$ are lower than previously observed, the carbon clad $2D$ column increased the f_{cov} values by a factor of 1.25 to 3 depending on the $1D$ column used.

Abstract Text

Polysorbate is commonly used in therapeutic monoclonal antibody (mAb) formulations to prevent protein aggregation and adsorption. Polysorbate may degrade through different pathways like hydrolysis and oxidation overtime and lose the surfactant function. The analysis of polysorbate in mAb formation is highly challenging, not only due to the heterogeneity of polysorbate component structures and no-UV chromophores, but also due to the significant interference from high concentration therapeutic proteins. To understand the stability of polysorbate and the degradation mechanism in mAb drug formulations, we used two dimensional UHPLC coupled with MS and charged aerosol detector (CAD) to analyze polysorbate 20 in different protein formulations. Orthogonal separation mechanisms such as mixed-mode, ion-exchange and reversed-phase chromatography were used in different dimensions to remove protein interference, as well as to separate the different components and degradation products of polysorbate 20. MS was used not only to identify the components, but also served as the third dimension to further separate polysorbate ester subspecies. We found some polysorbate 20 esters degrade faster than others, and the degradation rates are different with and without the presence of antibodies.

Abstract Text

In this work we will discuss the results of recent simulations and experiments aimed at comparing one-dimensional (1D) and two-dimensional (2D) separations of moderately complex mixtures, such as those encountered in the analysis of an active pharmaceutical ingredient and its impurities. We are interested in the potential of 2D separations to simplify method development and reduce analysis time, when compared to 1D methods, because of the increased resolving power that can be realized from 2D separations under certain conditions. At this point in time users of 2D-LC are exploring a number of implementations of the technique, ranging from offline to online methods, and from single heartcut (LC-LC), multiple heartcut (mLC-LC), selective comprehensive (sLCxLC), and fully comprehensive (LCxLC). In the case of moderately complex mixtures (e.g., 10 to 50 components), it is not clear which of these 2D techniques will provide the best compromise of resolving power and ease of method development, implementation, and use. In previous work we simulated 1D, LCxLC, and the simplest possible implementation of sLCxLC separations and found that sLCxLC is predicted to provide analysis time savings of up to 70% compared to 1D and LCxLC for mixtures containing 20 compounds. In this presentation we will describe simulations and experiments involving more flexible implementations of mLC-LC and sLCxLC, and share our perspective for the potential of these techniques with respect to method development and ease of implementation and use.

Abstract Text

In the past decade, the advancement of two-dimensional (2D) chromatographic technologies has led to the development of instrumentations and methodologies for scientists to perform analysis and separation of complex materials. In general, 2D chromatographic separations offer higher resolving power than conventional one-dimensional (1D) chromatography. However, for preparative scale separations of 2D chromatography, the applications are limited due to three challenges: 1) the high flow rate of the chromatography in both first and second dimensions, 2) large volumes of solvent or large quantities of samples loading on to the columns, and 3) the compatibility of the large volume of solvent transferred from the first dimension to the second dimension. We have developed new methods and instrumentations for preparative 2D chromatography (2D LC-LC/MS and 2D SFC-SFC/MS) to improve the process of separation of complex pharmaceutical samples. Most recently, we have designed and developed the preparative 2D LC-SFC/MS system.

The presentation will discuss the instrumentation designs and applications of preparative 2D LC-LC/MS for the achiral-achiral purifications of complex samples and preparative 2D SFC-SFC/MS for achiral-chiral purification of enantiomers. The applications of case studies will demonstrate the utilities of 2D chromatography on a preparative scale to solve the separation challenges of complex pharmaceutical samples for drug discovery and development.

Abstract Text

The detection and prevention of economically motivated adulteration (EMA) in foods is central to the U.S. Food and Drug Administration's (FDA's) mission to protect consumers. However, developing analytical protocols to combat EMA can be more challenging than producing methods to analyze trace contaminants. There can be multiple approaches used to adulterate a particular food commodity, and adulterants are often selected specifically to avoid detection. In addition, testing procedures must be able to provide sufficient evidence to distinguish between foods which have been economically adulterated, as opposed to results which are simply due to the natural variation in a given food commodity. This presentation will highlight the procedures that have recently been used by the FDA to detect EMA in a number of food commodities including pomegranate juice, honey, milk, palm oil, and lemon juice. The rationale in the selection of analytical protocols will be discussed, as well as some unique and unexpected challenges that resulted from testing these products.

Abstract Text

Economically Motivated Adulteration (EMA) is a criminal activity, a fraud economically motivated. The objective is essentially that the amount of adulterant added to food must bring some economic gain, as seen during the melamine scandal in infant formula that surfaced in China in 2008. From an industry perspective, it is pivotal to understand the potential vulnerabilities of the different raw materials to economic adulteration and to assess the business risk. Raw material vulnerabilities are dependent on several parameters such as the raw material composition, level of processing (e.g. thermal treatment) and the criteria used to set the price (payment criteria). Reviews of past cases of raw material adulteration definitely help to provide complementary information on the sensitivity of each raw material to economic adulteration. In the case of beef for example vulnerabilities may include species substitution or adulteration with non-authorized preservatives.

Ensuring authenticity of raw materials in an efficient and lean way can only be achieved by combining appropriate mitigation strategies. These can vary and include the implementation of multiple analytical approaches, raw material procurement traceability, supplier audits, specification management, etc. An approach to evaluate raw material risk of adulteration will be presented, that includes how to establish priorities and to mitigate risk. One of the major difficulties and challenges in addressing EMA is the availability of suitable analytical methods to determine food adulteration, keeping in mind that the adulterant is not always known upfront. Analytical techniques used must encompass both targeted and non-targeted methods, keeping pace with continuously evolving fraudulent practices. An overview of current methods implemented at both the raw material collection centres and factory gate (e.g. FT-IR) are presented as well as more sophisticated laboratory methods (e.g. LC-MS/MS, PCR, NMR).

Abstract Text

Olive oil is one of the most adulterated food products of the world due to its relatively low production and higher prices as compared to vegetable and seed oils. The study from UC Davis Olive Center in 2010 and 2011 showed that more than 65% of extra virgin olive oil sold at the US supermarkets did not meet the USDA "extra virgin" grade standards. The findings from this study received more than one thousand media coverage worldwide, including the New York Times, CNN, The Dr. Oz Show and CBS News. While these reports have helped to raise awareness in consumers and food buyers, there are a lot of challenges ahead in developing more efficient analytical methods and establishing better standards. In this talk, we will discuss about these challenges and recent analytical advancements on the authentication and adulteration of olive oil.

Abstract Text

Coconut water is one of the fastest growing categories of fruit juice beverage in the US market. Very little has been published as yet regarding the composition of coconut water, providing an opportunity for its economically motivated adulteration. The presentation will discuss work we have done on the composition of coconut water and on how that information can be used for assessing the purity and authenticity of coconut water products.

Abstract Text

Economic adulteration of extra virgin olive oil (EVOO), the highest grade of olive oil, is a threat to its authenticity. Cases of fraud of EVOO have long been reported by the media and in the scientific literature. To meet the EVOO Standard, an olive oil must meet chemical and organoleptic parameters. While FDA has jurisdiction over deceptive label declarations often found with adulterated EVOO, the Agency is also mandated (according to FSMA, SEC. 106) with the protection of the US public against the intentional adulteration of foods. The most serious issue facing regulatory agencies has been the relative ease to adulterate EVOO with lower grade olive oils or seed or nut oils while meeting the physical and chemical property limits of various established standards. While the FDA does not have regulations for addressing authenticity, quality, and purity of olive oils, the USDA and various other standards specify quality and purity criteria that include organoleptic characteristics, and designate specific official methods of analysis to be used as reference methods in determining the grade, quality, and purity of olive oils. The USDA standards also state that alternative methods may be used, provided they give equivalent results. NIR spectroscopy (using benchtop spectrometers and/or portable analyzers) and univariate and/or multivariate statistical analyses were applied to the rapid screening of 93 commercial EVOO purchased locally. Other untargeted and targeted complementary analytical tools and/or discrimination algorithms were also used. Depending on analytical methodology used approximately 5-20% of the oils were flagged as outliers. Adulteration at 10% and 20% (w/w) of an authentic EVOO reference with 10 different foreign oils, including palm olein and hazelnut oil, was also detected.

Abstract Text

The folding, structure, and function of membrane proteins are often influenced by their surrounding environment but lipid interactions are often difficult to characterize. As a step towards understanding these interactions, I will describe an approach that we have developed to measure resistance to unfolding in the gas phase to rank the effects of lipid binding to membrane protein complexes. First, we had to overcome the tendency for membrane proteins to unfold in the gas phase, due to the activation needed to emerge these complexes from detergent micelles. After establishing the conditions that preserve the folded state of membrane proteins, as assessed by ion mobility MS, we selected three membrane proteins anticipated to respond differently to the lipid environment: the mechanosensitive channel, aquaporin Z, and the ammonia channel. We then established conditions whereby we could resolve individual phospholipid-bound states of membrane proteins, in solutions containing vast excesses of detergent and lipids, and then ranked bound lipids based on their ability to prevent gas-phase unfolding. Combining our IM-MS data for the three protein complexes with molecular dynamic (MD) simulations we identified probable lipid binding sites. Phosphatidylglycerol, identified as significantly stabilizing the ammonium channel, prompted us to determine its crystal structure in this lipid environment. The 2.3Å resolution structure that we determined reveals bound lipids in one of the sites predicted using MD simulations filtered by IM-MS measurements and, by comparison with previous structures, distinct conformational changes induced by lipid binding that reposition residues to interact with the lipid bilayer. Overall our results allowed us to conclude that resistance to unfolding correlates directly with specific lipid-binding events that not only modulate membrane protein stability but may also induce conformational change.

Abstract Title **Does Binding of Cholesterol to the Amyloid Precursor Protein Promote Alzheimer's Disease?**

Primary Author Charles R. Sanders
Vanderbilt University

Date: Thursday, March 12, 2015 - Morning

Time: 09:10 AM

Room: 262

Co-Author(s)

Abstract Text

It is known that elevated cholesterol promotes amyloidogenesis, but the mechanism has not previously been clear. In this study the structure of the transmembrane C-terminal domain of the amyloid precursor protein (C99) was determined using NMR spectroscopy and found to have several surprising features to provide insight into how this protein is proteolytically processed in the pathway to formation of amyloid-beta, which is closely associated with the etiology of Alzheimer's disease. It was also discovered that C99 is a cholesterol binding protein. Based on this and additional data, we propose a unifying model for how cholesterol promotes the amyloidogenic pathway. We then tested the hypothesis that C99 has an intrinsic affinity for raft-like liquid ordered (Lo) domains and that its domain preference is regulated by cholesterol binding. Fluorescence microscopy shows that C99 undergoes efficient partitioning into Lo domains relative to the co-existing liquid disordered (Ld) phase in giant unilamellar vesicles, establishing C99 as the transmembrane protein with the highest affinity for Lo domains known to date. This is reversed upon mutating residues that are critical for cholesterol binding to C99, indicating that binding of this sterol is a critical determinant of the phase preference of the protein. Addition of a raft-breaking sterol that can compete with cholesterol for binding to C99 shifts partitioning away from the Lo phase. These findings identify cholesterol binding as a novel mechanism that controls the raft targeting of C99 and suggest that pharmacological inhibition of this process could potentially be exploited as a therapeutic approach to avoid or treat Alzheimer's disease.

Abstract Text

Peripherin and its homologue ROM1 are retina-specific members of the tetraspanin family of integral membrane proteins required for the morphogenesis and maintenance of photoreceptor outer segments, regions that collect light stimuli. Over 100 pathogenic mutations in peripherin cause inherited rod- and cone-related dystrophies in humans. Peripherin and ROM1 interact in vivo and are predicted to form a core heterotetrameric complex capable of creating higher order oligomers. However, structural analysis of tetraspanin proteins has been hampered by their resistance to crystallization. Here we present a simplified methodology for high-yield purification of peripherin/ROM1 from bovine retinas which permitted its biochemical and biophysical characterization. Using size exclusion chromatography and blue native gel electrophoresis, we confirmed that the core native peripherin/ROM1 complex exists as a tetramer. Peripherin, but not ROM1, is glycosylated and we examined its glycosylation site and glycan composition by LC MS/MS. A novel form of native mass spectrometry was used to analyze the complex in detergent micelles, demonstrating its tetrameric state. Our electron microscopy-generated structure solved to 18 Å displayed the tetramer as an elongated structure with an apparent 2-fold symmetry. Lastly, we demonstrate that peripherin/ROM1 tetramers induce membrane curvature when reconstituted in lipid vesicles. These results provide critical insights into this key retinal component with a poorly defined function.

Abstract Text

Due to their strategic location at the cell surface, integral membrane proteins (IMPs) play a crucial role in the regulation of cellular processes making them important and attractive pharmaceutical drug targets. Lead optimization of drug compounds can be accelerated with the availability of IMP co-crystal structures, but this has traditionally been hampered due to the numerous challenges associated with their low heterologous expression and low intrinsic stability in detergent micelles. G protein-coupled receptors (GPCRs) present added challenges because they are conformational flexibility, making it difficult to crystallize these receptors in a single stable conformation. The recent advancements in methodologies and analytical approaches that have enabled a number of groups to circumvent the obstacles to GPCR crystallization and structure determination will be presented.

Abstract Text

Membrane proteins currently represent approximately half of all potential therapeutic targets and are involved in many biological functions. Biophysical characterization approaches such as X-ray crystallography and NMR are challenging due to poor expression levels of the membrane protein and also protein solubility. Native membrane protein analysis by mass spectrometry (MS) is an attractive alternative, however, to date has remained very challenging. A nanodisc, as the name implies are discoidal structures comprising of two membrane scaffold proteins acting as a belt, holding together a lipid bilayer, made up of around 160 phospholipids depending on MS-activating voltage used. As we demonstrate herein, the nanodisc is amenable to native MS and ion mobility analysis.

Upon mild ion activation in the atmosphere/vacuum interface region, a broad heterogeneous charge state distribution can be observed on QTOF, OrbiTrap and FT-ICR MS systems. The heterogeneity is attributed to varying levels of phospholipid incorporation into the nanodisc. However, significantly lower source activation conditions are required on the FT-ICR MS instrument to obtain well resolved spectrum in the high m/z region. This has interesting implications for native ion desolvation and will be discussed further in the context of instrument vacuum and ion residence times. Quadrupole ion selection, followed by mild collisional activation conditions, were performed on both instruments, resulting in a much simplified empty nanodisc spectrum.

Atomic force microscopy images show individual nanodiscs absorbed on the surface, multiple overlapping and multiple stacked (double) discs. The dimensions of the disc are approximately 20 nm in diameter and thickness approx. 1.5nm. The travelling wave and RF-confining drift-tube \square dimension measurements are consistent with the AFM measured dimensions, suggesting that the fidelity of the gas-phase and solution phase structures have been maintained.

Abstract Text

Wearable sensors have garnered considerable recent interest owing to their tremendous promise for a wide range of healthcare, military, sport and wellness applications [1]. Such sensing platforms provide new avenues to continuously monitor individuals and can thus tender crucial information regarding a wearer's health and performance in real time. This presentation will discuss recent developments in the field of wearable sensors and biofuel cells (BFC), integrated directly onto both textile materials and on the epidermis for various non-invasive monitoring and energy-harvesting applications. The preparation and characterization of such textile-based and skin-worn electrochemical sensors and BFC will be described, along with their performance and the influence of the stretching and bending. Such mechanical stress studies indicate that tattoo and textile-based printed electrochemical sensors survive large deformations. Technical challenges and prospects for using textile- and tattoo-based electrochemical sensors for monitoring the wearer's health, fitness, or surrounding environment will be discussed, along with several demonstrations and prospects for future healthcare and sport applications.

Abstract Text

A need exists to develop simple, low-cost methods for pollutant sampling and quantification to support both health-based research (i.e., epidemiology) and citizen-based science. Our group has developed alternative approaches for metals speciation using paper-based microfluidic devices. Traditional and paper-based microfluidics are poised to overcome many issues associated with chemical analysis of metals in air, water, and soil, namely: cost, ease-of-use, and sensitivity. Results can be read using either the naked eye or simple, low-cost instrumentation (i.e., a handheld or mobile device). Such assays cost only a few dollars and can be conducted by virtually anyone after simple training. We have developed microfluidic assays on paper to measure reactive oxygen species and metals (Fe, Ni, Cu, Cr, Pb, Cd) in air and water using a combination of colorimetric and electrochemical detection motifs. Detection limits of 0.1 [micro]g (1-5 ppm solution levels) were achieved for colorimetric assays (appropriate for occupational exposures) while electrochemical assays provided detection limits of 0.1 ng (1 ppb solution levels; appropriate for environmental exposures). We have also validated these techniques against standard reference methods with relatively good agreement. To complement these analytic techniques, our group has also developed a series of low-weight, low-burden sampling devices. These devices feature micropumps that provide silent operation and a leap in energy efficiency, allowing significant reductions to size, weight, and cost. Initial prototypes are hand-held (or wearable, in the case of air monitoring), weigh less than 150g, and cost about ten times less than the current state-of-the-art samplers.

Abstract Text

Metals are ubiquitous in the environment and have long been recognized to pose significant threats to human health. Blood lead (Pb) has been consistently associated with deficits in IQ and academic achievement in numerous controlled studies. Manganese (Mn) is an essential element, yet neurotoxic in excess, capable of crossing the blood-brain barrier and accumulating in the brain. Current approaches for measuring such exposures suffer from high costs including extensive labor, equipment and time-consuming laboratory procedures, and often, demonstrate long turnaround times. Our group is addressing this need by developing point-of-care sensors for assessment of metal exposure by integrating the electroanalytical techniques of stripping voltammetry with microfluidics. While anodic stripping of Pb has been well-reported in literature, stripping analysis of Mn on microscale remains a critical challenge due to the strong negative potential of its stripping peak. Necessity for low limits of detection, high reproducibility, and low (disposable) sensor costs present additional challenges. This talk will discuss our recent results that show feasibility of measuring of Mn and Pb metals with point-of-care sensors. Our goal is to demonstrate rapid, point-of-care, multi-analyte assessment of Mn and Pb metals in a finger prick of blood.

Abstract Text

We are developing screening methods that use microchip electrophoresis to determine quantitative differences in the serum N-glycan profiles of disease-free individuals and patients with cancer. Electrophoretic analysis easily resolves glycan structures and their isomers and provides complementary information to mass spectrometric (MS) methods. N-glycans are enzymatically cleaved from glycoproteins in serum and derivatized with 8-aminopyrene-1,3,6-trisulfonic acid to impart charge needed for electrophoresis and a fluorescent label for detection. For each sample, an N-glycan profile is generated from the electrophoretic analysis, and statistical analyses reveal differences among the profiles of the various sample groups. We have evaluated samples from esophageal adenocarcinoma, ovarian cancer, and colorectal cancer, and the serum samples from each type of cancer are readily distinguished from the samples of disease-free individuals. Through direct comparison of electrophoretic mobilities with MALDI-MS data and standard addition with N-glycans from common glycoproteins, we have identified a number of the N-glycans that contribute to the differences in disease states.

Abstract Text

Magnesium and its alloys exhibit properties such as high strength, light weight, and slow corrosion in aqueous environment that make them promising candidates for the development of biodegradable metallic implant materials for bone repair, stents and other medical applications. Electrochemical sensors can be used to monitor the corrosion process of magnesium and its alloys by measuring the concentration of the reaction products magnesium ion, hydroxyl ion and hydrogen gas. The permeability of hydrogen gas through skin allows direct monitoring of corrosion of an alloy implanted beneath the skin by detecting hydrogen gas at the skin surface. An amperometric hydrogen gas sensor was used to map hydrogen concentration in the vicinity of an implanted magnesium alloy by placing the sensor tip adjacent to the skin to measure the hydrogen passing through the skin. The level of hydrogen detected is a measure of the corrosion rate of the implanted sample. Biomedical applications for this novel use of hydrogen sensing will be discussed.

Abstract Text

The recent revolution in nucleic acid sequencing and other methodologies permitting comprehensive, molecular-level characterization of biological samples is on the verge of transforming patient care to an extent not seen since the late 19th century. The initial assembly and continuous refinement of the reference human genome, together with a dramatic drop in the cost of sequencing, have enabled clinical applications that include not only the rapid identification of germline mutations in rare Mendelian diseases but also the detection of tumor- and disease stage-specific mutations in cancer and the discovery of genomic variants underlying common diseases with complex patterns of inheritance. The promise of this transformation is that it will lead to better understanding of disease pathogenesis and risks, more accurate prognostication and assessment of response to therapy and, most importantly, to a new standard in medicine wherein individual patients, rather than disease entities diagnosed by conventional approaches, are matched with specific therapeutic options. However, the genomic revolution also poses several new challenges including conceptual, technological and ethical hurdles. Arguably one of the greatest challenge is represented by the biological problem of how the information 'hard-wired' in the genomic sequence limits and regulates its own expression under the influence of signals from the environment in normal and diseased cells and the related technological problem of how this complex control system—termed 'epigenetic' for its role in regulating gene expression 'above and beyond' changes in DNA sequence—can be interrogated and modulated for the purpose of clinical diagnosis and therapy. This talk will review key elements of epigenetic control, currently available epigenetic methodology and highlight critical barriers to applying these concepts and techniques to individualized medicine. Supported by the Mayo Clinic Center for Individualized Medicine.

Abstract Text

This presentation will describe the fabrication and use of cross-sectional size-adjustable elastomeric channels to linearize and image single chromatin fibers. These normally-closed channels are fabricated by controlled fracture of brittle films sandwiched between poly(dimethylsiloxane) (PDMS). Arrays of these crack-based conduits with defined spacing between channels are created by introducing flaw-shielding structures and applying a tensile strain that matches the channel spacing desired. Crack depth is controlled by using brittle films with relatively small mechanical property mismatch with the bulk substrate. By controlling thickness of the brittle film, channels can be created with widths and depths of tens of micrometers down to nanometers. The nanometer sized channels are useful for linearization of single chromatin fibers. These channels are loaded with chromatin by simply stretching open the normally-closed channels. The wider channel openings, coupled with the associated inflow of fluids enable easy biopolymer loading without use of any other fluidic pumping or electrophoresis. Once inside the channel, the biopolymers can be linearized by releasing the tensile strain to narrow the channels. The combined hydrodynamic fluid flow together with nanoconfinement aids in linearizing, then trapping the linearized biopolymers. This method is gentle enough to distinguish differences between chromatin reconstituted with and without histone H1 and is also sufficiently forceful to enable linearization of lambda DNA up to ~97% of its contour length. This presentation will focus on application to multi-color analysis of histone modifications.

Abstract Text

Epigenetic mechanisms such as histone post-translational modifications (PTMs), small non-coding RNAs and DNA methylation play crucial roles in the establishment and induction of gene expression patterns that regulate several aspects of cellular biology. While it is appreciated that activation of cells and thus signaling pathways affect gene expression, exactly how this is accomplished is not well understood. We will present data on new approaches to determine how signal transduction pathways make their way into the nucleus to affect histone modifications and gene expression patterns using chemical biology and quantitative proteomics. These approaches involve new isotopic labeling methods that specifically labels phosphorylated proteins, as well as a covalent labeling method to affinity purify out phosphorylated proteins on chromatin associated nucleosomes, with an emphasis on the EGF signaling pathway.

Abstract Text

Epigenomic tests, and in particular assays that probe protein-DNA interactions, are an emerging tool in the development of personalized cancer treatment strategies. Chromatin immunoprecipitation (ChIP) is the gold standard for analyzing protein-DNA interactions; however, conventional ChIP is limited in its clinical utility as it is extremely laborious and requires large cellular input (1-10 million cells). These requirements significantly reduce the applicability of ChIP in a clinical setting—particularly when minimal sample is available, such as in the analysis of tumor biopsies, stem cells, or circulating tumor cells.

Microfluidic devices offer many attractive benefits over traditional macro-scale methods including reduced volume requirements, parallelization capability, and automated operation, which make them particularly well-suited to sample-constrained epigenomic analyses. We are developing a powerful and versatile, droplet microfluidics-based platform that will allow for automated ChIP analyses. Our platform incorporates every major step in the ChIP workflow into an automated device, including cell lysis, chromatin digestion, immunocapture, and DNA purification. Importantly, these processes will be carried out at the single cell level, which promises to provide unique insights into epigenomic tumor heterogeneity. Beyond single cells, the unprecedented ability to handle samples of variable input will also facilitate robust validation against traditional ChIP assays to demonstrate broad genomic coverage. Taken together, we feel that the resulting platform will be a powerful new tool that helps enable the translation of epigenomic insight into individualized cancer treatment at the point of care.

Abstract Text

Vibrational spectroscopy, attenuated total reflection (ATR) FTIR and Raman spectroscopy, has numerous applications in forensic chemistry providing confirmatory identification of analytes. The technique is non-destructive, rapid and requires little or no sample preparation. Furthermore, portable ATR FTIR and Raman spectrometers are readily available allowing for crime scene accessibility. Vibrational spectroscopy offers several advantages over the current methodology for gunshot residue (GSR) analysis. The technique was shown to detect components from both the organic and inorganic constituents of GSR. This is contrary to current GSR elemental analysis methods which rely solely on the detection of the heavy metals (lead, barium and antimony). This is problematic since environmental concerns have led to the increased popularity in heavy metal free or "green" ammunition that severely hindered the identification of GSR by the current elemental analysis techniques. We will discuss a recent development in the application vibrational spectroscopy for detection and identification of GSR.

Abstract Text

Recent applications of new and existing microextraction sampling methods developed for the classification of a wide variety of forensic specimens are being presented. Volatile organic compounds from individuals have been employed to differentiate persons. This type of evidence is also capable of providing information about an individual's shared traits such as age and gender and may prove useful in instances when other trace evidence such as DNA is unavailable. The classification power of this technique will be presented from three different ethnic groups sampled. In addition, sampling involving headspace solid phase microextraction (SPME) was used for the identification of bath salts, to determine their volatile organic odor composition to provide greater reliability for detection by law enforcement canines. Gas chromatography chemical ionization mass spectrometry was used to characterize bath salts by sampling its volatile organic composition. This coupled with novel canine training methods utilizing a patent pending universal calibrant will allow for the reliable identification of contraband. In addition to SPME, Fabric phase sorptive extraction (FPSE), a new generation sample preparation technique that possesses over 200 times more sorbent loading surface area than SPME, was developed and will be presented. This highly sensitive microextraction medium allowed the extraction of non-volatile, polar, medium polar, nonpolar organic pollutants, ionic species, organometallic compounds as well as heavy metals. The superior performance and ease of use of FPSE will be discussed for the sampling of environmental water, urine and raw milk for antibiotics hormones, BTEX, pesticides and polycyclic aromatic hydrocarbons. As a result of the high preconcentration factor achieved when using FPSE, no solvent evaporation and sample reconstitution is needed, significantly reducing sample prep as well as minimizing toxic solvent usage.

Abstract Text

Ambient ionization sources for mass spectrometry are promising technologies for use in fieldable forensic mass spectrometry. While current ambient methods are suitable for molecular analysis in the field, there has been limited development of ambient ionization methods appropriate for elemental analysis. In forensics, elemental analysis is critical in trace evidence analysis as well as in sourcing the origin of explosive devices. The focus of this talk is on the development of technologies for atomic mass spectrometry and combining those methods with molecular ionization sources. To this end, a microwave plasma torch (MPT) was coupled with a Thermo LTQ XL ion trap mass spectrometer and used to directly analyze the elemental and isotopic composition of a variety of substrates. Materials can simply be placed in the plasma without sample preparation at ambient pressure to yield atomic composition. As little as 10 [micro]g of material was detected using direct MPT sampling. At lower powers, the MPT yielded molecular ions for compounds on the substrate surface. The MPT can be used either for direct elemental or molecular analysis of a solid substrate by simply varying the power. Additionally, the MPT was coupled with laser ablation (LA-MPT-MS) to enhance sensitivity in a technique that is a fieldable alternative to LA-ICP-MS. Current work is focused on coupling the MPT with a portable mass spectrometer (MassTech MT Explorer 50) for fieldable, multimode atomic and molecular analysis.

Abstract Text

Isotope ratio mass spectrometry (IRMS) is becoming more user friendly and a more common tool for answering a variety of forensic, ecological, geological, anthropological and environmental questions. In the forensic community, IRMS is already in use in many government forensic laboratories and has passed Daubert standards for admissibility in court on many occasions. This presentation provides two studies involving source attribution using IRMS.

In the first part of the talk, we use two different methods to classify and attribute human hair to subject groups such as body mass index, age and sex. One method uses the absolute abundance of the amino acids in human hair, as determined by derivatization GC-MS. The second approach uses bulk- and amino-acid-specific isotope analysis as input variables for classification. Statistical techniques such as canonical discriminant analysis (CDA) are used to overlook the covariance of amino acid values between individuals caused by dietary factors and instead highlight the selective differences caused by grouping factor(s) such as age, body mass index and sex.

The second part of the talk uses isotope ratios to link blowfly larvae, pupae and adult flies to different food (carrion) sources. Ecologists often use isotope ratio analysis to determine the trophic level of organisms and their primary food sources. However, such analyses are rarely interested in linking adult insects to a specific meat source in a forensic context. In this study, we present a proof of concept study to test the hypothesis that adult blowflies can be linked to specific food sources via their stable isotope ratios.

Abstract Text

The development of microfluidic paper-based analytical devices (μ PADs) is described for application to rapid, on-site detection of improvised explosives. Five lane μ PADs were designed and printed using wax ink on chromatography paper to create hydrophobic channels. Each channel contains colorimetric reagents capable of reacting with one or more explosive compounds resulting in a specific colorimetric reaction. Two devices were prepared, each capable of performing five simultaneous analyses on a single μ PAD. The first μ PAD was developed to detect inorganic explosives such as black powder, flash powder, and ammonium nitrate. It detects nitrates, nitrites, chlorates, and perchlorate oxidizers, as well as ammonium. The second μ PAD was developed to detect military explosives such as TNT and RDX along with other high explosives like urea nitrate. It also detects organic peroxides such as TATP and hydrogen peroxide. All experiments were performed by dissolving the explosives in deionized water or 50:50 acetone/ H₂O as transport solvents with a detection time of around 5 minutes. Detection limits ranged from 0.39 – 19.8 μ g of explosive compound. These two customized μ PAD devices permit the on-site forensic testing of unknown explosives, thereby supplying law enforcement and first responders with a resource for rapid and simple detection of explosive compounds.

Abstract Text

The Curiosity rover has been exploring the geology and habitability of Gale crater near Mars' equator since 2012. Its ChemCam instrument suite provides laser-induced breakdown spectra (LIBS) of rocks and soils up to 7 m from the vehicle and also provides the highest resolution remote images from the rover. The fine-scale LIBS spot size (0.3-0.5 mm) has opened new vistas for Mars geochemistry, with observations at > 4500 locations on > 1000 targets along the rover's traverse. Each observation consists of multiple laser shots which first remove surface dust, then probe into the surface of the rock. Accurate pointing has facilitated vertical line-scans within the rover's drill holes as well as chemostratigraphy—analyses across multiple rock layers at an outcrop. New rover software is being tested to robotically select targets based on albedo, size, and shape. The ChemCam spectral database, archived by NASA with nearly 200,000 spectra, represents one of the largest publicly available calibrated LIBS data sets and will be mined by scientists for years to come.

Results include the discovery that Mars soil and dust is hydrated (1.5-3 wt % H₂O). The soil consists of multiple components, some of which reflect weathering of local rocks. Igneous float rocks are alkaline and appear to originate in more evolved magmas than those found at previous landing sites, indicating that Mars is more diverse than previously observed. ChemCam provided the first comprehensive window into trace elements like Li, F, Rb, and Sr, and has found strong Mn and Zn enrichments, apparently emplaced by subsurface fluids. As the rover nears Mt. Sharp we expect to discover new insights into the geology and habitability of Mars.

This presentation will also provide details of the SuperCam instrument selected for NASA's Mars 2020 rover. SuperCam includes the LIBS and imaging capabilities of ChemCam and adds co-boresighted stand-off Raman, time-resolved fluorescence, and infrared reflectance spectroscopies.

Abstract Text

The determination of lowest level amounts of certain elemental or even isotopic species in various types of analytical samples is of highest relevance for a multitude of research fields and applications. In particular, long-lived radioisotopes of natural or anthropogenic origin are of concern not only regarding radiotoxicity in the environment but may also serve as tracers for dedicated geological, astrophysical and increasingly bio-medical studies. Multi-step resonant atomic excitation and ionization using tunable lasers is coupled to well adapted mass spectrometry to provide the essential selectivity in respect to the element under study. Suppression of isobaric contaminations and the high ionization efficiency of the RIMS technique ensures lowest detection limits. Today it is applied e.g. for routine inspection of Pu isotope content and composition in environmental samples with LODs as low as 10^5 atoms corresponding to activities below mBq. In addition, analytical studies and spectroscopic investigations on ^{41}Ca , ^{90}Sr , ^{99}Tc as well as the minor actinides Np, Am, Cm up to Es are carried out. Revealing the complex atomic structures and deriving ionization potentials serves as prerequisite for further optimizing analytical atom counting. In the cases of ^{90}Sr and ^{41}Ca , highest isotopic selectivity is realized by employing the optical isotope shift through narrow bandwidth laser radiation to suppress contributions from the stable isotopes of these ubiquitous elements. Finally the resonance ionization technique is nowadays leading in the field of on-line production of short-lived exotic radioisotopes at large scale research facilities like CERN in Geneva, Switzerland.

Abstract Text

In the past decade there has been rapid growth in the use of low-power plasmas as sources for ambient ionization mass spectrometry. The plasmas differ in their geometries, excitation modes, powers, and support gas composition. Although individual plasmas have been studied with optical spectroscopy, and some comparisons among different plasma types have been reported, it has proven difficult to make direct connections between the fundamental plasma properties and mass spectrometric performance. We will present detailed characterizations of four distinct ambient ionization plasmas based on optical spectroscopic measurements, and will draw connections, where possible, between the plasmas' optical characteristics and their performance as ambient ionization sources for mass spectrometry.

Abstract Text

The development of knowledge on nanotechnology is having a great impact in analytical chemistry like in mass spectrometric techniques, SERS, high resolution microscopy and gas sensors. The nanometric scale of particle dimension causes peculiar physical features for what concerns their electrical, optical and thermal properties that have been intensively investigated in the last decade.

Starting from these considerations we have recently proposed Nanoparticle Enhanced Laser Induced Breakdown Spectroscopy (NELIBS) in order to enhance the efficiency of the laser-matter interaction and to consequently increase the emission LIBS signal. NELIBS is based on the deposition of a colloidal solution of noble metal NP on the sample surface and virtually does not require any change in the LIBS set-up. As examples in the case of conducting samples, NELIBS allows a signal enhancement up to tow orders of magnitude as a consequence of electron field emission during the laser-matter interaction. Instead in the case of transparent media, it is possible to obtain enhanced spectra with respect to conventional LIBS by inducing changes in the optical properties, without damaging or cracking the sample itself.

In this work the fundamental aspects of NELIBS is discussed in correlation with quantitative analysis of different kind of samples ranging from metals and alloys to glasses. Further perspective of nanoparticles applications to LIBS will be discussed as well.

Abstract Text

Inductively coupled plasma–atomic emission spectrometry (ICP–AES) has become the workhorse for routine multi-element determinations at major to trace levels. However, it can suffer from errors of 30% or more when the matrices of the sample and the calibration standards are not matched. Worse, there is generally no simple way to tell if such interferences are present. It is clearly desirable to have available a method that flags and warns the analyst when an interference exists.

There are three categories of matrix effects (sample-introduction-related, plasma-related, and spectral interferences), and their characteristics and behavior are all different. Recently, we developed a unified interference-flagging method that is effective for all three matrix-effect categories. Moreover, this indicator can be employed in an online fashion during an analysis, is applicable to both conventional lateral-viewing (i.e., side-on) and axial-viewing (i.e., end-on) observation modes, and can be automated.

This simple all-in-one indicator is based on the fact that plasma behavior and excitation conditions vary from one location to another in the ICP. As a result, the relative magnitude and even the direction of the change in emission intensity caused by a matrix are not constant, but are spatial-location dependent. The addition of a new dimension – the spatial direction – to ICP measurements then allows any matrix interference, if present, to be automatically flagged. To elaborate, because the apparent concentration of an analyte in a sample is related to the measured intensity, any change in matrix effects along the spatial profile will cause the determined concentration to be spatially dependent, thus allowing the interference to be detected. In this presentation, the theoretical basis of this matrix-effect indicator and the spatial characteristics of matrix interferences in both ICP observation modes will be discussed, and their effectiveness will be evaluated.

Abstract Title **IF-AT Scratch-Offs Engage Analytical Students with the Chemical Literature**

Primary Author Helen M. Boylan
Westminster College

Date: Thursday, March 12, 2015 - Morning

Time: 08:35 AM

Room: 269

Co-Author(s)

Abstract Text

Immediate Feedback Assessment Technique (IF-AT) is a multiple choice scratch-off sheet that allows students to learn from their mistakes. Developed by psychology professors Dr. Michael Epstein and Dr. Gary Brosvic, IF-AT is based on psychological principles related to learning and memory. This approach of “answer until correct” using IF-AT scratch-offs has been used in both sophomore level analytical chemistry and junior/senior level instrumental analysis courses at Westminster College since 2007. IF-AT is a low-tech method for facilitating learning during an assessment and has been proven to improve retention of content. At Westminster, IF-AT is used in conjunction with chemical literature reading assignments where students work in small groups on in-class journal article quizzes. They debate each multiple choice possibility and come to a consensus, ultimately celebrating correct answers and critically analyzing incorrect answers before scratching off a different selection. This engaging approach improves students’ understanding of the chemical literature as well as reinforces the analytical content.

Abstract Text

Analytical methods can be taught in any setting with a little planning. I have had the opportunity to teach in a very small town in Southern France twice and have brought analytical chemistry into the fold both times. Preparing labs for study aboard courses is very challenging when you have to bring all the materials needed for the entire course. Fortunately companies are making instrumentation that is perfect for this type of adventure.

Ambialet, France is a perfect sight for teaching chemistry, especially environmental chemistry. Surrounded by the Tarn River, the number of water samples to test is infinite. Water quality assessment is easily taught using the Pasco GLX units for data collection. The Pasco GLX units are compact and have many useful probes for testing chemical properties of water. Portable spectrometers and gas chromatography units are also available for analysis and attach easily to student laptops with Pasco software

Tying the class into Ambialet's history was easy since mining was a major part of industry in the area. With mining comes the need for metals analysis. Metals analysis is also important for water quality in the old buildings in the area. A compact instrument for metals quantitation is a potentiostat for electrochemical analysis of metals. Two pine potentiostats were utilized to expose students to detection and quantitation of metals. Statistical analysis and literature research rounds out the experience for our chemists and world travelers.

Abstract Text

The development of microfluidic devices is a forerunning theme in analytical chemistry research. While undergraduate students are now being exposed to concepts of microfluidics and lab-on-a-chip devices in lectures, only a small number of laboratory experiments have been reported in the chemical education literature. To this end, an advanced analytical chemistry laboratory module has been developed. This module has been designed to provide students with an experiential learning opportunity that includes exposure to practical skills development for the cleanroom-free fabrication of microfluidic devices, the opportunity to explore fluid flow in microchannels (through zeta potential, electroosmotic flow velocity, Péclet number, and diffusion coefficient determinations), and the opportunity to develop a lab-on-a-chip device for analysis of a DNA ladder sample that incorporates microchannel electrophoresis and on-line line fluorimetric detection.

The outcomes of work done on the development and implementation of this 4-week laboratory module will be presented. Feedback received from students that have completed this laboratory module and refinements made to improve the module based on this feedback and student observation will also be included.

Abstract Text

The laboratory portion of the analytical chemistry course can be made more relevant and interesting by incorporating a forensic chemistry project as a culminating activity. A variety of physical evidence – instrumental technique pairings can be wrapped into a crime scenario to form the basis of a multi-week project. Examples of the pairings include the discovery of ignitable liquid residues by GC-MS, identification of bulk drugs by ATR-FTIR, matching of inks from pens and paper by LC with multi-wavelength detection, and characterization of glass shards by atomic spectrophotometry. The author's decade-long experience with these forensic analytical chemistry laboratories will be described.

Co-Author(s)

Abstract Text

Throughout the semester of the Instrumental Analysis course, the students are introduced and given the opportunity to use an atomic absorption spectrometer (AA), a laser induced breakdown spectroscopy (LIBS) system, a UV/visible spectrometer, a fluorimeter, a Raman spectrometer, a Fourier transform infrared (FTIR) spectrometer, a gas chromatograph/mass spectrometer (GC/MS), and a high pressure liquid chromatograph (HPLC) through various laboratory experiments. These experiments use around nine weeks of the semester. For the remaining six weeks, the students are assigned a project where they develop their own lab using any of the above instrumentation. They are given guidelines to follow. The students meet with me individually to discuss their idea (which does not have to be novel) and to determine if it is feasible. Once they are given the approval to continue with their idea, they have to prepare their own standards, obtain and prep their samples, and work on the method development for analysis. A final aspect of this assignment is that the students are required to write a research paper on their topic; they are to follow specific guidelines which mimic what would be completed for a real journal submission.

There have been numerous projects developed from this assignment over the past two years. Students take the experimental part very seriously and have done some excellent work. Some projects that have been developed include analyzing gasoline samples for ethanol concentration using the GC/MS, analyzing lead in paint using LIBS, calculating the potassium concentration in bananas using the FAA, and determining the naproxen concentration in over-the-counter migraine medicines using HPLC. Overall, this project is a great learning experience for the students and the students generally enjoy it because it is their own idea.

Abstract Text

This presentation will focus on analysis of runoff from the abandoned Marchand coal mine and remediated at the Lower abandoned mine drainage (AMD) treatment facility in southwest Pennsylvania, and its application to the CHEM 0260 (Introduction to Analytical Chemistry Laboratory) course offered annually at Pitt-Greensburg. This project, begun during the Fall Term 2013 offering of CHEM 0260, is a collaboration with the Sewickley Creek Watershed Association (SCWA) and the Rho Theta Chapter of the Gamma Sigma Epsilon National Chemistry Honor Society. AMD is the most common form of water pollution in southwest Pennsylvania, due to numerous abandoned coal mines that accumulate water with time. The insoluble hydrated iron(III) oxides produced may potentially contaminate streams and render well water unfit for human consumption. The objectives of this project include: 1) determination of selected analytes in AMD within the 15-week framework of the CHEM 0260 course, 2) introducing students to sample collection and preparation, and analytical methodologies for determination of analytes in AMD, 3) reinforcement of the importance of accuracy and precision in all determinations, and 4) exposing students to community and professional service by providing SCWA and Rho Theta with reliable results for analytes in AMD.

☐

Sample collection and preparation, determination of analytes (alkalinity, acidity, pH, sulfate, chloride, total suspended and dissolved solids, iron, aluminum, manganese, and calcium), and the results of determinations performed to date, future plans for this project, and collaboration with the SCWA and Rho Theta, will be presented and discussed.

Primary Author A Carl Sanchez
Phenomenex

Date: Thursday, March 12, 2015 - Morning

Time: 08:35 AM

Room: 274

Co-Author(s)

Abstract Text

Method translation for reversed phase, gradient elution methods is a frequently encountered task but one that requires careful consideration of many variables to maximize the likelihood of success. Failure to properly account for even one key variable can lead to undesirable changes in selectivity or failure of the transferred method. This issue has been discussed extensively in the past but its relevance has reemerged recently by the accelerating trend of replacing existing HPLC methods with new ones relying on UHPLC systems and columns. Additional variables must be adjusted to account for differences between HPLC and UHPLC columns and systems such as when switching from columns made with fully porous to core shell sorbents. In this presentation, the key variables to account for during HPLC to UHPLC method transfer (column porosity, system delay, column optimum flow rate, etc.) will be reviewed and recommendations for successful method transfer will be given. Additionally, a method translation tool that incorporates many of the key variables, thus greatly simplifying method translation, will be shown.

Abstract Text

Superficially porous particle (SPP) technology has been rapidly adopted by chromatographers in the past several years due to its convincing performance advantage over totally porous particles (TPP). This is evident from the numerous commercial introductions of large number of new SPP products, including more particle sizes (e.g. 1.7 μ m or 4 μ m), more pore sizes (e.g. large pore for proteins and peptides) and more phase chemistries (e.g. almost all phases on totally porous particles are available on superficially porous particles).

The wide variety of phases available on SPP greatly facilitates method development. Using the Hydrophobic Subtraction Model, we will show that different phase chemistries, such as polar-embedded phase, PFP phase and cyano phase, give different selectivities compared to C18 phase. In addition, we will discuss an innovative hybridized superficially porous particle that is designed to resist degradation in high pH mobile phases. It is well known that mobile phase pH can substantially change selectivity for ionisable compounds but operation in high pH requires chemically stable columns. By using this new high pH stable SPP column, one can run separations in low, neutral and high pHs as a way to gain different selectivity. We will show examples of the combination of different phases on silica-based SPP and the hybridized SPP in a method development system to help find the optimum method to achieve good resolution in a short amount of time, taking advantage of the speed offered by the SPP technology.

We will also discuss method transfer from totally porous particles to superficially porous particles. The difference in particle porosity due to different particle morphology will be considered in method transfer to ensure the same selectivity is obtained. Practical examples in both isocratic and gradient mode will be shown.

Abstract Text

Many of the problems encountered executing HPLC methods are a result of decisions made during the early method development process. The objective of this effort is to discuss the critical variable of stationary phase chemistry. In practice, many analysts will reach for their favorite C18 upon commencement of method development; however alkyl (Cn) phases are often not the most appropriate tool for a given set of separation. When retention or resolution is not readily achieved, analysts will often resort to the addition of ion-pair reagents or other complicated mobile phase preparations to force them to work. This common practice often results in the development of complex methods that suffer from lack of transferability, robustness and ruggedness.

There are many choices for alternative stationary phase chemistries that render the phase decision difficult. In this work we discuss two stationary phase classes, embedded polar group (EPG) and aromatic that are highly complementary to alkyl phases from a fundamental molecular interaction point of view. An understanding of the contrasting interactions that these different classes of stationary phase chemistries provide leads to more effective decisions during the process. This critical information promises to facilitate method development and generate simpler, more reproducible separations.

Abstract Text

Several advantages have been demonstrated through the use of fast and high efficiency HPLC column technologies. Column technologies such as those of sub-2 micron and superficially porous particles have been evaluated extensively and display the potential to provide benefits across various industrial applications. However, as alluring it may be to incorporate these technologies, some considerations should be taken into account in a pharmaceutical setting. One major consideration is the capabilities of the laboratory that will eventually need to run the method. In some instances a laboratory may not have the proper instrumentation and/or training to incorporate these column technologies which can lead to undesired consequences during method transfer. Furthermore, options to proactively avoid this issue can be complicated by regulatory bodies of various countries requiring testing in laboratories on their soil.

In this presentation we explore the scalability of HPLC methods across various column technologies for a number of pharmaceuticals. Successful scaling is demonstrated by changing column format while maintaining specificity. This approach provides laboratories with the ability to tailor a method based on needs and capabilities with minimum to no additional method development efforts.

Abstract Text

High performance liquid chromatography (HPLC) is the predominant analytical technique in pharmaceutical, agricultural and food industries. Modern quality control (QC) laboratories rely heavily on HPLC analysis for product release and process monitoring. More reliable, efficient and cost-effective analytical methods are desired by the industries. Recent advancement in LC column technologies led to significant improvement in separation efficiency and method reliability. Column packed with core-shell particles allowed faster and more efficiently separation to be carried out on conventional instruments and is a lower pressure alternative to columns packed with sub-2- μm particles. Albeit the advantages, there are practical considerations to be taken in order to take full advantage of these new technologies. In this presentation, a few applications in the separation of natural product and small molecule agricultural products will be given and benefits and limitations of these advanced LC column technologies will be discussed. Systematic method development and method transfer with core-shell columns will also be discussed.

Abstract Text

To support in vitro human skin penetration studies of topically applied anti-wrinkle peptides, a rapid hydrophilic interaction liquid chromatography with tandem mass spectrometry (HILIC-MS/MS) method for the simultaneous quantitation of two peptides, Ac-EEMQRR-amide and H₂N-EEMQRR-amide, was evaluated and successfully applied to the analysis of various samples including emulsions, receptor fluids, cotton-tipped applicators, and human skin layers such as stratum corneum tape strips, epidermis, and dermis. Stable isotopically labeled peptides, corresponding to native Ac-EEMQRR-amide and H₂N-EEMQRR-amide, were used as internal standards to correct for loss of recovery and matrix effects. Electrospray ionization (ESI) was used in the positive mode. Depending on the sample matrix, this analytical procedure involved extracting samples with 0.1:0.1:85:15 trifluoroacetic acid:formic acid:acetonitrile:water (v:v) or with 0.05:90:10 ammonium hydroxide:acetonitrile:water, followed by analysis using HILIC-MS/MS. For receptor fluids, epidermis, and dermis samples, it was necessary to first separate the two peptides from the sample matrix using HILIC-solid phase extraction (SPE) to minimize the serious ion suppression prior to HILIC-MS/MS analysis. The recoveries for Ac-EEMQRR-amide and H₂N-EEMQRR-amide ranged from 89% to 101% and 80% to 100%, respectively, at three spiking levels for the stratum corneum, epidermis, and dermis samples. The amount of Ac-EEMQRR-amide ranged from 249 ng/cm² detected in the first layer of the stratum corneum to 5.3 ng/cm² found in the thirteenth layer of the stratum corneum. The amount of Ac-EEMQRR-amide found in the epidermal layer was 23 ng/cm². Neither of these peptides was detected in the dermis or receptor fluid samples. H₂N-EEMQRR-amide was not detected in any samples.

Abstract Text

Black cohosh (*Actaea racemosa* L.) has become increasingly popular as a dietary supplement in the United States for the treatment of symptoms related to menopause. However, it has been known to be adulterated with the Asian *Actaea dahurica* (Turcz. ex Fisch. & C.A.Mey.) Franch. species (syn. *Cimicifuga dahurica* (Turcz.) Maxim). It is important to develop a method for the identification and differentiation of American black cohosh from other closely related species. However, the existing methods for identification and differentiation of black cohosh are usually long and laborious. Mass spectrometric fingerprints were obtained in the negative ion mode using flow injection mass spectrometry (FIMS) for 77 black cohosh samples and their related species. The analysis time for each sample was less than 2 min. All data acquired were processed using principal component analysis (PCA).

Abstract Text

Allergens are well known to affect between 1-3% of the population. Affected consumers have to avoid the offending proteins at all cost. If a person is milk protein allergic, it is obvious that milk should not be consumed. But how about processed products? If you are soy allergic, and a product contains vegetable proteins, does it contain soy? In the worst case scenario, allergens end in a product through cross contamination or carry – over. In those cases, the offending allergens will not be mentioned in the ingredient list, and the only option is to analyse. But to what levels should be analysed? This question is equally important for food manufacturers who need to know if they production lines are sufficiently clean, as it is to consumers, who need to know if the allergen is potentially present. In many parts of the western world Risk Assessment Agencies set limits for dangerous substances. For allergenic consumers, certain proteins are dangerous. So far, none of the agencies has set thresholds for allergens, above which products should be labelled, even if the allergen is not part of the recipe. Clinical research has generated plenty of data and scientists seem to agree that thresholds for most allergens should be in the lower ppm (mg/kg) range. But without legal framework those values may not hold if challenged in court. But even if threshold values had been set: would food industry and consumer be better off? That is questionable, since once of the main impact factors has not really been addressed: the analysis. At present, especially with highly processed foods, analytical methods can give strongly varying results. Those methods range from PCR and immunological methods (lateral flow device, sandwich ELISA, competitive ELISA) to mass spectrometry. And even within the same group of methods, (e.g. immunological assays), results can vary significantly. So how can confidence for food manufacturers and consumers be achieved?

Abstract Text

Ambient mass spectrometry (AMS) has been used to perform analyses under ambient conditions without sample pretreatment. The ESI-based AMS is useful for characterizing polar and large compounds, while APCI-based AMS is useful for characterizing small, less polar or even nonpolar compounds. A combination of both ionization methods will extend the detective mass range as well as polarity. In this study, we combined a thermal desorption laser sampling unit with a mass spectrometer equipped with a dual ambient ESI+APCI source so both polar and nonpolar polymeric fragments released from food packing polymeric materials were rapidly characterized.

The ion source having the functions of ESI and plasma APCI was constructed by inserting a fused silica capillary into a stainless steel tube that was enclosed in a glass tube. An AC high voltage was applied to the ring electrode attached to the glass tube to discharge a stream of N₂ gas flowing between the stainless steel and glass tube. A DC high voltage was applied to the ESI solution to generate an ESI plume at the capillary tip. A piece of food packaging material was set on a titanium foil and was pyrolyzed by laser irradiation. The desorbed neutrals were post-ionized via subsequent reactions with the reactive species in ESI and plasma APCI plumes. In addition, by controlling the high DC and AC voltages applied on the dual ionization source, the ionization can be operated in ESI-only, APCI-only and ESI+APCI mode, respectively. This technique was used to rapidly characterize the chemical compounds in various food packing materials which were made by different types of polymers including polyethylene (PE), polypropylene (PP), polystyrene (PS), poly(methyl methacrylate) (PMMA), polylactic acid (PLA), polycarbonate (PC), synthetic rubbers, etc. Besides, principal components analyses (PCA) was used to rapidly classify the polymeric materials based on the results from laser desorption-ESI+APCI/MS.

Abstract Text

The analysis of very polar compounds in food has been considered to be one of the most challenging topics. The polar compounds are usually eluted in the void volume when separated with reversed-phase LC (RPLC). However, they may be the important target components in food analysis. A novel stationary phase was introduced in this study, and its advanced applications were demonstrated for food safety.

Time: 10:25 AM

Room: 267

Co-Author(s)

Abstract Text

Dietary copper deficiency is associated with a variety of manifestations of the metabolic syndrome, including hyperlipidemia and fatty liver. In order to investigate whether copper deficiency plays a role in fructose-induced fatty liver, male weanling Sprague-Dawley rats (35–45 g) were housed in stainless steel cages in a temperature and humidity controlled room with a 12:12 h light–dark cycle. All rats were allocated into four groups. Each group of rats was fed either an adequate copper or marginally copper deficient diet. At the same time, distilled water or distilled water containing 30% fructose (w/v) was given ad lib for 4 weeks. Fructose enriched drinking water was changed twice a week. At the end of the experiment, all the animals were killed under anesthesia with pentobarbital (50mg/kg I.P. injection). Feces were collected and snap-frozen with liquid nitrogen for metabolomics study. Metabolites were extracted using a solvent mixture of methanol and water. The extracted metabolites were derivatized using N-(tert-butyldimethylsilyl)-N-methyltrifluoroacetamide (MTBSTFA). The derivatized samples were analyzed on both LECO Pegasus 4D GC×GC-TOF MS and GC-HRT-MS instruments, respectively. Experimental data were processed by ChromaTOF software for peak selection and compound identification, followed by MetPP software for retention index matching and metabolite quantification. Preliminary analysis shows a significant metabolite profile difference between sample groups. Several analytes not confidently identified in the GC×GC-TOF MS experiment have been assigned identities based on the accurate mass analysis in GC-HRT-MS data. The fecal metabolites profile reveals novel mechanism underlying marginal copper high fructose diet-induced NAFLD.

Abstract Text

Mass spectrometry (MS) instruments have significantly advanced in recent years, providing superior sensitivity, selectivity and ruggedness. Therefore, modern MS detectors can be used not only as a detection tool for chromatography, but also as a stand-alone detection / identification tool, thus allowing to eliminate time consuming chromatographic separation. The objective of this study was to develop and evaluate a novel screening method for selected pesticides and mycotoxins in cereal-based food samples using flow injection tandem mass spectrometry (FI-MS/MS). To ensure reliable MS identification in absence of retention time (tR) in FI-MS/MS analysis, additional MS parameters, such as enhanced product ion and multi-stage MS (MSn) were investigated. Prepared extracts of wheat, rye, barley and soy were ten-fold diluted and fortified at 10, 50 and 500 ng/g of the contaminants. The identification was performed using LC-MS/MS QTrap (API 5500, Applied Biosystems) with electrospray ionization in positive mode. Ion suppression, interferences and selectivity were evaluated. The method detection limits (MDL) were 1 - 4 ng/g for aflatoxin B1, fumonisin B1 and B2, ochratoxin A, T2 and HT2 toxins; and 8-12 and 5-25 ng/g for zearalenone and deoxynivalenol, respectively. For pesticides, the MDLs were at or below 10 ng/g. The results suggest the method is applicable for fast screening of selected pesticides and mycotoxins at or below the established maximum residue levels in grains/cereals.

Abstract Text

Highly-developed downstream processes require a strict quality control of the generated synthesis gas. Being poisons to the used catalysts, the determination of sulfur compounds is absolutely crucial. Despite fulfilling these demands, sulfur selective detectors, like the Sulfur Chemiluminescence Detector, can be difficult to operate.

This work deals with a feasibility study of an alternative analytical system consisting of a Compact-GC equipped with a Plasma Detector. The work is focused on the determination of the detection limits of the different components, repeatability and general performance of the detector.

Abstract Text

Tiger Optics has developed the Prismatic 2, a new generation of Continuous-Wave Cavity Ring-Down spectrometer that transcends the bandwidth limitation of high-reflectivity mirrors by employing Brewster prisms, which exploit total internal reflection, to form a broadband, high-finesse cavity. Integration of multiple diode lasers, combined with such a cavity, allows real-time detection of multiple analytes with very high sensitivity.

The Prismatic 2 analyzer is best suited to serve applications requiring detection of multiple analytes in a single gas stream. Multi-species capability is required in a wide range of applications such as quality control of high-purity gases, hydrogen analysis for fuel cells, and emission monitoring. In fuel cell applications, it is crucial to monitor contaminations in the hydrogen gas because their efficiency and lifetime is dictated by the purity of the hydrogen. This requires simultaneous monitoring of critical impurities, such as CO, CO₂, CH₄, H₂O and others in bulk hydrogen. The Prismatic 2 offers simultaneous detection of these impurities and other trace level contaminants, including NH₃, HCN, H₂S, and AsH₃, as a real-time monitoring system. Therefore, it also provides numerous opportunities for multi-species trace gas detection beyond fuel cell applications. Gas companies typically monitor gas quality using a gas chromatograph and several single-species instruments; the ability to replace these with one instrument significantly simplifies the process and reduces cost, and is therefore affords significant savings, while improving yield and throughput.

The presented data illustrates simultaneous detection of CO₂, CO, H₂O and CH₄ in hydrogen, achieving detection limits of 150, 100, 10 and 1 parts-per-billion (ppb), respectively, and demonstrates fast speed of response, excellent linearity and repeatability over a wide range of analyte concentrations.

Abstract Text

For many reactive gases adsorption and reactions are limiting factors in gravimetric preparation of stable reference gas standards at trace levels. The influence of adsorption of low concentrations of ammonia on cylinder surfaces has been investigated at VSL. This resulted in the development of certified reference gas mixtures at few ppm levels with reduced uncertainty. In order to support the measurement of formaldehyde levels in outdoor and indoor air, research has been conducted to assess the reliability of formaldehyde gas standards in cylinders. The study aimed in particular at evaluating the stability of formaldehyde at few ppm levels. The presentation will provide the results of this study.

Abstract Text

Phosphine is used as a precursor for the deposition of Group III-V compound semiconductors, and as a dopant in the silicon semiconductor manufacturing process. It is used in large amounts for the manufacture of LED and photovoltaic products. In the case of III-V materials such as InP, absence of other hydride dopant impurities such as moisture, silane, germane or hydrogen sulfide is critical as they can have a profound effect on the performance of the final device. In particular, incorporated sulfur from hydrogen sulfide and carbonyl sulfide may affect electrical properties of the device such as carrier concentration and electron mobility. Dopant impurities may also impact the electroluminescence properties of LED products. Determination of these compounds at ppb levels and below is therefore very important. This presentation reviews the analytical technology available using gas chromatography, including column choices and detectors. One of the most challenging measurements has been the determination of hydrogen sulfide due to the difficulty in detection at trace levels as well as its chromatographic behavior with respect to that of phosphine.

Abstract Text

Specialty gas is a somewhat vague term often confused with industrial or bulk gas. While specialty gases, or gas mixtures, are used in industry they differ in the characteristics of high purity and/or complexity and certified composition. A novel vacuum ultraviolet (VUV) absorption spectroscopy technique has recently been introduced that provides unique capabilities for gas phase analysis. The instrument can be used as a gas chromatographic detector or for direct injection gas phase spectroscopy. The instrument rapidly collects continuous absorption spectra from 120nm – 240nm. Most gas phase molecules have very strong and unique absorption cross sections in the VUV, which enable sensitive and selective analysis. Results of the analysis of different specialty gases are presented. The versatility of the VUV detector software is demonstrated using spectral filters to overcome matrix effects, and spectral deconvolution for co-eluting components. Applications such as TO-15, natural gas, permanent gas analysis and the presence of H₂S in phosphine will be discussed.

Abstract Text

In this paper we will discuss progress on the development of HEMS, a technology used to enrich impurities in hydrogen for analytical applications. The technology consists of a pre-concentrator, coupled with a mass spectrometer-based analytical unit used to detect impurities. By increasing the concentration of impurities, this technology has the potential of reducing the cost of trace analysis in hydrogen for a variety of applications from fuel cells to semiconductors.

In this paper we will focus on HEMS-M, an analyzer designed to verify compliance with hydrogen purity standards SAE-J2719 and ISO 14687. The instrument is designed to be deployed at hydrogen filling stations for real time operation and thus allowing interruption of dispensing hydrogen in the event that the limits on the impurities specified by the standard are exceeded. We will report on progress on the analytical figures of merit for the analytes tested.

The core of the technology is a palladium-alloy micro-channel membrane. The membrane acts as a pre-concentrator by selectively permeating hydrogen, thus enabling an increase of the impurities present at trace levels. The alloy composition, temperature of operation and coating of the membrane are designed to reduce the reactivity of the trace species to be analyzed. Successful enrichment of ammonia in a hydrogen gas stream has been demonstrated. The analytical requirements will be discussed, including the wide dynamic range for the different species.

Abstract Text

Over the last years, on line analysis has become currently used for the instrumentation of industrial plants (process monitor and control) as well as the equipment of research and development pilot plants (chemical, petrochemical, green chemistry, ...). In the last years, new technologies were put in the market like NeSSITM and miniaturized systems which enable new on line analysis concepts. For industrial applications, numerous benefits of these new concepts can be foreseen : reduce greatly the response time, increase the safety level of analysers (reducing transport and volume of samples), decrease the detection limits (no sampling, no contamination), open the way for new optimisation applications in order to perform new measures at low investment cost, define new standards of components, reduce the cost of maintenance with reduction of spares, increase flexibility of analytical applications with easy addition or replacement of micro analysers using the ISA SP 76 standard. Trends in R&D is toward downscaling and process intensification (micro reactors, string pellet reactors), which put new constraints on analytical systems. Downscaling results in less product available and requires the development of new analytical tools and strategies: bring the analysis directly on the process streams. To implement these tools in or as close as possible of the reactor, they must become smaller with no loss of performance. New projects from IDEEL (new French company) aim at fostering innovation in the field of industrial analysis by catalyzing the development of adapted in situ tools. It gathers partners from R&D (academic centers, instrumentalists) to the market (industrialists).

This paper will present some major actual and future trends and needs for on line micro analytical instruments and micro captors for R&D (process intensification) and industrial plants. This paper will be illustrated with different examples of sensors and analyzers: μ densimeter, μ GC, μ NIR, μ Raman.

Abstract Text

Many customers experience serious delays to their manufacturing work flow when waiting for analytical results. Such at risk work flows may be found in various industries such as pharmaceutical, food and commodity manufacturing. An analytical solution for this problem is to provide a secure and easy to use UPLC system for implementation at the manufacturing location.

A novel instrument has been introduced that provides access to the speed, sensitivity and resolution of UPLC technology. This instrument has been designed with security measures to track chain-of-custody compliance ensuring controlled access to the instrument, the samples being analyzed and the results generated. The bar code initiated analysis permits all levels of personnel expertise to run samples and to obtain quantitative results. The instrumentation also provides for multiple levels of dilution ensuring a workflow that decreases or even eliminates the errors in creation of multi-point calibration curves and sample preparation.

Several pertinent product samples, which may be subject to regulatory audits, will be used to illustrate the use of this instrument.

Abstract Text

Analysis can be found everywhere within Air Liquide. Increasingly, industrial applications require analytical systems which have a higher degree of accuracy at lower levels with an increasing array of components within the sample. These analyses must be conducted in shorter time frames and with less operator intervention.

This presentation will describe the application development for trace hydrocarbon, CO₂, N₂O analysis in oxygen streams with the unique Very High Resolution Tunable Laser source technology. Detection system developed by ONERA (the french aerospace lab) and Blue Industry and Science.

The developed laser source is tunable over a wide range of the infrared spectrum (between 2300 and 3100 cm⁻¹ in the current version) with a very high resolution (0.01 cm⁻¹). With a single laser source, the VHR- TL technology works like hundreds of diodes connected in parallel, which can be activated on demand to fit the application needs. This technology yields performances similar to those of TDLAS, with real multi-gas possibilities (more than 300 gases are measurable with detection limits between 1 and 100 ppb).

Abstract Text

X-ray Fluorescence (XRF) is a widely accepted technique for elemental analysis of a large variety of materials, including solids, liquids, powders and thin films. Traditionally two techniques exist: energy dispersive and wavelength dispersive XRF, both offering distinct advantages for particular applications, elements and concentration ranges. In this study, recent technical advancements in both energy and wavelength dispersive XRF will be discussed in detail. Various application examples will be shown for which these advancements result in significantly improved analytical capabilities.

Abstract Text

The Laser Induced Breakdown Spectroscopy (LIBS) is based on the spectrum of small plasma induced by irradiation of high peak power laser applicable to gas, aerosol and solid-phase samples. This method can also detect almost all elements in the sample. A key advantage is that pretreatment is not required as the laser is focused on the sample surface and consequently induces the plasma. These characteristics provide a great advantage for onsite real time analysis in an industrial environment. Our objective is to apply this method for quality control of trace metal particles in liquefied electronic specialty gases.

Initial experiments were conducted with an aqueous sample containing ppm_w Zn, Mn, Fe and Cr nano particles. The experiments were conducted using a home-built LIBS with Nd:YAG laser. The laser beam is focused in the middle of the sample solution in a quartz cell and the optical emission light is observed by spectrograph equipped with an intensified charge coupled device as the detector. The probability of the breakdown was quite different for each metal. Zn and Cr were relatively easy to generate the breakdown but Mn and Fe were not. Furthermore, the spectra of constituent metal atoms were observed, but the appearance of the atomic spectra is unstable with a large shot-to-shot difference. The equipment and method evaluation will be discussed of this technique along with the stability and detection limits in static conditions.

Subsequently evaluation of metals in a liquefied gas in a pressure resistant gas cell with a quartz window will be also discussed.

Abstract Title **Characterization and Applications for In Vitro-Microdialysis: a Sampling Platform for Fast Analysis of Non-Electroactive Analytes in Cell Culture**

Primary Author Amy Stading
University of Minnesota

Date: Thursday, March 12, 2015 - Morning

Time: 08:30 AM

Room: 241

Co-Author(s) Michael Bowser

Abstract Text

Cell-based assays are used to obtain biochemical information while avoiding the inherent complications of in vivo systems. Though many advances to classic in vitro methods have been made, analysis is still primarily limited to either fast detection of electrochemically active events or time-delayed measurements of non-electroactive species with poor temporal resolution. There remains an analytical challenge in monitoring fast dynamics of non-electroactive molecules in vitro. We have previously developed an alternative in vitro sampling platform by culturing astrocyte cells directly onto a microdialysis probe coupled with an online high-speed capillary electrophoresis (CE) instrument. Dynamic changes in the relative abundance of analytes have been monitored with 20 second temporal resolution. To the best of our knowledge, release events of non-electroactive compounds in culture have not previously been observed on this time scale. To better understand the technical variables of this technique, we have been characterizing how variables such as temperature, size of environment, stirring, and strength of stimulation influence our ability to make these fast measurements. Efforts are also currently being made to couple the in vitro-microdialysis probe to a microfluidic chip capable of performing micro-free flow electrophoresis. Preliminary data suggests that amino acid transmitters such as glutamate and aspartate will be able to be monitored continuously at basal levels and in response to stimulation, allowing us to see fast-dynamics previously lost in temporal resolution.

Abstract Text

It is of great importance to understand biochemical systems' behavior toward environmental perturbations during the development of living organisms. Nevertheless, obtaining high-resolution spatiotemporal information during embryonic development is almost impossible with conventional biotechniques. A microfluidic system capable of developing a *Drosophila* embryo's anterior and posterior halves controlled at different temperature was established to study the embryo's reaction under environmental perturbations. The microfluidic chip (60 mm \times 60 mm \times 5 mm) consists of a polymethylmethacrylate substrate and a polydimethylsiloxane (PDMS) cover patterned with a 'Y' channel network (800 micrometer-wide and 400 micrometer-deep). The PDMS cover was bonded to the substrate with the embryo located right in the channel intersection. Temperature gradients (25 \square 16 \square , 25 \square 18 \square , 25 \square 20 \square) around the embryo were created by introducing two fluids with different temperature through the 'Y' side channels. The fluid temperature was measured by a superfine wire thermocouple (125 micrometer, o.d.). The microfluidic device was coupled to a confocal microscopy for real-time image acquisition. Histone-eGFP embryos were developed in the platform and monitored in situ. It was found that the warmer half of the embryo developed faster than the cool half at the beginning, but no difference was observed at the end of each cell cycle. The larger the temperature gradient, the more obvious difference for the development rate, but always within one cell cycle. It implies that the two halves of the embryo communicated during the development and there might be a check point in each cell cycle for the 14 cycles of *Drosophila* embryonic development.

Figure 1. Development rate difference between the two halves of an embryo exposed to a temperature gradient of 25 \square 16 \square . (a) Before cleavage stage. (b,c,d) during one cell cycle, (e,f,g) during the next cell cycle. The green fluorescent dots are histone-eGFP labeled nucleus.

Abstract Text

Adenosine is an important biomolecule involved in energy regulation in the brain during conditions such as traumatic brain injury (TBI) and stroke. Inosine and hypoxanthine, two metabolites of adenosine and guanosine, another purine nucleoside in the brain, have also been recognized as markers of cerebral ischemia. Under pathological conditions such as TBI and stroke, the extracellular concentrations of adenosine, guanosine, inosine and hypoxanthine in the brain are known to be increased. Simultaneous and continuous monitoring of these biomarkers is extremely important to better understand neurological disorders and also for evaluating potential drug candidates for treatment of TBI and stroke. However, clinical instrumentation for simultaneous online monitoring of these biomarkers is currently unavailable. Microdialysis coupled with microchip electrophoresis with amperometric detection is a powerful technique that can be used for fast and reliable monitoring of biological samples. Microchips electrophoresis with amperometric detection was successfully employed for the separation and detection of all four biomarkers. The chip was fabricated from PDMS and had a 5 cm long separation channel and a carbon fiber working electrode. The run buffer consisted of boric acid at pH 10.0 with 10% (v/v) dimethylsulfoxide and field strength of 222V/cm was applied. Under these conditions, all four compounds could be separated in less than 80s. Ultimately, this method will be coupled on-line to microdialysis sampling to monitor these biomarkers in extracellular fluid of the rat brain during ischemial reperfusion and TBI.

Abstract Text

Renal transplantation is the gold standard treatment for end-stage renal failure (ESRF), a disease affecting approximately 870,000 Americans today. Some 400,000 Americans require regular intensive dialysis therapy, travelling many miles to their regional dialysis centre up to 3 times per week. On top of this, they depend on multiple drugs and severely restricted lifestyles just to stay alive.

Approximately 170,000 Americans are living with renal transplants. Not only does a successful transplant restore quality of life and return people to work, but each year of transplant function can lead to individual cost savings of US\$50,000 or more.

There are of course some big socio-political and research issues surrounding renal transplantation including organ availability, patient matching and immunosuppression, but one area increasingly recognised as vital to the long-term function of a transplant is the pre-implantation care of the organ.

As yet there is no established methodology for successfully resuscitating and maintaining an organ during the time it takes to travel from its deceased donor to its living recipient, often many miles and hours away.

We have developed a continuous creatinine clearance monitoring system and demonstrate its efficacy in isolated perfused porcine kidneys. Creatinine clearance is a globally accepted clinical standard measure of renal function and reflects organ injury and dysfunction.

We believe this live functional data will change the face of surgical risk stratification and lead to improved patient outcomes as well as cross-fertilising other areas of renal transplantation research.

Abstract Text

Acute myeloid leukemia (AML) is a rapidly dividing tumor that can progress from a state with no morphologic evidence of disease to florid hematological relapse in weeks. Minimum residual disease (MRD) analysis is critical to overall survival. Multi-parameter flow cytometry (MFC) is the most common method of detecting AML MRD but has a poor LOD (1 target cell in 10⁴ background cells) and so requires a bone marrow aspirate drawn only once every six months due to patient discomfort. In contrast, we present an integrated microfluidic system to isolate low abundant leukemic blasts from 50-500 μ L of peripheral blood. Three microfluidic devices isolate highly pure fractions of three blast subpopulations by positive-affinity selection against CD33, CD34, and CD117 antigens, which together sample 80-90% of all patients. We have previously demonstrated markedly low limits-of-detection (1/10⁹) and purities >90% for this technology, which consists of a thermoplastic microfluidic possessing antibody decorated high-aspect ratio curvilinear channels (25 x 150 μ m). All subpopulations are immunostained on-chip against a panel of antibodies then sequentially released off-chip by enzymatically cleaving novel oligonucleotide linkers. The released cells are routed to a spectral-MFC system for immunophenotyping, which has an optical train consisting of only laser excitation, a spectrograph, and a CCD camera operated in a time-delayed integration (TDI) mode. In total, the system provides the same phenotypic information as conventional MFC but offers a sensitivity improvement of five orders of magnitude and enables MRD detection using peripheral blood instead of bone marrow aspirates, thereby permitting more frequent diagnostics.

Abstract Text

Transfusion of blood components to patient recipients has become a daily healthcare activity. Recently, our group has shown that the high concentration of glucose in currently approved blood storage solutions is having adverse effects on the stored red blood cells (RBCs). Investigating all of the storage solutions currently approved by the FDA would be time consuming and require numerous donations of blood. We have developed a 3D-printed microfluidic device that has 12 channels, is designed to fit into a commercial plate reader for high throughput optical measurement, and was re-used for months throughout the study. Next, we modified and maintained the glucose level of 3 popular hyperglycemic storage solutions (AS-1, AS-3, and AS-5) at 5.5 mM, the normal level of healthy humans. Flow-induced ATP released from RBCs stored in standard storage solutions, which are hyperglycemic, and normoglycemic versions of each solution, was determined with the luciferin/luciferase chemiluminescence assay. For example, on the first day of storage, RBCs stored in AS-1 released significantly less ATP (126.7 +/- 2.2 nM) in comparison with RBCs stored in a normoglycemic version of AS-1 (250.9 +/- 14.6 nM) ($p < 0.05$, $n = 4$ humans). This trend was continued to day 35 of storage where RBCs stored in AS-1 released 64.8 +/- 8.3 nM ATP, significantly lower than RBCs stored in a normoglycemic version of AS-1 (172.8 +/- 10.1 nM) ($p < 0.05$, $n = 4$ humans). The ruggedness of the 3D-printed devices is enabling us to study month-long processes with minimal variability and low-volume sample consumption.

Abstract Text

Exposomics is a relatively new recognized branch of science with an environmental human health focus based on realization that non-communicable diseases are caused by toxins in the environment, resulting in epigenetic changes and metabolic alterations in the human body. In a recent four-year study, over twenty unique personal chemistry indicators that are statistically significant at the 95% Confidence Interval have been determined in children with autism as compared to control children. The study was a clinical research trial of children with Autism compared to control children who were age, sex and socioeconomically matched within a one hour radius of Pittsburgh, Pennsylvania, USA. The experiments required over 300,000 individual biometric measurements of organic toxins, metals and elements, and two unique biomarker and epigenetic assays. New Direct Isotope Dilution and Speciated Isotope Dilution methods (D-IDMS and D-SIDMS) adopted by the United States Environmental Protection Agency (EPA) were optimized and applied. These methods are known as the EPA Method 6800, Update V, approved in 2013. The experimental protocol was designed with many goals and specific aims, including improvements or creation of advanced measurements to assist in differentiating the chemistry of the children as early as possible. This chemical differentiation may eventually lead to risk assessment and diagnosis of autism before symptoms and brain damage appear.

Abstract Text

A large proportion of analytical data acquired from Nuclear Magnetic Resonance (NMR), Liquid Chromatography (LC), and Mass Spectrometry (MS) instruments is used for routine analytical purposes such as structure confirmation and purity. In most cases the samples are relatively simple. For laboratories that acquire routine data and employ a range of instruments from different vendors the task of processing and analyzing the data is further complicated by the array of different vendors software they require. Here we present an innovative software platform that is designed specifically for routine analytical applications. It enables analytical data from a wide range of different vendors and analytical techniques to be captured and databased in a single repository. Since the data is live and accessible it can be searched and utilized within future analyses. It combines NMR, LC, MS, Optical Spectroscopy analysis and chemical structural information.

The presentation will demonstrate the platform working with several different datasets ranging from open access mass confirmation samples through to applications such as Met ID and automated structure verification by NMR. In the mass confirmation example chemical structures are utilized to further aid target identification through isotope and fragment pattern matching. Since the analytical data is accessed from a database the ability to mine this existing data will also be shown.

Abstract Text

Today's in-service fluid analysis programs have grown significantly in the past few years with many laboratories analyzing over 2000 samples per day. Each sample requires a detailed interpretation to provide the full diagnostic potential. This interpretation includes past data about the equipment the fluid is used, plus analytical data from a variety of techniques to characterize the properties of the fluid.

Historically, combining and generating information from disparate data sets could be time consuming and daunting from an interpretation perspective. Often users would look at the overall data searching for related information. With today's sample loads and volume of data, revealing information using these traditional approaches are unmanageable.

This presentation will discuss the latest tools for in-service fluid analysis data interpretation. We will discuss the fusion of data sets, in particular FT-IR and ICP and novel ways of looking at, cross-correlating, statistically processing and visualizing the relationships between the data to reveal more information.

Abstract Text

The Royal Society of Chemistry provides open access to data associated with tens of millions of chemical compounds. The richness and complexity of the data has continued to expand dramatically and the original vision for providing an integrated hub for structure-centric data has been delivered across the world to hundreds of thousands of users. With an intention of expanding the reach to cover more diverse aspects of chemistry-related data including compounds, reactions and analytical data, to name just a few data-types, we are in the process delivering a Chemistry Data Repository. The data repository will manage the challenges of associated metadata, the various levels of required security (private, shared and public) and exposing the data as appropriate using semantic web technologies. Ultimately this platform will become the host for all chemicals, reactions and analytical data contained within RSC publications and specifically supplementary information. This presentation will report on the challenges of managing "Big Data" for chemists around the world and providing access to tools for structure dereplication, spectral database searching and the crowdsourcing of the worlds' largest spectral database.

Abstract Text

The field of Laboratory Informatics is rapidly evolving with expanding functionality and fundamentally new tools which are changing how laboratories operate and deliver value to customers across all industry and laboratory sectors including health care, food, consumer, forensics, automotive, chemical, energy, manufacturing, mining, government / regulation, defense, nuclear and academic.

Supporting Laboratory Informatics standards are also evolving both within the laboratory and between external systems. Laboratory Informatics provides a vital link in the capture, processing, trending and reporting of information.

The focus of this discussion is on the newly approved ASTM E1578 Laboratory Informatics Standard Guide.

The scope of ASTM E1578 Laboratory Informatics Standard Guide was broadened to include the primary tools in today's laboratory informatics area (examples include: Laboratory Information Management Systems (LIMS), Chromatography Data Systems (CDS), Electronic Laboratory Notebooks (ELN) and Scientific Data Management Systems (SDMS). Additional terms related to laboratory informatics are now defined and new sections, including one on lean concepts and knowledge management.

A wide segment of laboratory informatics users, vendors and interested stakeholders participated in the recent revision of the standard. The primary audiences of the standard include: end users of Laboratory Informatics tools, implementers of Laboratory Informatics tools, information technology personnel, Laboratory Informatics tools vendors, instrument vendors, individuals who approve Laboratory Informatics funding, Laboratory Informatics applications support specialists and software test/validation specialists.

Abstract Text

Hydrogen sulfide, along with carbon monoxide and nitric oxide, is a gaseous signaling molecule known as a gasotransmitter. All of these molecules help regulate ion channels within the body, however there is a particular desire to selectively detect H₂S in vivo due to its physiological significance in the central nervous and cardiovascular systems. Independently detecting H₂S in the presence of NO and CO will allow for the full understanding of both its individual physiological roles as well as its interactions with NO and CO.

Unfortunately there is currently no method that allows for selective in vivo detection of H₂S. One possible method is to design an amperometric gas sensor which incorporates an electrocatalytic material that selectively oxidizes H₂S in the presence of NO and CO. Our group has been actively investigating cyanide coordinated to electropolymerized ferritroporphyrin (FePP) as such a material, which may be able to be incorporated into a future sensor design. However, the electropolymerization of FePP on Pt microelectrodes did not previously yield a layer with adequate selectivity for practical applications. This presentation will report our efforts in understanding and improving the FePP electropolymerization process, specifically with regards to optimizing the electrochemical reduction of graphene oxide in order to serve as a potential FePP support material. This work is sponsored through an award from the National Science Foundation.

Abstract Text

Tear glucose measurements have been suggested as a potential alternative to blood glucose monitoring for diabetic patients. While previous work has reported that there is a correlation between blood and tear glucose levels in humans,¹⁻³ this link has not been thoroughly established and additional clinical studies are needed. We previously reported that Roche's electrochemical Accu-Chek glucose test strips exhibit far superior analytical performance over other commercial brands with the low detection limit and high selectivity required for quantitating tear glucose.⁴ Herein, we evaluate the origin of the high sensitivity and selectivity of the Roche test strips and show that the use of pyrroloquinoline quinone (PQQ)-dependent glucose dehydrogenase (GDH) as an active enzyme reagent is responsible for the low limit of quantification (ca. 9 μ M). Further, it will be shown that the combination of a gold working electrode and a nitrosoaniline derivative as an electron transfer mediator is responsible for the high selectivity over ascorbic acid, uric acid and acetaminophen observed when using these test strips. The excellent analytical performance of these strips enables them to be applied for measurement of glucose levels in basal or reflux tears of both normal and diabetic human subjects to further understand the clinical utility of the glucometer test-strip method.

Abstract Title **Paper Electrochemical Device for Detection of Antibodies in Whole Blood by Target-Induced Dynamic Switching**

Primary Author Josephine C. Cunningham
University of Texas

Date: Thursday, March 12, 2015 - Morning

Time: 09:10 AM

Room: 253

Co-Author(s) Richard M. Crooks

Abstract Text

In this talk we report on a paper sensor for antibody detection in whole blood. The sensor uses the principle of target-induced dynamic switching to activate electrochemical detection. We have previously demonstrated the effectiveness of this type of paper esensor (Scheme 1) for detection of DNA and thrombin down to 30 nM and 16 nM, respectively, with device-to-device reproducibility below $\pm 10\%$ and a shelf life of at least 4 weeks [1].

As shown in Scheme 2, the new antibody esensor comprises electrode-bound oligonucleotide duplexes that have a pendant redox reporter (in this case methylene blue) and a relevant recognition element (in this case digoxigenin or dig for short) on the distal ends. In the absence of anti-dig antibody binding, the flexibility of the scaffold yields efficient electron transfer. When the antibody binds, there is a decrease in collision dynamics and therefore faradaic current, which is easily detected using alternating current voltammetry (ACV).

The data in Figure 1 shows that the initial peak current of 0.33 μA decreases by 30% after addition of 30 nM anti-dig antibody. By integrating a blood separation membrane [2] with our current esensor platform we can filter out interferences from whole blood and detect a specific antibody within a single finger prick ($\sim 15 \mu\text{L}$).

To summarize, we have reported a paper-based esensor for detection of proteins, DNA, and antibodies that is based on the principle of target-induced conformational or dynamic switching. This is a remarkably simple and robust approach to biosensing, and consequently it is especially well-suited to the equally simple and robust characteristics of the type of paper-based device described here. Moreover, the esensor is readily adaptable to other types of redox beacons, and hence it seems likely that it could be used as a commercial point-of-care sensor for a variety of targets.

Abstract Text

Prostate cancer is a leading cause of death among men in the United States and throughout the world. Current prostate cancer detection and staging strategies often fall short in terms of specificity, and ability to clearly identify aggressive forms of the cancer. This often results in unnecessary treatments that can adversely affect the patient's quality of life and increases healthcare costs. Assaying panels of biomarkers that are specifically involved in the pathobiology of prostate cancer holds enormous potential for not only diagnosis but also may give information regarding both the grade as well as the spread of the disease. Described here is a semi-automated microfluidic system for the on-line capture and detection of a panel of four biomarker proteins (CD-14, ERG, IGFBP-3 and GOLM-1) that have been reported to be involved in pathobiological model of prostate cancer. These protein analytes are captured from serum samples in an online microfluidic chamber by heavily enzyme- and antibody-labeled magnetic beads. Captured analytes are then magnetically separated, washed and introduced into a detection chamber housing an array of 8 nanostructured, antibody-labeled electrodes. Using this strategy, extremely low detection limits (fg mL^{-1}) have been achieved for each of these protein biomarkers. In order to accomplish multiplexed detection of these biomarkers in clinically relevant ranges, we tailored the dynamic range by controlling assay times. The measurement of these small panels of selective biomarkers holds remarkable promise for future cancer diagnostics and personalized cancer therapies.

Abstract Text

The biofilm architecture of [*Pseudomonas aeruginosa*] has been widely studied because it represents a major problem in oil, gas, and shipping industries, as well as in sewer lines, polluted coastal waters, and medical devices. Recent evidence from Dr. Sauer's laboratory proved that during biofilm formation, pyruvate was released by resident bacteria.

Additionally, the self-fermented pyruvate support further biofilm growth. Conversely, the depletion of pyruvate significantly impaired biofilm growth. Similar results were found in [*Escherichia coli*] (Gram-negative bacterium) and [*Staphylococcus aureus*] (Gram-positive bacterium). This evidence suggested that self-produced pyruvate, which could be detected in supernatants, is a fundamental indicator of biofilm colonization and development. In this work, novel biosensor for pyruvate was constructed using Pyruvate dehydrogenase (PDH) entrapped within conducting polypyrrole membrane, which was electrochemically-deposited onto microelectrode arrays with polyethylene terephthalate (PET) platform. PET substrate allows this sensor to be easily applied onto wound detection. The immobilized PDH catalyzed the conversion of pyruvate into acetyl CoA and NADH. This reaction was monitored electrochemically via a mediator. Preliminary results showed the linear range was between 1 mM to 2.5 mM with $R^2=0.9932$.

Abstract Text

All cells in the body continually exchange various ions with the external fluid (e.g., cellular fluid, blood, sweat and blood) surrounding them. This external fluid exchanges ions such as calcium, sodium and potassium with the blood being pumped throughout the body. Hence, the chemical composition of the external fluid is extremely important for the cell.

Ion concentrations in the external fluid are commonly measured by use of benchtop analyzer system for determining consumption and production of metabolites. However, this method are not appropriate for on-site measurement and monitoring because this system is too large to carry out, so it is difficult to easily and quickly measurement of changing chemical composition of the external fluid.

In this presentation, we propose new measurements by use of flat ion selective electrodes. By use of these instruments, we can easily and quickly measure ion concentrations of the external fluid.

Abstract Text

Solution and surface conjugation, or coupling, between substances with carboxylic and amino-functional groups, is very important in areas of e.g., bioconjugate, biosensing, and biosynthesis. We report herein the systematic electrochemical studies of the surface coupling under various experimental conditions. A monolayer of 1,7-diaminoheptane (diamine) or 4-aminobenzonic acid (4-ABA) was first electrochemically oxidized and deposited on the surface of a glassy carbon electrode, which subsequently reacted with an electroactive compound, ferrocene acetic acid or aminoferrocene, respectively, to form the surface-confined peptide bond under various buffers in the presence of the crosslinking agent 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDAC). The coupling efficiency, which was proportional to the amount of ferrocene moiety (Fc) covalently attached to the diamine or 4-ABA, was finally evaluated with cyclic voltammetry (CV), where the CV current of Fc directly corresponded to the number of peptide bond formed on the electrode surface. Effects of pH value of the reaction media, buffer composition, EDAC concentration, reaction time, and concentration of Fc on peptide bond formation will be discussed.

Financial support from the NSF CAREER Award (CHE-0955878) and the Eagle SPUR grant from the University of Southern Mississippi (JG) is gratefully acknowledged.

Abstract Text

The integration of biological building-blocks with synthetic nanomaterials may permit unprecedented ability to detect, disinfect and completely remove pathogens in water. We described the synthesis of biodegradable, interpenetrating polymeric networks of poly (amic) acid (PAA), glutaraldehyde-derivatized PAA (PAA-GA) and chitosan-modified poly (amic) acid (PAA-CS) using phase-inversion procedures. The characterization data from NMR, FT-IR, SEM and cyclic voltammetry confirmed the successful formation of electroactive, bifunctional, glutaraldehyde-linked PAA membranes. Toxicological, electrochemical and mechanical characterization data showed the successful formation of non-toxic, biodegradable, porous, free-standing and mechanically nanostructured membranes. PAA-GA showed the highest modulus of 568.1 Mpa followed by PAA-CS-GA (495.0 Mpa). The optimized membranes were tested against three of the most common drinking water contaminants, namely Escherichia coli, Citrobacter freundii and Staphylococcus epidermidis with 100% removal achieved using dead end filtration and tangential flow filtration.

Abstract Text

Phenols are classified priority pollutants and endocrine disrupters. Initial study of water systems in Cape Town indicated their presence in potable waters and in some fresh- and wastewaters. Their presence in potable waters indicated current problems in the city's water treatment processes in removing these compounds because of their recalcitrant nature. Advanced oxidation processes (AOP) using O_3 / H_2O_2 has been a possible chemical remediation route and in this work the focus was on the use of AOP enhanced by the use of iron nanorods ($\gamma\text{-FeOOH}$ nanorods). We report the catalytic properties of hydrothermally synthesised ultra-small $\gamma\text{-FeOOH}$ nanorods in the ozonation degradation of 4-Chlorophenol (4-CP). XRD, TEM, EDS, SAED, FTIR and BET were used to characterize the prepared material. Interaction between O_3 – $\gamma\text{-FeOOH}$ was evident from the FTIR results and was attributed to the high surface Lewis-acid sites of the ultra-small $\gamma\text{-FeOOH}$ nanorods. The catalytic properties of the material during ozonation were found to be pronounced at lower initial pH of 3.5. Two stage first order kinetics was applied to describe the kinetic behaviour of the nanorods at low pH. We also report the catalytic oxidation of 4-chlorophenol. The first stage of catalytic ozonation was attributed to the heterogeneous surface breakdown of O_3 by $\gamma\text{-FeOOH}$, while the second stage was attributed to homogeneous catalysis initiated by reductive dissolution of $\gamma\text{-FeOOH}$ at low pH. The process was found efficient for the remediation of 4-chlorophenol in water systems.

Abstract Text

Osorb media, an organically-modified silica adsorbent that is applied to water treatment applications, is also capable of regeneration with little loss of efficiency. One use of the media is for organic removal from oil and gas produced water streams as a final polishing step before discharge or reinjection into formations. The media is capable of reducing oil in water levels to below environmental regulations. If regenerated, the media is more cost effective than existing technology. Various regeneration methods are required depending on the type of organics the media has captured. This research focuses on the testing of Osorb media that has captured organics from produced water streams and then been regenerated, for its sustained efficiency at oil removal and its capacity for dissolved organics such as benzene, toluene, ethyl benzene, and xylenes (BTEX). Efficiency was evaluated by determining the percentage of oil removed by the regenerated media from an aqueous solution. Oil concentration was established using solvent extraction followed by infrared spectroscopy analysis. Capacity was assessed by flowing a saturated BTEX solution through fixed bed of regenerated media over a period of time. The BTEX concentration was calculated using solvent extraction followed by analysis on the gas chromatographer mass spectrometer. The capacity and efficiency of regenerated Osorb media was compared to new media to determine if regeneration was successful. We are presenting two methods that were able to return up to 90-95% of the efficiency and 50-95% of the capacity after media regeneration.

Abstract Text

High concentration of ammonia can complicate the chlorine-disinfection process. When adding sufficient chlorine to achieve breakpoint chlorination for ammonia removing, high levels of DBPs (THMs and HAAs) will be produced. In addition, if N-nitrosamine precursors present and react with monochloramine (MCA) and/or free chlorine, highly toxic N-nitrosamines, mainly NDMA, will be formed. The objective of this study is simultaneous removal of N-nitrosamine precursors and ammonia by using zeolite. Six-gang stirrers were utilized to simulate the water treatment process of water treatment facilities. Zeolite was added at the rapid mixing step and then proceeded through flocculation and sedimentation. The effects of lime softening, sweep flocculation, pH, zeolite dosage, and contact time on the removal of ammonia and N-nitrosamine precursors by zeolite were all evaluated. In addition, the removal efficiencies of ammonia and N-nitrosamine precursors by zeolite with and without the presence of monochloramine and /or free chlorine were also investigated. A UFLC-MS/MS method recently developed in our laboratory was used for quantitative measurements of N-nitrosamine precursors and HACH kit was used for free ammonia measurement. Results showed that the Zeolite removed N-nitrosamine precursors and ammonia effectively, and also reduced the formation of THMs and Nitrosamines. The detailed experimental conditions and the results will be presented at the conference.

This study was supported by Missouri Department of Natural Resource.

Abstract Text

Objective: To provide an overview of instrumental methods to analyze the off-flavors in aquaculture products.

Significance: Musty, muddy, off-flavors have been reported in farm-raised sturgeon, large mouth bass, tilapia, trout, salmon, barramundi, and catfish. The off-flavor metabolites 2-methylisoborneol and geosmin are produced by cyanobacteria and actinomycetes. Off-flavor occurs in open ponds, recirculation systems, and even in open bays and rivers. Some industries employ professional flavor checkers to limit the amount of off-flavor product from reaching the markets. Instrumental analysis can give a more accurate and precise result but is slower and more costly.

Experimental: Analysis of 2-MIB and geosmin in water is accomplished using GC/MS with SPME, purge and trap, or solvent extraction. An electronic nose has also been evaluated. Analysis in tissue is more problematic as the off-flavors tend to reside in the fat and are more difficult to extract. Tissue is generally homogenized with sample size ranging from 5 to 50 g. Solvent extraction and Microwave desorption/SPME of the tissue with subsequent analysis by GC/MS are the most prevalent methods for analyzing fish.

Results: Several factors influence the levels measured by these methods, including sample size, cooking time, temperature, fat content and possible compounds that affect the matrix. This talk will explore the strengths and weaknesses of the different analytical methods that are used to measure off-flavor compounds in aquaculture products.

Conclusions: This research provides qualitative information on the compounds found in the headspace of cooked fish and provides details for the quantification of 2-MIB and geosmin. These compounds can be detected by humans at concentrations as low parts per trillion ranges in water and at the sub parts per billion ranges in fish.

Abstract Text

In the study of an off-color problem with catfish fillets, the carotenoids causing the yellow-color problem needed to be isolated, identified, and quantified. The isolation of the carotenoids from the triacylglycerols, comprising the bulk of the oil extracted from the fillet, was explored by the use of solid phase extraction (SPE). Both silica and amine phase sorbents were tested. For the separation, identification, and quantification of the isolated carotenoids, high performance liquid chromatography (HPLC)-photodiode array (PDA)-mass spectrometry (MS) was used. For the chromatography, a comparison of C18, phenyl-hexyl, silica, and C30 column phases were investigated. For MS detection, electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), and atmospheric pressure photo ionization (APPI) sources were tested in both positive and negative ionization mode.

The four xanthophylls, lutein, zeaxanthin, diatoxanthin, and alloxanthin, in addition to two tentatively identified cis-isomers, 9'-cis lutein and 9-cis zeaxanthin were best separated and identified by LC-MS using silica chromatography and APPI positive and negative mode or APCI negative mode ionization. The C30 column also separated the four xanthophylls to a lesser degree, but no separation occurred with C18 or phenyl-hexyl columns. Protonated molecular ions [MH]⁺ were observed from the C30 column with ESI, but only non-protonated molecular ions [M]⁺ occurred with silica chromatography. Also noted was the unusual identical elution order from the normal (silica) and reversed-phase (C30) columns. The results show silica-APPI-MS as a possible improvement to the normal C30-ESI-MS method used for carotenoid identification.

Abstract Text

Rice bran contains several bioactive components that have been linked to the promotion of human health. Brown rice bran contains lipophilic components that include the tocotrienols and γ -oryzanol. Pigmented or colored rice bran contains different phenolic compounds including several anthocyanins in purple (black) rice. Some of these bioactive compounds individually have been shown to promote glucose uptake and aid in glucose homeostasis in animal studies. However, only recently has rice bran been examined for its potential to aid in glucose management. The objectives of this study were to: evaluate glucose uptake using 3T3-L1 cells and determine the anthocyanin composition of purple rice bran extracts.

Several commercially available rice varieties were chosen for this study. The brown rice bran variety Cocodrie was used in the glucose uptake assay for comparison. The purple rice used in this study were Blanca Isabel (Rush Rice Products), Forbidden (Lotus Foods) and Black Japonica (Lundberg Farms). Rice bran will be milled directly before use. Bran samples for glucose uptake will be extracted with 70% ethanol, dried, and reconstituted in DMSO (100 mg/mL). Rice bran extracts were applied to mature 3T3-L1 adipocytes 18h before glucose uptake determination using [3H]-2-deoxy-D-glucose. For quantitation of anthocyanidins, bran samples will be hydrolyzed with hydrochloric acid and quantitated by UPLC using available standards. LC-MS using an APCI source will be used to identify anthocyanin composition.

Abstract Text

The incidence of peanut allergy continues to rise in the US and Europe. Whereas exposure to the major allergens Ara h 1, 2, 3, and 6 can cause fatal anaphylaxis, exposure to the minor allergens usually does not. Ara h 8 is a minor allergen. Importantly, it is the minor food allergens that are thought to be responsible for Oral Allergy Syndrome (OAS) in which sensitization to airborne allergens causes a Type 2 allergic reaction to ingested foods. Furthermore, it is believed that similar protein structure, rather than a similar linear sequence is the cause of OAS. Bet v 1 from birch pollen is a common sensitizing agent and OAS results when patients consume certain fruits, vegetables, tree nuts and peanuts. Here, we report the 3-dimensional structure of Ara h 8, a Bet v 1 homolog. The overall fold is very similar to that of Bet v 1, Api g 1 (celery), Gly m 4 (soy) and Pru av 1 (cherry). Ara h 8 binds the isoflavones quercetin and apigenin, as well as resveratrol avidly. Using micro-chip technology we have mapped the important linear epitopes for IgE binding.

Abstract Text

Foods produced in large scale frying operations are heavily impacted by the condition of the frying oil. Color, texture and flavor of fried foods are greatly influenced by the condition of the frying oil, and the oil itself represents a significant portion of the production cost of the fried food. Decisions on whether to replace the oil, add new oil or continue using the oil currently in the frying system impact sensory characteristics of the final product, and can have a significant impact on profitability. Laboratory methods employed to assess quality factors in frying oils include determination of Free Fatty Acids (FFA), p-Anisidine Value, Total Polar Compounds and Polymerized Triglycerides. Each of these tests are performed as individual tests and employ reagents that require proper disposal, training of laboratory personnel, and labor to perform each of the tests.

In this paper we will present the use of FT-NIR to determine of quality factors in frying oils. FT-NIR calibrations for FFA, IV, p-Anisidine Value, Total Polar Compounds, and Polymerized Triglycerides are shown provide accuracy comparable to the standard error of the laboratory methods. Additional benefits of the FT-NIR method include the ability to perform all measurements using a single sample in less than 2 minutes, having a measurement precision significantly better than the repeatability of the individual laboratory methods, and require no chemicals or disposal fees. Accuracy, precision and speed of the FT-NIR method make it an ideal choice to monitor the condition of frying oils and enable plant personnel to make informed decisions to maintain cost controls and sensory qualities for the products they produce.

Abstract Text

In recent decades, the vitamin supplement product market has grown to a multi-billion dollar business. As the market grows rapidly, various types of vitamin supplements have been introduced to the market. Due to the increasing diversity of product matrices as well as its complexity of formulations of active components, preservation of those active components against any chemical reactions such as oxidation and interactions among active components has become more challenging than ever.

Liquid Chromatography Quadruple Time-of-Flight Mass Spectrometry was used as a forensic tool to investigate the cause of potency loss through profiling of degradation products under various conditions such as heat, oxidation, acid, base, and interaction with other components. LC-QTOF-MS was used to separately identify and profile Cyanocobalamin (B12) and Cholecalciferol (D3) degradation products. Based on published literatures, known degradation products of the vitamins were identified by matching molecular ions and sodium adduct ions. Also, unknown degradation products with accurate mass ions plus retention times on a chromatography system were successfully classified as a fingerprint against stress conditions with a good reproducibility. Finally, the practicality of the degradation product profiles by LC-QTOF-MS was successfully demonstrated for experimental formulations containing Cyanocobalamin and Cholecalciferol through identification of the cause of potency loss.

Abstract Text

Quality by Design (QbD) has been well established in the pharmaceutical industry for manufacturing processes [ICH Q8(R2)]. It is defined as a systematic approach to process development that begins with predefined objectives and emphasizes product and process understanding as well as process control, based on sound science and risk management. The QbD concept for process development can also be applied to the development of analytical methods in the laboratory. A major advantage of applying the QbD concept to analytical method development is enhanced robustness of the resulting method that meets all critical performance requirements during the method development.

The QbD concept was used to determine the relationship among various critical factors (UPLC column type, pH, hydrophobicity, gradient time) against the chromatographic resolution of water soluble vitamins in dietary supplement softgels and tablets during the long-term stability studies. Four different types of UPLC columns were evaluated at three different pH conditions (pH 2.0, 4.0, and 6.0), using acetonitrile as the organic solvent. Based on information obtained from the screening runs the effects of the major factors affecting chromatographic peak resolution were determined, and the operating space was established.

Abstract Text

Nutritional supplements can be effectively used to improve the nutrient status of many individuals. Robust and accurate analyses of vitamins for dietary supplements are required, particularly when working with micro-vitamins (Folic acid, Biotin and Vitamin B12) in multi-vitamin matrices. Because of the inherent complex nature of multi-vitamin matrices, and the added complexity due to the presence of flavors, using conventional HPLC-UV methods with an ion-paired column, the analyses of these compounds become more challenging than ever. The objective of this study was to develop a robust LC-MS method using LC-QTOF and QDa for the quantitation of Folic acid, Biotin and Vitamin B12 in dietary supplements using isotopic internal standard spiking.

LC-QTOF method in combination with a constant level isotope spiking was developed as a reference method for the accurate determination of micro vitamins. Each injection (standard and sample) was spiked with the respective isotope standard to determine the dynamic linear range and to compensate for ion suppression and/or enhancement. The injector program was used to spike samples with isotopic internal standard. The linearity, accuracy, precision and reproducibility of the method was evaluated.

This presentation covers the results obtained from the LC-QTOF using isotopic internal standard for Folic acid, Biotin and B12 and the results show how the LC-QTOF method can be adapted for routine analysis.

Abstract Text

There are many volatile compounds in wine that help define the complex sensory effects of wine. These compounds contribute to aroma character of wines such as fruity, vegetal, butterscotch, leathery etc. We analyzed several of these aroma compounds using a GC-quadrupole time of flight (q-TOF) mass spectrometer with a headspace autosampler. Target analytes were selected in the mass discriminating quadrupole of the qTOF, fragmented in the collision cell, and the spectral fingerprint generated was analyzed by the TOF end of the mass spectrometer. The MS/MS data generated for the target analytes was used to confirm the presence of these analytes. The GC-qTOF is a powerful technology to obtain high selectivity for identification of target analytes with full spectral information without losing sensitivity.

Abstract Text

The effect of different doses of *Baccaurea angulata* (BA) whole fruit juice (0, 0.5, 1.0, and 1.5 mL of juice per kg adult rabbits per day) given to high-cholesterol fed rabbits for 90 days was studied. The work was carried out to detect an accumulation of fatty streak, evaluate the percentage of atherosclerotic lesion accrued and intima-media thickness in the aorta of normo- and hypercholesterolemic rabbits. The result showed that the supplementation of high-cholesterol diet of hypercholesterolemic rabbits with only 0.5 mL BA /kg rabbit per day significantly ($p < 0.001$) attenuated aortic fatty streak development. The treatment with BA fruit juice also significantly ($p < 0.001$) reduced the atherosclerotic lesion compared to the negative control group, NgC ($94.37 \pm 1.09\%$). The various doses of BA at low, medium and high levels (LD, MD and HD) gave percentage reduction in the atherosclerotic lesion of 53.85 ± 1.48 , 28.13 ± 1.13 and $11.39 \pm 1.13\%$ respectively. There was significant ($p < 0.001$) less thickening of tunica intima to tunica media ratio in the low dose, medium dose and high dose groups (1.60 ± 0.10 , 0.25 ± 0.05 and 0.10 ± 0.06 respectively) compared to NgC (2.37 ± 0.06). Higher BA doses used (1.0 and 1.5 mL/kg rabbit per day) also significantly decreased further the development of aortic fatty streaks. Therefore, *Baccaurea angulata* possesses antiatherosclerotic potential benefit.

Abstract Text

Oxidation in hydrocarbons often begins with an external stress. This stress can be associated with mechanical fatigue, ultraviolet radiation, or heat. This results in the formation of a free radical which is susceptible to oxygen insertion and results in the formation of a carboxylic acid. Thermal Analysis in conjunction with Infrared Spectroscopy provides a unique vantage point to study the formation and propagation of oxidation by tracking changes in functional groups, heat flow, and weight loss. In this study, a series of edible oils will be characterized by their oxidative and thermal stability under inert and oxidizing atmospheres through Differential Scanning Calorimetry (DSC) and Thermogravimetric Analysis (TGA). Olive, coconut, canola, peanut, vegetable, sesame, grape seed, and corn oil will be the targets of this experimentation. A select few of the oils will also be subjected to pre and post oxidation testing by Fourier Transform Infrared Spectroscopy (FTIR), as well as the hyphenated technique of TGA-FTIR. Oxidative onset temperature by DSC (ASTM E 2009) will be one of the techniques utilized in the study. It will be shown that while some oils (coconut) have a significantly higher oxidative stability their overall thermal stability is considerably less than expected, especially in the presence of an oxygen-rich atmosphere. Principle Component Analysis (PCA) of the TGA-FTIR data will also be demonstrated as a tool to track decomposition within a material.

Abstract Text

Comprehensive two-dimensional gas chromatography (GCxGC) is recognized as the most powerful tool for the separation of complex mixtures of volatile and semi-volatile compounds. However, less than ideal chromatography is often produced when one utilizes GCxGC for the analysis of highly concentrated or active analytes. GCxGC chromatograms of such samples typically contain broad, tailing analyte bands. This results in difficulties with quantitation and poor utilization of the separation space. To investigate the source of these tailing bands, we studied the inlet and modulator as potential contributors. A simple inlet flushing device was developed to isolate the injector from the primary column after the injection, and a similar setup was used to isolate the modulator from the primary column. This device allows the user to divert carrier gas flow back through the injection port at a specified time after the injection, while allowing analytes to pass through the column for separation. Analytes retained within the injection port are prevented from entering the column, and are subsequently removed via the carrier gas split line. The study revealed that the injection port plays a critical role in the development of tailing chromatographic bands, while the modulator simply modulates the already tailing band. Using the device, GCxGC chromatography in several applications was improved. The design of the device, its performance and applications will be discussed.

Abstract Text

Previous research in our group has demonstrated the power of thermodynamic-based predictions of GC retention times, in both GC and GCxGC modes. Retention time accuracies are generally better than 0.5-1 s in 30-40 min in GC mode and within a few 10s of ms for the second dimension in GCxGC mode. More recently, we demonstrated a method whereby the thermodynamic parameters for a given molecule on a particular stationary phase could be extracted from a suite of 5 temperature-programmed GC separations. This permits the acquisition of thermodynamic data to be accelerated to upwards of 500 molecules per week.

With these successes, one key factor of the separation prediction is missing: peak widths. Herein, we present improvements to our predictive model that permit the width of GC (or GCxGC) peaks to be predicted. This is a crucial step in the development of optimization software which requires a prediction of chromatographic resolution for a pair of peaks. This is even more important in developing GCxGC methods as insight into the peak widths of analytes is required, not only to evaluate the resolution between peaks, but also in order to automatically optimize the modulation ratio and modulation period for the separation.

Abstract Text

The impetus for the measurement of low levels of sulfur compounds has come from the hydrocarbon process industry, where the requirement for lower sulfur measurements is steadily increasing. Common sulfur impurities in the feedstock, such as H₂S (hydrogen sulfide) must be carefully monitored. To monitor, control, and regulate compound, calibration gas mixtures must be used. For H₂S standard gas to be utilized successfully, it must be reliable with respect to stability (shelf life) of concentration. Significant challenges arise as the stability of the concentration of the reactive gas mixtures must remain constant, even as the cylinder pressure is diminished. Interaction on the cylinder surface, chemical reaction and adsorption, are often insignificant, with reactive gas concentrations in the range of 10ppm and above. These interactions become quite important with reactive gases at concentrations at or below 1ppm. Typically as the cylinder pressure decreases to as low as 3MPa, the H₂S concentration tends to change. Since accurate and reliable calibration mixtures are important for process evaluations as well as regulatory monitoring, an experimental study was designed to assess the effect of cylinder pressure on the stability of the H₂S concentration. Various low concentration H₂S mixtures (1,5,10ppm) in balanced with nitrogen were filled in specially treated cylinders and each concentration was monitored as a function of pressure from 8MPa down to 1MPa. H₂S was analyzed with GC equipped with a sulfur chemiluminescence detector. A Japanese accredited SO₂ mixture was used to quantify H₂S concentration indirectly.

This presentation will illustrate the necessity of suitably treated cylinder surfaces to achieve uniform concentrations throughout the cylinder depletion.

Abstract Text

Gas chromatography-mass spectrometry (GC-MS) is probably the most widespread tandem technique in the analytical laboratory today and deployed into nearly every industry. While MS provides a fast, sensitive and qualitative detection system for GC, it suffers from many disadvantages. These include varying detector responsivities requiring constant calibration, non-linear calibrations (poor dynamic range), difficulty in measurement during injection peak, solvent elution or elution of high concentration analytes, and an inability to differentiate many isomers. It also requires high vacuum, significant maintenance, He or H₂ carrier gases and significant compound separation (to prevent interference or chemical ionization).

If a detection system for GC could provide similar levels of sensitivity with greater qualitative capabilities and much greater dynamic range while removing all the aforementioned issues it is possible it could meet the need and improve the productivity of scientists and engineers in many industries currently served by GC-MS.

We will demonstrate a new spectroscopic detection system (MAX™) for GC that can measure from parts-per-trillion to % and provide full qualification and quantification of more than 1,000 compounds during a single analysis. The MAX™ technology can be setup in a laboratory in less than a day, requires no high vacuum or expensive He or flammable H₂ to operate and is not damaged if too much sample or analyte were to reach the detector. This detection system will be ideal for laboratories or businesses where productivity is improved by eliminating needless calibration or where known or unknown samples can wreak havoc with large concentration swings potentially affecting results or the operation of the analyzer.

Abstract Text

Your lab contains several carrier gas lines, pneumatic gases, cooling gases, and flammable gases. Discussed are recent advances in installation technics that now allows fewer components to be used in the lines and does away with the need to purge the lines with each cylinder change. These new devices allow you to maintain the purity of the gas delivered to your site all the way to your columns. This will mean longer column life and fewer very expensive column change outs. They also make the handling of high-pressure gases safer and less strenuous to accomplish.

Abstract Text

Recycle Chromatography is a method that allows samples to pass two columns alternately many times to achieve a system with millions of theoretical plates. The separation power is high enough to facilitate separation of isotopically different compounds and isomers, which is difficult in conventional GC. However, since all the compounds of the sample must be kept in one column to avoid peak loss as the columns are switched, there is a small time window, or peak capacity. This is particularly problematic for peaks with a large R value; peak width increases very quickly within the cycle, causing a dramatic drop in peak capacity for a fixed time window. To address this situation, one of the columns has been equipped with resistive heating and a negative thermal gradient program (TGP). The TGP is capable of re-focusing the sample (that is, making a wide sample band narrower), maximizing peak capacity throughout the cycle.

Abstract Text

Method development in gas chromatography has traditionally been carried out through controlled experimentation directed by chromatographic theory and the intuition of the experimenter. There are many parameters to be optimized in a modern capillary GC system including the choice of carrier gas, column stationary phase, column dimension, and temperature program to name a few. Each of these parameters can have a dramatic effect on chromatographic run time and resolution, also, they are often interdependent forcing a chromatographer to make tradeoffs in method performance.

Computer assistance can be a powerful tool in streamlining the method development process saving time, expense, and lowering the number of optimization experiments needed. A computer program will be discussed that can produce accurate model chromatograms under a wide range of instrumental conditions, column dimensions, and across different chemical classes of analyte. The program can be used to obtain a good starting point for developing a new method or to optimize an existing one.

In essence a user is able to analyze the effect that changing method parameters will have on a separation without running an actual GC experiment. It will be demonstrated that the model's output corresponds well with reality, giving the user confidence that the predictions are reliable.

Abstract Text

Continuous measurement of hydrocarbon gas concentration is crucial to mud loggers at the drilling site. Hydrocarbon measurement information provides operators with valuable geological formation insight during vertical, intermediate, lateral, and hydraulic fracturing drilling processes. As a result of technological advancement in gas detection, sample composition can now be measured within minutes leading to nearly real-time analysis. Gas chromatography (GC) is a well established technique used to analyze extracted gas to provide accurate, on-site gas composition information. The INFICON Micro GC Fusion is the latest innovation that utilizes temperature programmable columns and micro-machined components to analyze C1-C8 compounds in less than two minutes or C1-C5 compounds in less than 30 seconds on a 24x7 basis. This expanded compound range and speed allow for more data to be acquired compared to traditional GC equipment. The instrument's transportable and compact architecture makes it ideal at drilling sites where space is limited.

Abstract Text

A new generation of Core-Shell materials were introduced in 2007 that were specifically engineered for the separation of small molecules. These materials saw the average column performance increase 30-50% over fully porous particles of similar size. Subsequent releases of these materials have made them available in particle sizes ranging from 5 μm to 1.3 μm giving average column performances between 180,000 – 450,000 plates/m. Maybe even more so than their fully porous counterparts, core-shell particles 3.6 μm and below require significantly increased linear velocities to obtain maximum resolution. While a benefit of the increased linear velocities is much faster separations, there can be drawbacks as well. A simple way to reduce flow rate is to decrease column size. The flow rate will be proportional to the column cross sectional area. The drawback, however, to decreasing column i.d., is that peak volumes also decrease. This leads to more loss of efficiency due to system dead volume contributions to peak dispersion. In this presentation we will investigate the benefits of reducing core-shell column i.d. to 1.0 mm, and contrast these benefits with the available (U)HPLC systems and their dispersion effects on column performance in this dimension.

Abstract Text

This work reports a comparison of HPLC separations of enantiomers with chiral stationary phases (CSPs) prepared by chemically bonding brush type chiral selectors on fully and superficially porous particles (SPPs). The chromatographic performance of superficially porous CSP based columns is compared with columns packed with 5 μm and 3 μm fully porous particles (FPPs). Only one earlier example of a chiral phase being produced using SPPs and it showed that the particle properties rendered the SPPs not useful for the preparation of coated polymeric chiral selectors, resulting no improvements in resolution. However, theoretical treatments indicate that SPP based CSPs may show increases in resolution. Herein, true gains in efficiency and resolution are obtained using SPP CSPs. For example, when using a cyclofructan based CSP, at a flow rate of 3.0 ml/min, the number of plates on column afforded by the SPP column was $\sim 7\times$ greater than the number of plates on column (same length) obtained when using the 5 μm FPP based column. It was found that the selectivity and resolution of the separations were comparable between fully porous and superficially porous based columns (under constant mobile phase conditions), even though the SPP column contained lower absolute amounts of chiral selector. When tested under constant retention conditions, the SPP based CSP greatly improved resolution compared to the FPP based columns. At high flow rates the efficiency gained by using superficially porous CSP was accentuated. The advantages of columns based on SPPs become more obvious from the viewpoint of plate numbers and resolution per analysis time.

Abstract Text

Hydrophilic interaction liquid chromatography (HILIC) is an increasingly popular mode of liquid chromatography. HILIC uses polar stationary phases in conjunction with reversed-phase type eluents (commonly acetonitrile and water) to separate mixtures of highly polar compounds (e.g. pharmaceuticals and metabolites) [1]. HILIC retention arises mainly from partitioning of the analytes into a water layer that forms on the surface of the stationary phase [2]. Additional interactions such as ion exchange contribute to differences in selectivity [3]. In previous work, Ibrahim et al. [4] utilized a sub-set of Dinh et al.'s [3] HILIC classification probe data to create a simple graphical means to classify the selectivity of different HILIC phases based on the hydrophilicity and ion exchange properties of the phases. This work, however, was only performed under a single mobile phase condition.

In this work the effect of different mobile phase conditions (pH and buffer concentration) on the HILIC selectivity plot was investigated. Separations of cytosine, uracil, and benzyltrimethylammonium (BTMA) were performed on several classes of HILIC columns (e.g. bare silica, amine, amide, zwitterionic) at three different pH values (3, 5, 6.8) and two different buffer concentrations (5 and 25 mM). Preliminary studies demonstrate that increased buffer concentration masks ion exchange interactions in all HILIC columns. Moreover, an increase in pH increases the cation exchange character of the column. Further investigations of these trends with additional classes of HILIC columns are currently ongoing.

Abstract Text

It has been demonstrated that liquid water is forced out of the nanopores of hydrophobic packing materials when the pressure on the reversed-phase liquid chromatography (RPLC) columns filled with water is released. This phenomenon is a natural consequence of the existence of capillary pressure in the pores of hydrophobic materials unwetted with water and the remaining pore space is occupied by a gas phase. The fact that this phenomenon causes rather drastic retention losses for many compounds indicates that, in aqueous systems, it is the interface between the bonded layer and water that has a key role in retention.

The incorporation of a gas phase into the pores of hydrophobic materials in contact with an aqueous solution reduces the area of the water/hydrophobic interface or the volume of the interfacial water. Since the volume of the gas phase in the pores can be changed by the applied pressure, the area of the water/hydrophobic interface can also be controlled by the pressure. On the other hand, the amount of the hydrophobic moiety remains constant independent of the volume of the gas phase. This means that we are able to make a hybrid stationary phase consisting of the interfacial water, hydrophobic moieties, and gas phase, and change the structure of the stationary phase by the applied pressure. Therefore it is expected that the tunable hybrid RPLC system enables us to manipulate the separation selectivity. The fixed nanoscale gas phases may also function as the stationary phase for volatile compounds.

In the present study, we present a new type of liquid chromatography, surface bubble modulated liquid chromatography (SBMLC), that uses the stationary phase incorporated with surface nanobubbles. We will demonstrate that SBMLC is a very useful separation method that enables a sophisticated separation by manipulating separation selectivity through the pressure applied to the column.

Abstract Text

Previously in our lab, lyotropic liquid crystalline gel phases of binary mixtures of guanosinemonophosphate (GMP) with other nucleosides and nucleotides have been studied, with particular focus on mixtures of GMP with guanosine. The gels are a tunable, stable and biocompatible, offering possible applications of these materials in diverse areas such as biomedicine, pharmaceuticals, "green" architecture, and nanotechnology. From a more fundamental standpoint, the formation and characteristics of these gels could have important implications for the RNA world hypothesis in origins of life research.

Here we describe the use of NMR to study the structures resulting from self-assembly of GMP in mixtures containing other nucleotides. Previous papers have reported peaks characteristic of the formation of hydrogen-bonded G-tetrads and alternative, continuous helical structures in the 1D 1HNMR spectra of GMP. We are investigating how the addition of a second nucleotide such as adenosine monophosphate or a nucleoside such as guanosine affects the organized GMP structure. In addition to 1D 1HNMR, we are also performing 2D experiments such as Nuclear Overhauser effect spectroscopy (NOSY) and Diffusion Ordered Spectroscopy (DOSY) in order to determine the responses of the GMP spectra to the second component in the mixtures.

Abstract Text

We will describe several sample pre-treatment approaches by sequential injection (SI) for on-line reaction monitoring by low-field nuclear magnetic resonance spectroscopy (NMR). The picoSpin™, a low-field (45-82 MHz) benchtop NMR system, was interfaced to SI for automated on-line measurements. Three SI methods were studied: (i) solid-phase extraction with a monolithic disk column, (ii) liquid-liquid extraction based upon differential flow velocities (Lucy & Yeung, Anal. Chem. 66, 2220), and (iii) membrane separation with a parallel-plate dialyzer. The results of optimization studies for each method will be presented, focusing primarily on variation of the types of stationary phases, extraction solvents, and membranes, respectively. To demonstrate the utility of the SI-NMR system, we applied the method to on-line monitoring in which a reaction vessel was sampled periodically. Specifically, we will compare the figures of merit for each of the three SI methods as applied to a study of the reaction between alpha di-carbonyl compounds and amino acids.

Abstract Text

In this study the amide proton exchange rates of oligosaccharides derived from chondroitin sulfate (CS) are determined using ¹H NMR and ESI MS. The aims of this work are to examine the effects of oligosaccharide structure on exchange rates and to compare the results obtained by the complementary methods of NMR and MS. CS belongs to the family of glycosaminoglycans (GAG) known for their complexity and heterogeneity, hence pure samples suitable for amide proton exchange studies are not commercially available and must be isolated in-house. Isolation of CS oligosaccharides involves the enzymatic depolymerization of the intact polysaccharide, separation by size-exclusion chromatography (SEC) into similarly-sized fractions and preparative-scale strong anion exchange (SAX) HPLC resolution and isolation of the component CS oligosaccharides from each SEC fraction. The CS enzymatic digestion was monitored by ¹H NMR to obtain desired degree of depolymerization. Individual CS oligosaccharides isolated from the SAX separation were desalted and their structures elucidated by 2D NMR experiments and MS measurements. ¹H NMR has been previously used to determine NH exchange rates for several GAGs and has even revealed the presence of a stable solution-state intermolecular hydrogen bond in the synthetic heparin drug fondaparinux (Arixtra). Though mass spectrometry has been primarily used to measure NH exchange rates in proteins, it should be possible to extend these studies to study the amide protons of CS and other GAGs. The results of both methods will be compared and contrasted to highlight the relative advantages of each technique in terms of the sample quantity required, experiment time, range of exchange rates that can be addressed and the robustness of the measurements.

Abstract Title **Multinuclear (¹H, ¹³C, ³¹P) and Multidimensional (1D and 2D) NMR (Nuclear Magnetic Resonance) Spectroscopy on Composition and Chain Microstructure of Copolymers**

Primary Author Guangxin Lin
SABIC Innovative Plastics

Date: Thursday, March 12, 2015 - Morning

Time: 10:05 AM

Room: 271

Co-Author(s)

Abstract Text

The chain architecture can play an important role in determining a copolymer's physical and chemical properties. The characterization and quantification of chain microstructures (such as, monomer composition, sequence distribution, and end groups) is essential for the understanding and investigation the relationship between the structures and properties of copolymers.

NMR is a powerful technology for both the qualitative and quantitative characterization of these copolymer materials. 1D ¹H and ¹³C NMR spectra acquired with long relaxation delay times ($d_1 \geq 5 \sim 7T_1$) can be used for the quantitative analysis of comonomer compositions and sequence distributions. ³¹P NMR and phosphorus derivatization are useful for quantitative determination of the functional groups such as hydroxyl and carboxylic acid end groups. 2D NMR (homonuclear and heteronuclear correlation spectroscopy) is used for the resonance assignments and structure elucidation.

¹³C NMR spectroscopy is a very sensitive method useful in determining the chain microstructure of bisphenol-A based copolymers. It can, for instance, distinguish sequence compositions and their distributions up to many bonds away for bisphenol-A based co-polycarbonates. This method relies on the differences in the ¹³C chemical shifts of the interested carbons caused by the different sequences on their nearest neighbors in the polymer chain. This presentation will illustrate the application of this method to two commercial copolycarbonates: Bisphenol TMC (Bisphenol 3,3,5-trimethylcyclohexanone) / BPA (Bisphenol A), and PPPBP {3,3-bis(4-hydroxyphenyl)-2-phenylphthalimide}/BPA. The different diads and triads sequences can be well identified and distinguished by the resonances of carbonate carbonyls and the two quaternary carbons of the BPA.

Abstract Text

Customs and postal seizures of illicit drugs expose a wide variety of illegal and “legal or not” synthetic designer drugs, structural analogues of controlled substances. An increase in the variety of designer drugs from several classes, most notably phenethylamines and cathinones, flooding borders is partly due to ambiguities in legislation surrounding the legality of structural analogues. The result is a dizzying array of structurally similar drugs that challenges presumptive testing methodologies with low discriminating power. There is a need for time-sensitive, rapid screening methods for initial drug identification with increased structure selectivity and high discriminating power to help identify designer drugs. Proton NMR spectroscopy offers a solution to the challenge by providing structure selectivity and high discriminating power in a compact benchtop instrument. Successful rapid screening identification of synthetic drugs using benchtop NMR involves the development of a spectral library of reference compounds. Characteristic NMR signatures related to the parent structure are used to discriminate both the class of compound and derivatives within the class. A standardized approach to sample preparation and analysis must consider variability of structures and composition of case samples in order to minimize the complexity of resulting spectra. Using a benchtop NMR spectrometer, an SOP was developed to acquire spectra from a series of derivatives of amphetamine and methamphetamine, and the resulting spectral library is presented. Chemical signatures are used to discriminate between the different compound classes and to identify individual compounds.

Abstract Text

This presentation will detail an innovative transfer system that almost entirely eliminates band spreading that generally occurs as sample materials in microfluidic/lab-on-a-chip systems pass between component devices.

Most microfluidic systems are constructed in a planar format. In this two-dimensional format, larger volume component, such as sample reservoirs, reaction chambers, and sensors, generally require the use of wide, flat geometries. To minimize turbulence during the transition of fluid in and out of these components, triangularly shaped regions are often incorporated at the ends of the component. Inlet and outlet connections are made at the apices of the triangles. It is these transition zones that introduce the band spreading. As fluid medium and entrained samples enter the component from the inlet, the fluid fans out producing a crescent-shaped fluid front across the component that persists as the fluid travels the length of the device. At the other end of the component, the fluid then funnels from across the width of the component to the outlet. As a consequence, sample particles follow flow paths of varying length. A particle on a direct line between the inlet and outlet along the center of the component travels a significantly shorter distance than one that first diverges from the inlet to the component's width before converging at the outlet end. Path length variations of 20% are not uncommon.

This presentation will describe the progression of steps taken to address this path inequity problem and its ultimate solution. Although the presentation will concentrate on microfluidic systems, the work actually has applications almost anywhere incongruent connections are made to ribbon-shaped channels. The developed system is particularly applicable to high-throughput systems where material or sample bands must be closely spaced without significant dispersion during transport through the fluid handling system.

Abstract Text

Graphene nanodots are considered nascent quantum dots (QDs) as they combine several favorable attributes of traditional QDs without the disadvantages of toxicity and tedious and costly synthesis. Nitrogen doped graphene quantum dots (N-GQDs) in the 4-6 nm size range, synthesized via a hydrothermal reaction between the selected carbon and nitrogen sources, have demonstrated high and stable photoluminescence (quantum yield as high as 94%), excellent water solubility, resistance to photo-bleaching, and ease of bioconjugation. These properties make N-GQDs sensitive and cost-effective substitutes for gold nanoparticles, widely-used labels in lateral flow immunoassays (LFIA). In this work, a novel lateral flow immunoassay platform was developed by applying N-GQDs for the first time as LFIA labels to target the liver cancer biomarker- α -fetoprotein (AFP). Detection limits and reproducibility for these LFIA tests were compared to those for gold nanoparticle based AFP LFIA tests. The introduction of nascent material N-GQDs into the LFIA world could open a new era for LFIA tests. N-GQDs have great potential of offering higher sensitivity and lower cost, and to be applied to medical diagnostics, forensics, therapeutic monitoring, environmental analysis, food safety monitoring and biodefense.

Abstract Title **A Microfluidic Device to Measure Entrainment of Insulin Secretion from Islets of Langerhans**

Primary Author Lian Yi
Florida State University

Date: Thursday, March 12, 2015 - Morning

Time: 09:10 AM

Room: 272

Co-Author(s) Michael G. Roper

Abstract Text

In vivo, insulin oscillations are found with a period of ~5 min. This oscillatory insulin signature is due to synchronization of millions of islets of Langerhans. Synchronization may occur through entrainment from in vivo glucose oscillations. Although intracellular [Ca²⁺] oscillations, which have been used as mimics of insulin oscillations, have been entrained to oscillatory glucose levels, there have been few demonstrations of direct entrainment of insulin secretion. To achieve this goal, a microfluidic system was developed that was capable of measuring temporally resolved insulin secretion from islets and was coupled with a gravity driven perfusion system to test if glucose waveforms can entrain insulin oscillations.

Gravity-driven flow through flow splitting channels was used to generate and deliver complex glucose waveforms to the islet chamber. This system was able to deliver sinusoidal waveforms with a period as low as 1.15 min with minimal peak broadening. Islet chamber dimensions and perfusion flow rate were adjusted for efficient sampling from single or groups of islets. Insulin secreted from islets was electrophoretically sampled and measured every 10 s with an online competitive immunoassay. This assay showed good reproducibility of the B/F with RSDs <4% and a detection limit of 2 nM.

Results showed insulin secretion from single islets was oscillatory with ~5-min periods. Both single and groups of islets were entrained to glucose sine waveforms. In addition to examining entrainment, this system will be useful for further studies of insulin secretion mechanisms and drug testing.

Abstract Text

Separation of DNA has been central to advances in our understanding of human biology and health. Separation based on DNA fragment length alone is not enough. DNA of same length, however, often needs further analysis to determine the presence of different sequences. This can be achieved by DNA sequencing, which is becoming cheaper and faster. In some situations, however, sequencing is not practical, such as point-of-care, remote clinical settings, or rapid monitoring of changes in a pathogenic organism in response to an environmental stressor. Separation of DNA based on sequence provides a possible option. In this study, a microfluidic chip for simple, rapid, and low-cost DNA separation in two dimensions, length and sequence, was investigated. A cross channel was design and microfluidic chips were fabricated by wet etching of one piece of soda lime glass and bonded with a cover glass. Both loading and separation of samples were achieved by applying reverse voltage using a voltage supplier. The detection of signals was with the help of an inverted fluorescence video microscope. Separation of DNA in the first dimension of length was achieved using POP-4 as the matrix. For the second dimension based on sequence, separation was obtained by investigating the effects of different matrices on separation.

The research was supported by the National Institutes of Health.

Abstract Text

The combination of surface-enhanced Raman scattering (SERS) and microfluidic analytics become a vivid subject due to its advantages of small sample volume and multi-function integration. In this work, we will present several microfluidic SERS chips developed, involving decorating the microfluidic channels with Ag nanoparticles contained polymer fibers by electrospinning¹ and an ordered Ag nanodot array by depositing Ag on an AAO template² and etc. In addition, we will introduce the development on the microfluidic Raman spectrometer with an inverted configuration and imaging function, which can cope with the current difficulty of focusing laser spots onto the SERS-active surface.^{3,4} Also, the qualitative and quantitative on-chip SERS sensing of organic pollutants and pesticides will be presented.

Abstract Text

Microfluidic technologies have shifted molecular characterization toward nanoliter volumes. Microfluidic analogues have been developed for many existing chemical techniques, including chromatography, electrophoresis, electrochemistry, and biochemical reactions. To boost the usefulness of these techniques, molecular characterization in microfluidic devices is key. Infrared (IR) spectroscopy is a clear choice, since it is highly sensitive to analyte structure and local environment. While IR spectroscopy has been successfully used in combination with these devices, to fully realize these applications, the sensing portion of the device needs to be more chemically compatible, background free, and offer higher sensitivity. We have developed a microfluidic chip made from a broadband IR transparent crystalline material that can address all of these challenges. We demonstrate the utility of these chips by monitoring chemical reactions and protein conformation changes in IR transmission and multi-reflection attenuated total reflection (ATR) measurements. Multi-channel, multi-reflection ATR techniques will also be presented.

Abstract Text

Herbicides and pesticides have adverse affects on human and environmental health. Common use of these products necessitates monitoring water systems for hazardous levels due to run-off. Aptamers are an exceptional class of molecular recognition elements that selectively bind and release the target molecule. Immobilized aptamers are combined with capillary electrophoresis to create biosensors to detect herbicides and pesticides in environmental samples. Crosslinking chemistry is utilized to attach aptamers to magnetic silica particles in order to enhance detection limits through analyte concentration. With this capillary electrophoresis method, herbicides and pesticides are separated and quantified within 10 minutes. The aptamer-based biosensors are applied to detect and quantify atazine in river water [1]. In the future, the method will be translated into a portable microfluidic system for in-field analyses.

Abstract Text

Autophagy is a cellular process that breaks down damaged components for recycling. Dysfunctional autophagy is implicated in the process of aging as well as various diseases including Alzheimer's and Parkinson's disease. Mitochondria are degraded in an organelle-specific process termed mitophagy. The individual contribution of mitophagy to global autophagy cannot be quantified by traditional analysis methods. Traditional methods used to monitor mitophagy including western blotting and fluorescence microscopy are limited by the fact that they measure organelle markers at the bulk level. Capillary electrophoresis with laser induced fluorescence detection (CE-LIF) can detect molecules at the zeptomolar level, thus detection of individual organelles with fluorescent labels is possible. This technique can monitor the number of organelles present in a sample and provide insight into their heterogeneity based on their distribution of electrophoretic mobilities, indicative of their surface properties.

In principle, CE-LIF is capable of monitoring multiple types of organelles simultaneously, which would be advantageous to track mitophagy by monitoring both mitochondria and autophagy organelles at once. To demonstrate this approach we labeled mitochondria with the mitochondria-specific dye Mitotracker Red and autophagosomes with anti-LC3 antibody conjugated to Dylight 488. The fluorophores were excited by an Argon ion laser at 488 nm and emit at 644 nm and 518 nm respectively. Separations were performed with running buffer containing sucrose (250 mM) and HEPES (10 mM) at pH 7.4. Dual labeled events were not detected above the false positive rate, which was expected because autophagy was not induced. In ongoing work we will perform pharmacological treatments (vinblastine to halt mitophagy and hydrogen peroxide to increase mitophagy) to confirm that dual-labeled events, indicative of mitochondria inside autophagosomes, are indeed associated with mitophagy.

Abstract Text

The goal of this work is to develop a method for ambient laser ablation sampling for mass spectrometry and other bioanalytical techniques. An optical parametric oscillator laser system operating in the 3 μm wavelength region of the mid-infrared is used to ablate material from a cell or tissue sample that is drawn into a capillary by means of suction. The 1 mJ pulse energy beam is focused onto a tissue section on a microscope slide from the back in transmission mode or from the front in reflection mode. The transmission mode approach is most useful as a sample preparation method because the tissue slide can be held close to the suction capillary. The material is drawn into a peek capillary tube connected to a filter or impactor for collection. The collected material is brought into solution and further processed, for example by liquid chromatography separation, before being sent to an electrospray source for ionization. Alternatively, the solubilized material can be deposited on a target for matrix-assisted laser desorption ionization analysis. We have found that it is possible to transfer intact biomolecules such as peptides and proteins from thin tissue samples at a resolution of 130 μm . Both transmission and reflection modes methods have been tested. The ablation process greatly reduces the complexity of the tissue matrix. In both cases, digestion of captured protein material has been performed without any other extraction, detergent addition and/or purification step.

Abstract Text

Supported Liquid Extraction (SLE) has become popular amongst labs that are looking for a fast and effective approach to sample preparation. Traditional SLE relies on diatomaceous earth (DE) to perform extractions. The process is simple and when formatted into a 96-well plate it can be automated for high throughput. However, as a natural material DE is known to exhibit lot-to-lot variances and supply of suitable low density porous material can be limited. In response to these challenges, a novel, synthetic SLE sorbent, Novum, has been developed.

Using protocols that are similar to DE SLE we illustrate the extraction efficiency of the Novum sorbent with common solvents (Ethyl Acetate (EtOAc), DCM, and MTBE). Extractions of NSAIDs, corticosteroids, as well as a panel of pain management drugs from human plasma are shown to be both fast (<5 minutes) and efficient (>80% recovery).

A major cleanup benefit of LLE and SLE is the elimination of phospholipids. Plasma samples were diluted 1:1 with water and were analyzed using two batches of Novum, and two batches of DE SLE. Using EtOAc as an elution solvent, phospholipids in the resulting extract were analyzed by LC/MS/MS using m/z 184-184 (as a measure of general cleanliness). Both lots of the synthetic SLE removed >99.9% of 5 major classes of phospholipids. The DE SLE, however, allows the partitioning of the phospholipids into the organic and shows a large variance between lots (up to 9 fold; as a function of variable loading capacity). Generally with DE SLE, solvents such as DCM or MTBE can completely remove phospholipids from an extract, but this can compromise recoveries of more polar analytes. This result shows that nearly complete elimination of phospholipids, and efficient extraction of both polar and non-polar analytes can be achieved using Novum and EtOAc as an extraction solvent.

Abstract Text

DNA extraction represents a significant bottleneck in nucleic acid analysis. Traditionally, liquid-liquid extraction with phenol-chloroform was used for the purification of DNA from biological samples. Several adaptations to this method involving the addition of detergents to assist in the removal of proteins and polysaccharides have been made. However, the dependence of these protocols on organic solvents and often time-consuming centrifugation steps has resulted in the development of more environmentally benign techniques that are capable of high sample throughput. This talk will discuss the synthesis of hydrophobic magnetic ionic liquids (MILs) and their implementation as solvents for the rapid and efficient extraction of DNA from aqueous solution. The DNA-enriched MIL microdroplets were manipulated by application of a magnetic field. The MILs examined in this study exhibited unique DNA extraction capabilities when applied towards a variety of DNA samples and matrices. High extraction efficiencies were obtained for smaller single-stranded and double-stranded DNA using the benzyltrioctylammonium bromotrichloroferrate(III) MIL, while the dicationic 1,12-di (3-hexadecylbenzimidazolium) dodecane bis[(trifluoromethyl)sulfonyl]imide bromotrichloroferrate(III) MIL produced higher extraction efficiencies for larger DNA molecules. The recovery of DNA from the MIL extraction solvent and its implications in downstream analysis including polymerase chain reaction will be discussed.

Abstract Text

Hollow fiber based liquid phase micro-extraction (HF-LPME) technology has proven to be a unique technology that can be used for the analysis of compounds in many areas, especially in pharmaceuticals. For example, it can be used for the determination of log D, permeability and protein binding, etc. Specifically, we design and fabricated a 96 well plate with HF tubing sit right in the center of each well. One end of the HF was sealed while the other end was open and linked to the injected plastic 96 well plate base, which was specifically designed. On the side, another hole was made on the plastic plate for the delivery and extraction of liquid for the well. This 96 well plate based HF-LPME system is perfectly suited for the preparation of a few dozen microliter samples. At the same time, a proper auto-sampling device was made to accommodate this 96 well plate device making it ideal for the automation of isolation and sample clean-up in a high throughput fashion. With this new system, we were able to develop various analytical methods for the analysis of drugs in complex samples. We will report our recent progresses in the determination of log D and permeability of compounds. Plus, we will show our results for the determination of drug-protein interaction as well as the determination of drugs in complex biological samples. It is anticipated that this novel HT-HF-LPME technology will facilitate the drug discovery process with saving in both time and compounds/reagents.

Abstract Text

Ablation by a picosecond infrared laser (PIRL) based on the principle of ultrafast desorption by impulsive vibrational excitation (DIVE) offers a novel tool to extract biological samples for analysis and diagnosis, while their integrity and function are preserved through the ablation. Featured by its wavelength at 3 μm and its pulse width of 300 ps, the PIRL ablation under DIVE conditions is a highly efficient process using water molecules to propel surrounding biological complexes into the gas phase. This well-confined ablation process minimizes shock wave damage and thermal degradation to biological samples. The PIRL ablation was applied to ferritin, recombinant Green Fluorescence Protein (rGFP), Tobacco Mosaic Virus (TMV), and *Saccharomyces cerevisiae* (*S. cerevisiae*) cells in frozen aqueous solutions or suspensions. Techniques including microscope imaging and analytical methods were used to demonstrate intact quaternary structure of ferritin, sustained fluorescence and absent degradation of rGFP, intact structure and preserved infectivity of TMV, and intact biological activities of *S. cerevisiae* cells collected from the ablation plumes. The collected ablated biological complexes are virtually identical to their controls and serve as valid samples for downstream analysis. The PIRL ablation presents a simple and direct method to extract biological entities with preservation of morphological and chemical properties, and biological activities. With no sample preparation required, great amount of time and effort can be spared using the PIRL ablation to extract biological entities for diagnosis, which is especially beneficial to disease control.

Abstract Text

Paper-based biosensing platform or "lab on paper" has been exploited in analytical and clinical chemistry due to the fact that it is cheap, easy to use, disposable and environmental friendly. Chemiluminescence (CL) is a very sensitive detection method that requires no light source. We have combined two paper-based analytical methods with chemiluminescent detection; one is with immunoassay method for cotinine detection while the other is with paper chromatography for dichlorvos (DDV) detection. Laminated paper-based analytical devices (LPAD) with origami-enabled CL immunoassay have been developed for the detection of cotinine. Cutting/Lamination methods were used to fabricate LPAD and the simple origami step was adopted to eliminate possible reagent diffusion and flow during antibody immobilization steps and numerous washings. By incorporating luminol-based CL for detecting horseradish peroxidase-conjugated cotinine, cotinine in mouse serum was detected by using competitive immunoassay. The detection limit was determined to be 5 ng/mL. For the paper-based device for DDV detection, chromatographic separation for a sample was first accomplished in 12 minutes in a paper substrate (0.8×7.0 cm²). The interference patterns can be developed at different spatial locations and the detection area of DDV was cut to make a paper-based device for CL detection. By using luminol CL system, DDV can be detected with the detection limit of 3.6 ng mL⁻¹.

Abstract Text

Glutathione (GSH) serves vital cellular biological functions, and its abnormal levels are associated with many diseases. To better understand its physiological and pathological functions, efficient methods for monitoring of GSH in living systems are desired. Although quite a few small molecule-based and nanomaterial-based one photon fluorescence probes have been reported for GSH, two-photon (TP) probes, especially nanoprobe with good membrane-permeability, are more favorable for bioimaging applications, since TP fluorescence imaging can provide improved spatial localization and increased imaging depth. In this work, we for the first time reported a "turn-on" TP fluorescence nanoprobe for efficient detection of GSH in aqueous solutions, and TP excited fluorescence imaging of GSH in living cells and tissues. The nanoprobe consists of two-photon mesoporous silica nanoparticles (TP-MSNs) with a large TP excitation action cross-section (σ value of 103 GM; and MnO₂ nanosheets, which show intense and broad optical absorption and could act as efficient quenchers for TP fluorescence. In the sensing system, the negatively charged MnO₂ nanosheets are adsorbed on the positively charged MSNs through electrostatic interaction, resulting in efficient quenching of their fluorescence, with very low background fluorescence observed. The addition of GSH could reduce MnO₂ into Mn²⁺, lead to the decomposition of the MnO₂ nanosheets, and thereby result in remarkable enhancement of both one photon and TP excited fluorescence of the nanosystem. The nanoprobe shows a highly sensitive response to GSH in aqueous solutions, with a detection limit of 200 nM achieved. It also exhibits a high selectivity toward GSH relative to other biomolecules and electrolytes, with good membrane-permeability and excellent biocompatibility. The nanoprobe was successfully applied in monitoring the change of the intracellular GSH in living cells and tissues via TP fluorescence imaging, demonstrating its value of practical application in biological systems.

Abstract Text

Nanotechnology is a growing interest of many different scientific disciplines. Nanomaterials have secured an eminent position in many consumer products and medical applications. Better understanding of their effects on living organisms will enable us to rationally design more biocompatible nanomaterials for a wide variety of applications including design of smart drug delivery vehicles and probing of how brain functions. In this study, we investigated the mechanisms of effects of purified and well-characterized nanoparticles (NPs) on embryonic developments, specifically neurological development. To that end, we selected vital protein biomarkers that play important roles in neurological development, used transgenic embryos that express the protein biomarkers fused with fluorescence proteins as model organisms, and studied the effects of NPs on their functions using fluorescence microscopy and plasmonic spectroscopy. Updated results and applications will be discussed in this presentation.

Abstract Text

A plasmonic nanopipette based on a patch clamp pulled capillary will be presented. Plasmonic nanopipettes were fabricated using different methodologies, including direct deposition of different types of gold nanoparticles on nanopipette, focus ion beam milling of a gold film, glancing angle deposition, and polymer-assisted nanotemplating. The characterization of the optical properties of plasmonic nanopipettes with SEM, dark field microscopy, and Raman microscopy will be presented. The nanopipettes are envisioned as nanoprobes to monitor molecules with high spatial resolution and so, will allow a selective quantification of molecules (e. g. ATP and BMP-2) inside and nearby cells. Micro and nanoscale electrodes are used in several analytical techniques like patch clamp, and electrochemistry due to their non-destructive nature on the substrate justifying their use as a tool to study metabolites around living cells. However, specific analytes such as electroactive species are required. On the other hand, plasmonic materials used in biosensing allow quantification of multiple biomolecules due to their universal quantification behavior. By coupling these techniques, plasmonic nanopipettes allow localized quantification of molecules by the use of a SERS response based on a sandwich assay using a gold nanoparticle (AuNP) tagged with a Raman active reporter. Sensitivity, limit of detection (LOD), and reproducibility of the nanopipettes will also be optimized for the detection of IgG.

Abstract Text

Surface plasmon resonance (SPR) spectroscopy and SPR imaging (SPRi) have proven to be powerful analytical tools in the label-free analyses of molecular interactions, especially those involving supported bilayer membrane (SBM) systems. While the technology behind creating supported lipid bilayers on glassy surfaces is well developed, one current issue is the long-term stability of lipid membranes on the surface. Typically, lipid vesicles must be used soon after preparation, and once assembled into a bilayer must remain in aqueous conditions, thus limiting the large-scale production and application of such systems. Recently, a method that involves an anhydrobiotic sugar, trehalose, for preserving intact lipid vesicles has attracted attention. Once rehydrated, the trehalose dissolves into solution, and lipid vesicles immediately rupture and fuse into a continuous bilayer at the deposited surface. We have applied this technology toward creating lipid microarrays for SPRi analysis. The arrays can be generated in quantity and are viable for weeks. The resulting trehalose-facilitated bilayers were studied by SPRi and fluorescence recovery after photobleaching to confirm they retained the lateral mobility characteristic of typical SBMs. Finally, varying concentrations of the GM1 receptor were mixed with the lipids before desiccation and used for SPRi analyses of cholera toxin interactions to demonstrate the feasibility of long-term storage for high-throughput SBM substrates.

Abstract Text

Formaldehyde (FA) is a hazardous chemical and found not only in industrial products but also in living bodies. It usually exists in mix gas, making it difficult to identify. Therefore it is highly demanded to develop a technique allowing sensitive and selective detection of FA vapor.

Here we performed detection of gaseous FA transpired from food samples (Shiitake mushrooms) using a fiber-optic biochemical gas sensor (bio-sniffer). Owing to formaldehyde dehydrogenase (FALDH) employed in the bio-sniffer, nicotinamide adenine dinucleotide (NADH) is produced as a result of the enzymatic reaction with FA. Finally NADH is excited with UV light and emitted fluorescence is detected (Fig. 1). These enzyme and fluorescence lead to high selectivity and sensitivity for the FA measurement.

With standard gas generators, the LOD for FA vapor was determined as 1.1 ppb that is about 80-fold lower than WHO guideline for residential indoor air quality. When flowing the gas sampled from the dried mushrooms, the fluorescence intensity drastically increased (Fig. 2), indicating that the bio-sniffer is capable of detecting FA in complex gaseous samples as well as in pristine ones. In conclusion, the bio-sniffer can be a powerful tool for gas monitoring in the environment or gas analysis for medical diagnostics.

Abstract Text

Accurate detection of protein levels in biological samples is critical to understanding various biological processes and disease states. However, the direct detection of protein levels in natural samples is inherently challenging due to the extreme complexity of the sample matrix. One way to get around this limitation is to use an array of cross-reactive sensor elements which respond differently to different proteins. Herein, we report a fluorescence sensor array fabricated by using a Group of Uniform Materials Based on Organic Salts (GUMBOS) for highly sensitive detection and discrimination of proteins. These GUMBOS were prepared by pairing a derivative of naphthalenesulfonate anion with five different phosphonium cations. The GUMBOS and proteins exhibited efficient and discrete Förster Resonance Energy Transfer (FRET) between them. The FRET signal patterns of proteins generated from GUMBOS sensor array were statistically analyzed by using principal component analysis and linear discriminant analysis in order to accurately identify proteins. Overall, this array is very promising for facile, inexpensive and label-free detection and discrimination of proteins with a high degree of accuracy.

Abstract Text

Recent studies reveal that 47% of all the marketed small molecules drugs act on enzymes. Indeed, many drugs based on enzyme inhibition have been commercialized, demonstrating the importance of enzyme inhibitors. Diagnosis of enzyme inhibition and determination of inhibition constant are often found in papers dealing with bioassays and biosensors. Although the huge number of papers published in this field, analyzing all reaction time-course of progress curve of enzyme inhibition is scarce although it contains additional information about the properties of the enzyme.

In this work, the advantages of a progress curve analysis versus an initial rate approach will be highlighted. Inhibitor concentration was determined by means of "half time reaction" estimated by progress curve, avoiding the use of end-point and initial rate approaches. Simplified equations and a novel graphical method are proposed, valid for all types of reversible inhibition, for the determination of the inhibitor concentration with an extended linear range and for the estimation of the inhibition constant K_i . Practical examples of inhibition of catalase by cyanide, cholinesterase by fluoride, peroxidase by sulphide and chromium and carbonic anhydrase by sulfonamide are reported. Limitations of the proposed method and results of real sample analysis will be discussed.

Abstract Text

The rapid spate of development of many industries leads to wastes containing heavy metals being directly or indirectly discharged into the environment. This study employed the adsorption of cadmium (II), cobalt (II), and nickel (II) on corncob, an agricultural waste has been studied in batch mode at room temperature using flame atomic absorption spectroscopy for metal estimation. The study investigated the influences of adsorbent dosage, solution pH, contact time, and initial metal concentration on the removal of metal ions. The Langmuir and Freundlich isotherm models were used to fit the equilibrium biosorption data. The reaction kinetics of the cadmium (II), cobalt (II) and nickel (II) removal from the aqueous solution were identified and correlated to the pseudo first- and second-order kinetic models. The results show an increase in adsorption by metal ions studied with an increase in adsorbent dosage. Metal uptake showed a pH-dependent profile with optimum at pH values 4.0 for Cd (II) as well as Ni (II), and 8.0 for Co (II) ions. The Freundlich adsorption isotherms model fitted the experimental data best with the regression coefficient ranging between 0.837 and 0.989 for the metal ions. A kinetic study of the adsorption process showed that adsorption of cadmium (II), cobalt (II), and nickel (II) on corncob was observed to follow closely to the pseudo-second-order. It was concluded that corncob exhibited rapid adsorption capabilities and high efficiency in removal of cadmium (II), cobalt (II) and nickel (II) ions from aqueous solution.

Abstract Text

In the biopharmaceutical industry, there is an increasing interest in monitoring the effect that carbohydrate components have on the structural and functional roles of a therapeutic glycoprotein. Glycosylation patterns of recombinant glycoproteins are influenced by factors including the expression and growth conditions. These patterns affect the biological activity of proteins, such as the immunogenicity and receptor binding, which may subsequently affect the efficacy and safety of the final product. The goal is to determine the carbohydrate composition of immunoglobulin G (IgG) monoclonal antibody, a model glycoprotein, produced in miniature bioreactors compared to bench-scale models. Work will be performed using the complimentary techniques of HPAEC-PAD and LC-MS for profiling and characterization.

HPAEC-PAD glycan profile analysis used enzymatically cleaved glycans from IgG3 by PNGase F and isolated with carbon top-tips. The monosaccharide sequence of glycans will be characterized via LC-MS fragmentation studies using a carbohydrate mixed-mode column.

Three major glycan structures were found and characterized as asialo-fucosylated, asialo-monogalacto-fucosylated, and asialo-agalacto-fucosylated biantennary glycans. Mass spectrometry sequencing experiments were performed for insulin and streptokinase using top-down and bottom-up approaches, and 100 percent sequence coverage was achieved through the bottom-up method. Full intact protein identification was verified with the top-down approach. These methods will be applied to IgG3. Although the mini-HTB is able to overcome the previously mentioned issues, it introduces the need to analyze relatively small volumes of sample. The methods of LC-MS and HPAEC-PAD offer the needed sensitivity to work with small sample quantities.

Abstract Text

Polysorbate 80 is commonly used for biotherapeutic products to prevent aggregation and surface adsorption, as well as to increase the solubility of biotherapeutic compounds. A reliable method to quantitate and characterize polysorbates is required to evaluate the quality and stability of biotherapeutic products. Several methods for polysorbates analysis have been reported, but most of them require time-consuming sample pretreatment such as derivatization and alkaline hydrolysis because polysorbates lack sufficient chromophores. Those methods also require an additional step to remove the biotherapeutic compounds. Here we report a simple and reliable method for the quantitation and characterization of polysorbates in biotherapeutic products using two-dimensional HPLC.

A model sample was prepared for this study. The model sample contained 20 mg/mL of human IgG and 0.1 mg/mL of polysorbate 80 in 10 mmol/L phosphate buffer pH 6.8. This sample was injected on a Shimadzu Co-sense for BA two-dimensional HPLC system coupled with a Shimadzu LCMS-2020 single quadrupole mass spectrometer. The IgG was separated from the polysorbates which were retained on a 5mm x 2.0mm trap column. The polysorbates were then introduced to an analytical column by valve switching. The polysorbate 80 was detected by the mass spectrometer.

The trap column, Shim-pack MAYI-ODS, successfully separated the analytes from the IgG. Polysorbates are complex mixtures of polymeric compounds, so many peaks were present on the total ion chromatogram. A selected ion monitoring mode and a short analytical column were used for quantitation and a total ion chromatogram and long analytical column were used for characterization.

Abstract Text

The non-enzymatic glycation of blood and tissue proteins has been shown to lead to the formation of Advanced Glycation Endproducts (AGEs); factors contributing to many of the chronic complications of diabetes such as renal failure, atherosclerosis and cataract formation. The clinical and medical significance of AGEs has promoted interest in several areas including methods to characterize AGEs and parameters/reagents that influence the glycation process. The objective of this study was twofold: 1) using fluorescence spectroscopy to characterize the side chain modification of human serum albumin glycated by dihydroxyacetone (DHA), a commonly used tanning reagent in cosmetic products, 2) to identify by peptide mapping the amino acid sites in albumin vulnerable to DHA glycation. Fluorescence studies showed that DHA was a potent glyicator of albumin, extensively modifying the protein's lysine and arginine residues. Peptide mapping of early glycation products identified lysine 201 as the major site of glycation with MALDI-TOF studies demonstrating an average of 5 DHA molecules bound to the protein. The reactivity of DHA with lysyl residue 201 was interesting because this site was never reported as a principle site of glycation in HSA.

Abstract Text

Arsenic speciation in urine is one of the most common HPLC-ICP-MS analyses due to the importance of distinguishing toxic and non-toxic species. Most work has focused on anion exchange separation of the various arsenic species. Although successful, this separation scheme suffers from several drawbacks, the most notable being the difficulty in measuring low-levels of inorganic arsenic (specifically trivalent arsenic, AsIII) in the presences of high levels of non-toxic organo-arsenic compounds (specifically arsenobetaine, AsB). While inorganic arsenic is present in low-levels in a variety of foods, AsB enters the body through consumption of marine organisms, which metabolize arsenic to form AsB.

With most anion exchange separation methods, AsB elutes just prior to trivalent arsenic. Since AsB levels are usually much higher than AsIII, the broad peak with long tail from high levels of AsB can obscure the presence of AsIII.

This work will explore an alternate separation scheme which changes the order in which the arsenic species elute, thus allowing low levels of AsIII and AsV to be determined in the presence of high levels of AsB.

Abstract Text

The Maillard Reaction is a complex series of reactions between an amino acid and a reducing sugar that has important physiological implications, particularly for diabetes mellitus. In this presentation, we will describe the application of a sensitive and selective analytical method that we have developed to study the kinetics of the initial stages of the Maillard Reaction. The method is based upon sample pre-treatment by sequential injection (SI) prior to detection by low-field nuclear magnetic resonance spectroscopy (NMR). The SI-NMR method improves the sensitivity and selectivity of the picoSpin™ detector by effectively pre-concentrating the sample before the sample zone enters the flow cell of the spectrometer. The initial steps in the reaction between alpha-dicarbonyl compounds (e.g., glyoxal and methyl glyoxal) and primary amines (e.g., methylamine and lysine) were monitored on-line with SI-NMR. This approach allowed for the determination of the rate constants, reaction orders, and structures of the intermediates that were formed. A mechanism for the production of the Amadori product will also be proposed.

Abstract Text

F2-isoprostanes are lipid markers of oxidative stress in animal host systems. F2-isoprostanes have been identified as biomarkers of cardiovascular disease, pulmonary disease, neurological disorders and various conditions related to the health and function of the kidneys and liver. Strategies to measure these analytes are typically laborious multi-step procedures that are plagued with low recovery sample preparation strategies leading to poor method precision. In a broader scope, targeting endogenous lipids as analytes of interest is challenging since modern solid phase extraction procedures (SPE) typically aim to remove lipids in favor of targeting small molecules. For these reasons, method optimization strategies are required to improve the efficacy of current testing protocols. In this work, the automation of an existing SPE procedure was implemented. A dual stage cleanup strategy was employed. Automation was achieved using a RapidTrace+ system with data acquisition software. The SPE platform was 3 mL cartridges supporting 500 mg sorbent beds. Detection of the target analytes was optimized using a Shimadzu gas chromatography system (QP-2010) coupled to a quadrupole mass selective detector. The GC column was an Rtx-5 30 meter, 0.32 mm ID, 0.25 μ m df, Restek Corp, Bellefonte, PA. The ion source was operated in the negative ion chemical ionization mode. It was determined that there were several observed advantages to this approach vs offline manual preparation including laboratory efficiency and figures of merit describing data quality. It is anticipated that this report will have impact in labs that provide testing platforms for population studies focused on lipids as markers of oxidative stress. This automation platform demonstrates an improvement in lab efficiency and data quality. Preliminary data for this study was generated at the University of Kentucky.

Abstract Text

Imaging mass spectrometry (IMS) has been used by a variety of scientists to address research questions of chemical and biochemical significance. In terms of data processing, traditional two-dimensional heat maps of single ions lack sophisticated analytical detail, yet manual analysis of multiple peaks across hundreds of pixels within an entire image is time-consuming, tedious, and subjective. Here, various chemometric methods are used to analyze datasets obtained by matrix-assisted laser desorption/ionization (MALDI) IMS of a three-dimensional cell culture system. HCT-116 colon carcinoma multicellular spheroids are an excellent *in vitro* model that mimic the three dimensional morphology and cellular heterogeneity of tumors *in vivo*. This particular dataset is especially challenging to process because all cells within the image are genetically identical which can sometimes result in only subtle differences in protein expression (and thus the mass spectral profiles) within the image. First, principal component analysis (PCA) was used to isolate relevant pixels within the recorded MALDI IMS image. The data was further processed prior to a second round of PCA whereby mass spectral features were identified within the image. Next, clustering methods were used to identify subpopulations of pixels within the image that exhibited similarities in spectral content. Finally, discriminant analysis was used to identify spectral features present in spatially heterogeneous locations within the image. These exploratory data analysis tools allow for the isolation and detection of biochemical phenomena within IMS datasets in an easy, rapid, and unbiased manner.

Abstract Text

As a simple and rapid single reagent colorimetric assay, the PierceTM 660 nm Protein Assay is one of the commonly used methods for protein determination. Certain substances, such as detergents, reducing agents, and buffers may interfere with the PierceTM 660 nm Protein Assay. In our study, we analyzed the interfering effects of the detergent Sodium Dodecyl Sulfate (SDS) and the reducing agent Dithiothreitol (DTT) present in samples for protein determination using the PierceTM 660 nm Protein Assay microtiter format. We also explored the correlations of the measured protein concentrations with these interfering substance concentrations to target protein values. Multiple concentration levels of Bovine Serum Albumin (BSA) were prepared in matrices containing various levels of SDS and DTT. The results of the analyses demonstrated that the measured protein concentration was decreased with an increase in SDS concentration, and the percent decrease was independent from the protein concentration of the samples. The effects of both SDS and DTT presence in the sample matrices analyzed for protein concentration were explored with and without the usage of the PierceTM Ionic Detergent Compatible Reagent (IDCR).

Abstract Text

Size Exclusion Chromatography is a well-established technique for biomolecule analysis, particularly for quantitation of monomer, dimer and higher aggregates in biotherapeutic manufacture. Such proteins form aggregates under stress conditions and can arise at many stages of manufacture – during isolation, purification, concentration or storage. Conventional silica-based stationary phases provide good resolution of such molecules, separating the molecules based on their size in solution. In order to overcome non-specific interactions that occur between basic sites on the proteins and acidic silanol groups of the silica stationary phase, the mobile phase includes a high concentration of salt (0.3 – 0.5M is not atypical). Such mobile phase conditions are satisfactory for concentration detectors such as UV or DAD, however this prevents more sophisticated detectors such as MS being used.

In this poster, we will show results obtained on an optimized size exclusion chromatography column that overcomes some of these limitations. Carefully controlled pore size distribution ensures the column is targeted specifically towards the molecular weight range of interest, and the particle size is designed to provide high separation efficiency. Furthermore the stationary phase is bonded to minimize secondary interactions and enables separations to be carried out at low salt concentrations and low ionic strength. We will illustrate some of the benefits of these new columns, particularly when coupled to advanced detectors and instrumentation.

Abstract Text

Gangliosides have been identified as potential biomarkers in neurological disorders. They are expressed highly in the central nervous system and play a major role in regulating vital cellular processes including:intracellular signalling, molecular recognition and cell adhesion. There is a growing interest in the spatial distribution and expression of these molecules in the brain. We imaged the localization of gangliosides and other bio-active lipids in C57BL/6NJ mouse tissue with MALDI-TOFMS. Preliminary complementary images of small molecule metabolites in the brain were produced from adjacent coronal mouse brain sections. We hope to expand our study to mine lipid and metabolite data for dynamic relationships and expression patterns within the brain.

Abstract Text

The feature of superficially porous (core shell) particle used as a highly efficient material is existence of a core, a thin porous layer and narrow particle size distribution, which lead to higher efficiency than totally porous particle. Recently a core shell particle with wide pore for biomacromolecular separations has developed by a few manufacturers. It has been said that thin porous layer of core shell particle have an advantage for separation of large molecules such proteins because a diffusion coefficient becomes small to proportional to a molecular weight and a mass transfer speed also decreases. In this paper, thickness of porous layer of core shell particle was evaluated to separate proteins. 2 kinds of thickness of porous layer such as 0.2 μm and 0.5 μm thickness were applied for separation of standard protein samples. On fast separation, 0.2 μm of porous layer showed sharper peaks than 0.5 μm of porous layer. However at 80 degree Celsius and using 60 min gradient time program, 0.5 μm of porous layer showed much sharper peaks than 0.2 μm of porous layer. It was considered that 0.5 μm of porous layer had the a wider specific surface area than 0.2 μm of porous layer and this wider specific surface area leaded separation efficiency concerning the partition interaction on the stationary phase to be large.

Abstract Title **Determination of the Constituents of the Essential Oil from Fleurya Aestuans, A Uterotonic Plant by GC-MS**

Primary Author Modupe M. Ogunlesi
University of Lagos

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Edith U. Ofor, Tobi C. Aleshinloye

Abstract Text

Fleurya aestuans is used in Alternative as a uterotonic agent to shorten labor and hasten the detachment of the placenta. It is also used as an antimicrobial, astringent, and in the management of menopausal and liver disorders and burns. The purpose of the study is to identify constituents of the essential oil from the plant which may exhibit these bioactivities. The essential oil was extracted by hydrodistillation using a Clevenger apparatus and collected into hexane in two modes, namely: a continuous collection for four hours and hourly collection over the same period. The essential oil samples were analyzed on Agilent GC 7890A fitted with an HP 5 MS column 30 m x 0.320 mm x 0.25 μ m using a temperature program of 80 deg.C (2min) increased at 5 deg./min to 120 deg.(2min) further increased at 3.5 deg./min to 240 deg. (15min) using helium as carrier gas. Mass spectrometry of the constituents was on Agilent MSD 5975C. The major constituents in the samples are 2-pentadecanone,6,10,14-trimethyl (25.6-48.3%) and phytol (18.6-56.1%). Minor constituents include tetradecanal, dibutyl phthalate, docosane and tetracosane. Phytol has been reported to exhibit anti-inflammatory and anti-tumor properties and found effective in suppression of arthritis, lowering of serum levels of triglycerides and management of diabetes, obesity and cardiovascular diseases. Thus phytol may promote wellness in pregnant women especially those who may develop diabetes or hypertension, hence the description of the plant as being a pregnancy booster. It may also shrink hemorrhoids. Isophytol has been reported damage fetus and may expel placenta or induce labor. Long chain alkanes may produce soothing effects in burns while 2-pentadecanone,6,10,14-trimethyl and tetradecanal may function as astringent. The constituents of the essential oil samples thus have bioactivity related to some of the medicinal uses of the plant.

Funding is by the University and the authors.

Abstract Title **Development of On-Column Detection with Dual Au/Hg Electrodes for Capillary Electrophoresis**

Primary Author Nhan To
University of Kansas

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Craig E. Lunte

Abstract Text

Capillary electrophoresis is a powerful separation method due to its high efficiencies and its ability to analyze nanoliter volume samples, making it ideal to couple with microdialysis sampling. Electrochemical detection (EC) offers several advantages over other detection methods, notably its subnanomolar detection limits, and biological analytes of interest are already electrochemically active. However, capillary electrophoresis produces high separation currents that can greatly affect the EC detector. A decoupler is a solution that provides a break in the capillary, which is then covered by a semi-permeable material that will allow only current to escape the capillary. This permits the separation current to exit the capillary and into ground, while analytes remain in the capillary and are pushed towards the working electrode with the assistance of electrophoretic flow. A decoupler mechanism, previously designed in our lab, was implemented where a capillary was ablated with several holes using a CO₂ laser, and cellulose acetate was used to provide a membrane. This design can dissipate larger amounts of current compared to previous designs, while providing improved structural support. Thiols and disulfides are biomarkers of oxidative stress. Thiols react with reactive oxygen species and are converted into disulfides. The ratio of thiols and disulfides can provide information on the amount of damage to DNA, proteins, and/or lipids. In particular, N-acetylcysteine, cysteine, cystine, homocysteine, homocystine, glutathione, and glutathione disulfides were detected in a parallel-opposed dual Au/Hg electrode design. This design allows for the simultaneous or individual detection of thiols or disulfides.

Abstract Text

Many laboratories use GC/MS (Gas Chromatography/Mass Spectrometry) and GC/MS/MS for the analysis of steroids and hormones to detect and monitor health disorders. While LC/MS/MS (Liquid Chromatography/MS/MS) performed with triple quadrupole instruments is being used more frequently, it suffers from being a target analysis technique. Only the target analytes are detected, and it is not possible to retrospectively query the data for unexpected steroids, precursors, or derivatives in novel metabolomes. GC/MS is non-selective, providing a comprehensive view of all steroids in the metabolome for non-targeted steroid profiling. GC/MS also allows for spectral searching of unknown compounds against large libraries of reference spectra. LC introduction has the advantage that derivatization is generally not required, whereas GC typically requires it because of thermolability at the high analyte boiling points.

The technique of Cold EI GC/MS allows the introduction of high flow rates of carrier gas into the MS interface. Using relatively short GC columns, the high flow rates reduce the temperature required to elute the analytes and minimize decomposition. The Cold EI axial flow-through ion source and supersonic jet expansion reduces ion source decomposition compared with conventional closed EI source designs by eliminating analyte contact with hot source walls. Cold EI also enhances the molecular ion intensities, improving technique specificity. When used in a novel q-TOF configuration the enhanced molecular ion also increases MS/MS quantitative sensitivity, selectivity, and information content.

This paper will discuss the application of Cold EI GC/MS and GC/MS/MS to the analysis of underivatized steroids, simplifying and cost-reducing laboratory workflows.

Abstract Text

Protein diversity in biological systems is quite large, but short term (<1 hour) changes due to a particular stimulus will cause only subtle changes in very specific protein expression levels. Excessive sample-handling/processing methods often add significant noise to overall experimental results. Here, we use a combination of a simple sample preparation technique, the extremely reproducible Thermo Scientific™ Dionex™ Vanquish™ UHPLC system, and a robust mass spectrometer platform to afford researchers the ability to use massive protein/peptide libraries for quantification of several thousand proteins.

An in vitro model was created using live gram positive and gram negative bacteria spiked into whole blood and after which both the plasma and the Peripheral Blood Mononuclear Cells (PBMC) are extracted. The proteins were digested and a portion of each was used to make pools (plasma and PBMC protein digest pool). These pools were fractionated using an orthogonal high pH reverse phase gradient. The library was generated by spiking retention time QC standard peptides into each fraction, and each fraction was injected onto the identical LC method to be used for quantification, with additional MS time dedicated to sequencing. The resulting data was then searched using Thermo Scientific™ Proteome Discoverer™ software, and the results were imported into Thermo Scientific™ PinPoint™. Individual sample analyses were then compared against the database, with <5 s retention time reproducibly. If a peptide was not sequenced in a data dependent acquisition strategy, or if its mass overlapped with another peptide, accurate quantification/assignment was still possible.

In this case, the accurate quantification of several hundreds of proteins in plasma, with sub 7% CV with an 850 (1%fdr) library, is reported. Furthermore, accurate quantification of several thousand PBMC peptides, with sub 7% CV, with a 6600 protein library was achieved.

Abstract Title **High Fructose Feeding Induces Copper Deficiency: A Fecal Metabolomics Study**

Primary Author Xinmin Yin
University of Louisville

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Craig McClain, Ming Song, Xiaoli Wei

Abstract Text

Dietary copper deficiency is associated with a variety of signs/symptoms of the metabolic syndrome, including hyperlipidemia and fatty liver. In order to investigate whether copper deficiency plays a role in fructose-induced fatty liver, male weanling Sprague-Dawley rats were housed in stainless steel cages in a temperature and humidity controlled room with a 12:12 h light–dark cycle. All rats were split into four groups. Each group of rats was fed either an adequate copper or marginal copper deficient diet. At the same time, distilled water or distilled water containing 30% fructose (w/v) was given as free access drinking for 4 weeks. Fructose enriched drinking water was changed twice a week. At the end of the experiment, all the animals were killed under anesthesia with pentobarbital. Colon stools were collected and snap-frozen with liquid nitrogen for metabolomics study.

Metabolites were extracted using a mixture solvent (methanol and water, v:v=8:2). The extracted metabolites from each fecal sample were derivatized using N-(tert-butyldimethylsilyl)-N-methyltrifluoroacetamide (MTBSTFA) mixed with 1% tert-butyldimethylchlorosilane (TBDMSCI). The derivatized samples were analyzed on a LECO Pegasus 4D GC×GC-TOF MS instrument. Experimental data were processed by ChromaTOF software for peak picking and compound identification, followed by MetPP software for retention index matching, cross sample peak alignment, normalization and statistical significance tests.

Preliminary analysis shows a significant metabolite profile difference between sample groups. A list of compounds with significant abundance changes was identified via pairwise two-tail t-test with sample permutation. The fecal metabolites profile reveals novel mechanism underlying marginal copper high fructose diet-induced NAFLD.

Abstract Text

Many purified protein materials used as active components in clinical diagnostic reagent test kits contain readily oxidizable moieties that can cause storage instability of potency due to crosslink-driven oligomerization, peptide bond cleavage or alteration of binding surfaces. In order to assure storage stability for this type of protein reagent, oxidant-scavenging reducing agents are typically added to the solution matrix. Reduced-thiol molecules such as dithiothreitol (DTT), glutathione (GSH), N-acetylcysteine (NAC) and 2-mercaptoethanol (BME) are often employed to fill this antioxidant role. Over the storage and eventual processing times for the protein reagent, the reducing agent in the matrix is presumed to be consumed in reactions during protection from naturally occurring oxidizing species. To design an effective solution composition for the expected storage lifetime of this type of protein reagent, an analytical method for measurement and monitoring of remaining active-reducing thiol matrix is needed. Although the classic Ellman's method is a useful for measurement of total active thiol content in solutions, we also encounter a frequent need to quantify specific thiol-containing molecules in matrices with more than one of these analytes present. We have optimized and characterized a RP-HPLC method using a fluorescent thiol-reactive label for measurement of concentrations for several specific reducing thiol reagents typically used in protein storage solutions. Analytical performance characteristics for the optimized method will be discussed along with example applications of the method to the assessment of reduced-thiol stability in protein storage diluent formulations.

Abstract Text

Peptide mapping methods have historically been lengthy, time-consuming methods requiring large amounts of solvent. Modern instrumentation and smaller particle size stationary phases now allow for these methods to be scaled down; improving throughput, saving solvent, and increasing scientists' overall productivity. In this poster we investigate the use of YMC-Triart C18 1.9um hybrid and YMC Meteoric Core C18 2.7um core-shell materials for improving peptide mapping methods.

Abstract Text

Branched chain amino acids (BCAAs) – valine, leucine and isoleucine – have been found to be involved in nutritional signaling, synthesis of proteins and control of appetite. Circulating BCAAs are found elevated in obese individuals and have been linked with metabolic disorders such as diabetes. In vivo experiments provide the unique opportunity to examine overall dynamics of BCAAs within different types of tissue as they function within interworking bodily systems. Using an online microdialysis-capillary electrophoresis instrument allows for in vivo BCAA dynamics to be monitored in response to external stimuli such as glucose, insulin and artificial sweeteners. Microdialysis probes allow for continuous analysis with minimal damage to the surrounding tissue upon probe implementation. High speed capillary electrophoresis pairs well with microdialysis sampling by overcoming the limitation of small sample volumes and provides full separation of amino acids of interest within 30 seconds. Further investigation into the dynamics of BCAAs as they occur in near real time will provide a more complete understanding of their detailed role in metabolism and how their function is correlated with adipose tissue and obesity

Abstract Text

The determination of nitrite is important for quality control of food, particularly processed meats. We have shown that nitrite rapidly nitrosylates the R-SH compound captopril under acidic conditions to produce the R-SNO nitroso derivative with absorption bands at ~333 nm and ~546 nm. Maximum absorbance at 333 nm is reached in ~3 min at pH 1 or ~40 min at pH 2 when using equimolar nitrite and captopril concentrations at room temperature, indicating a molar absorptivity of about 1080. The optimum reaction time at pH 2 can be decreased to about 20 min when the temperature is raised to either 40 or 50 [sup]o[/sup]C. In addition, we have incorporated flow injection analysis (FIA) using a pump to propel the strong acid carrier (either sulfuric or perchloric acid) through two HPLC injection valves, a mixing tee, and a HPLC detector. Equal volumes of captopril solution at pH 1 and nitrite solution at moderate pH are simultaneously injected into the carrier stream and combine at the mixing tee. On-line absorbance measurements are performed using MeasureNet. Optimization of the flow rate showed the best response at 0.2 mL/min. Figures of merit including limit of detection, limit of quantitation, linear dynamic range and analysis time for the optimized flow system will be compared to the results of cuvette-based UV spectrophotometry. The effect of ionic strength and potentially interfering species on the absorbance signal will also be discussed.

Abstract Title **Use of Red Chili Pepper as Natural Antioxidant for Improving the Oxidative Stability of Edible Oil**

Primary Author Stefano Casiraghi
Velp Scientifica SRL

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Claudia Mancinelli, Stefania Corti

Abstract Text

The most important factor determining the shelf life of olive oil is its oxidative stability: lipid oxidation not only produces rancid odours, unpleasant flavours and discoloration, but it can also decrease the nutritional quality and safety of olive oil. Red chili pepper is widely used in its ground form, as natural antioxidant ingredient to retard or prevent lipid oxidation, to preserve the quality and to extend the shelf-life of food products, thanks to its high content of carotenoids, polyphenolic compounds and capsaicinoids, responsible for its characteristic hot taste.

In this work, the oxidative stability of the oil with chili pepper powder was investigated by accelerating the oxidation process using Oxitest reactor (VELP Scientifica; Italy), based on the use of high temperature and over-pressure of oxygen. The addition of few grams of red chili pepper powder to three edible oils (olive, extra-virgin olive, and seed oil), increases their stability since the beginning and during storage.

The investigation was also extended to the use of three pepper powders with different level of piquancy. Among the three pepper powders tested, the strongest effect was recorded with the less piquant one. Therefore, the antioxidant effect could not be attributed to the capsaicinoids, responsible for piquancy, but to the presence of other antioxidant phenolics. As the latest evaluation, a dose-effect relation was studied among different amounts of pepper powder and the stability of olive oil and extra-virgin olive oil. An evident linear dependence was found in olive oil, related to the higher oxidative stability of extra-virgin olive oil, due to its high content of natural polyphenols.

This study suggests interesting perspectives of the extension of shelf life using olive oil added with mild red chili pepper powder in the food industry, as canned food in oil production.

Abstract Title **Monitoring Basmati Rice Sensory Quality Thanks to An Electronic Nose**

Primary Author Jean-Christophe Mifsud
Alpha MOS

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Andrew Cowell, Fatma Ayouni, Herve Lechat, Marion Bonnefille, Valerie Vabre

Abstract Text

Basmati rice is a naturally fragrant variety of long grain rice mainly cultivated in South Asia. Its typical flavor is due to the presence of 2-acetyl-1-pyrroline. Difficulty in differentiating genuine basmati from other types of rice and the significant price difference between them has led fraudulent traders to adulterate basmati rice with cheaper crossbred basmati varieties or long-grain non-basmati varieties.

This study describes the analysis of several batches of so-called Basmati rice with an electronic nose. The objective is to quantify the concentration in 2-acetyl-1-pyrroline, an indicator of Basmati rice quality, and to characterize the overall aroma. Ten batches of Basmati rice (R01 to R10) from different suppliers were evaluated with HERACLES electronic nose, based on two-column fast gas chromatography. Before headspace analysis, rice is cooked by placing a fixed mass of rice in a vial containing an aqueous solution of saturated NaCl and heating. 2-acetyl-1-pyrroline is detected on the chromatograms at a retention time of around 71s on MXT-5 and around 76s on MXT-1701 column. Basmati rice usually contains 2-acetyl-1-pyrroline at a concentration of about 600 µg/kg whereas unflavored rice contains very low amounts (around 10 µg/kg). 2-acetyl-1-pyrroline is identified using the retention indices from AroChemBase database and its quantity is assessed on MXT-5 column on which no visible co-elution is observed. Unflavored rice samples R02 and R03 contain the lowest amounts of 2-acetyl-1-pyrroline (peak area near 0). Among the other samples of flavored rice, the Basmati ones (R01, R06, R07 & R08) show the highest amounts of 2-acetyl-1-pyrroline. The blend of Basmati & unflavored rice (R04) shows a concentration twice lower than pure Basmati rice (R01). The other volatile compounds contained in rice is also investigated using AroChemBase database and it appears that the majority peak corresponds to hexanal, which is an indicator of the level of oxidation.

Abstract Title **Scale-Up of Subcritical Water Extraction of Polyphenolic Compounds from Fruit Waste Material**

Primary Author Rolf Schlake
Applied Separations

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Al Kaziunas, Jerry King

Abstract Text

Polyphenolic compounds are valued for their health benefits and are widely used in the food, nutraceutical and cosmetic industries. These compounds are found in abundance in many natural products and their processed waste materials. Pomace, or marc are the solid remains of grapes, olives, or other fruit after pressing for juice or oil. It contains the skins, pulp, seeds, and stems of the fruit. Grape pomace contains many polyphenolic compounds, such as anthocyanins and procyanidins that have been traditionally extracted using methanol, acetone or other hydroalcoholic solvents.

Liquid water exhibits many changes in its characteristics as it is heated. Viscosity and surface tension decrease and solubility of solutes and their diffusion increases. In addition, the dielectric constant of water decreases significantly as it is heated and behaves like a mixture of water and alcohols when in the subcritical temperature range. Thus subcritical water may be used to extract many organic molecules with substantial environmental benefits compared to the use of conventional organic solvents.

Abstract Text

Electronic cigarettes utilize an atomizer to convert a liquid mixture into a vapor, which looks, feels (throat hit), tastes, and produces the desired attributes of conventional cigarette smoke. Little research has been done on electronic cigarettes and the complete chemical components list for these products is unknown. For this reason it is uncertain as to what toxins, if any, could be in electronic cigarette vapor. In this research, we have developed GC-FID and -MS methods for analyzing electronic cigarette liquid and vapor.

Using neat samples of e-juice (electronic cigarette liquid), we were able to develop methods for analyzing both the major and minor chemical components for different electronic cigarette companies. In addition, an exhaustive literature search indicates we are the first to analyze the vapor via thermal desorption. The methods developed for the vapor were used to show cigarette-to-cigarette variability, as well as puff-to-puff variability. These methods yielded both qualitative and quantitative results for the chemical components in electronic cigarettes.

Abstract Text

Proteolysis in cheeses has been characterized by chromatographic and electrophoretic techniques in many varieties of cheese. Manufacturing and ripening conditions of many cheeses are differ and these conditions (e.g., type of coagulant, type of starter culture, ripening temperature, ripening period, salting type or salt concentrations etc) significantly influence the quality of cheese. To understand the combined effects of some parameters on cheese quality characteristics, we aimed to produce a model cheese instead of the production of a defined cheese variety in the experimental study. Because, the results from the model cheese study will be more useful and may be ready for the application of any other cheeses. In this context, the influence of adjunct culture type on proteolysis in a model cheese during ripening were studied by taking into account some factors (e.g., type of culture, ripening time, ripening temperature and salt concentrations). The model cheeses were manufactured using the cultures including *Lactobacillus helveticus*, *L. casei*, *L. plantarum* and *L. delbrueckii* subsp. *bulgaricus*. Different salt concentrations (1-5%), ripening temperatures (4-20 C) and ripening times (1-120 days) were used as independent variables in the structure of the study. Response surface methodology was used to evaluate the effects of the above independent variables on the proteolysis of the cheese. The levels of proteolysis in cheese were monitored by determining of urea-PAGE of caseins, RP-HPLC of peptides and free amino acids, and soluble nitrogenous fractions. Results showed that the response surface methodology was useful tool to understand the effects of these variables on cheese proteolysis and optimization of experimental design to the next step of the study.

Abstract Title **Determination of Phenolic Compounds in Honeys and Their Antioxidant Capacities**

Primary Author Saliha Sahin
Uludag University

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Ayca Tosunoglu, Cevdet Demir, Mesut Ertan Gunes

Abstract Text

Chemical characterization has been carried out on 30 chestnut honey samples collected from Turkey. The phenolic compounds in chestnut honeys were determined by high performance liquid chromatography-diode array detection (HPLC-DAD). The antioxidant capacities of honeys were measured by 2,2-azino-di-(3-ethylbenzothiazoline-sulphonic acid) (ABTS) and a new chromium reducing antioxidant capacity (CHROMAC) methods.

Thirty phenolic markers were used for chromatographic comparison of data, but only 19 of the 30 phenolic compounds were detected in chestnut honeys. Nine of these phenolic compounds were characterized to be flavonoids and the rest of the compounds were phenolic acids. The phenolic compounds detected in the chestnut honey samples collected from different regions were quite different. Gallic acid, protocatechuic acid, p-hydroxybenzoic acid, caffeic acid, syringic acid, p-coumaric acid, ferulic acid, ellagic acid, hesperetin, quercitrin, salicylic acid, quercetin, kaempferol, apigenin, pinocembrin, chrysin, galangin, genkwanin and trans-ferulic acid were detected in chestnut honey. The chestnut honeys are the important antioxidant source for humans because of higher antioxidant capacities determined by ABTS and CHROMAC methods.

The phenolic compound composition of chestnut honey produced in Turkey was reported in detail for the first time in our knowledge. These data could be applied for honey characterization which has great importance for the honey industry due to its important role in the nutritional value of honey.

Abstract Title **Ash and Mineral Composition of Corbicular Bee Pollen from Cliserie System at Highland Mountains in Boyaca, Columbia**

Primary Author Guillermo Salamanca-Grosso
Universidad del Tolima

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Claudina M. Reyes-Villalba, July A. Hernández-López

Abstract Text

Corbicular bee Pollen is an apicultural product, used in human diet for its nutritional value. Daily ingestion of bee pollen is recommended because it is capable to regulate the function of intestines and has benefits on cardiovascular system, skin and vision. Mineral contents of pollen are variable, due to the factors like differences between the plants species, geographical area, and conditions of drying process. The aim of this work has been the determination of the components of the mineral fraction of samples of pollen corbicular in the Andean high plateau of Boyacá. 17 samples from 4 geographical places were collected and analyzed (Tutaza, Sotaquirá, Paipa and Paz del Rio), 2200 to 3100 o.s.v.l; 12-14.2 °C). The ashes were determined gravimetrically after dry digestion in furnace at 550 °C. Subsequently dissolved in nitric and chloric acid mixture. Flame atomic absorption spectroscopy we used in analytical determinations for Ca, Cu, Fe, K, Mn, Na and Zn. Additional measurement were made for total nitrogen and phosphorus. Total ash (g/100) dry pollen were between $2,15 \pm 0,30$ and $2,51 \pm 0,27$; mineral ash components in mg/Kg Ca (1461,7-3129,5); Cu (9,30-17,8); Fe (30,1 - 267,6); K (1769 - 5655); Mg (576,7-1023); Mn (4,92 - 49,1); Na (77,4 -211,5) and Zn (37,2 -143,5), with statistical and significant differences ($P_v < 0,05$) between samples from the same area. Total nitrogen (1,62-3,87) g/100g and Phosphorus (2225- 9790) mg/Kg. The observed differences between the samples may be explained under the botanical origin and the characteristics of the soil in each geographical area. The work contributes to the study of the products of the hive and the differentiation of Colombian types of bee pollen, a natural product of wide demand for human consumption.

Abstract Text

Sensory attributes of color and physicochemical properties of refined vegetable oils are important contributing factors in the determination of their market value. Lovibond system has been used as a tool in the industry of the edible oils for final quality control of color. Many difficulties in the use of this system have arising in practice; in that case the aim of this research was focused in the evaluation of transmittance spectra of commercial edible oils in Colombia. Additional characteristics were defined for their chromatic properties of luminance (L), red/green (a^*), yellow/blue (b^*) and chroma that were measured in Corn, Olive, Rapeseed, Soybean and Sunflower refined and oils under thermal treatment between 210-220°C. Complete information on the chromatic and color properties of a particular oil derived from the transmittance spectra between 400 and 700 nm, with specific shapes according quantity of pigment ported by the seeds. The well-defined absorption band centered for the oils at 450 and 550 nm. The luminance parameter was low in Olive and extra virgin oil. On the other hand chromaticity (a^* ; b^*) for Corn (-1.26; 23.3), Olive (-7.48; 23.3), Rapeseed (-4.92; 9.74), Soybean (-5.87; 9.51) and Sunflower (-3.03; 5.92) showed significant differences. Chroma properties were (24.5) Olive and Corn (23.3), Rapeseed (10.9). The order for luminance was (89.9) < Corn (98.2) < Soybean (99.1) < Olive (98.2). Chromatic properties and shape of transmittance spectra in every each oil change under thermal treatment. Physicochemical properties in fresh oils change after their use in frying process.

Abstract Title **Determination of Sulfur-Containing Species in Scotch Whiskeys Using Gas Chromatography With Pulsed-Flame Photometric Detection**

Primary Author J G. Slaton
Xylem/OI Analytical

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Cynthia Elmore

Abstract Text

The flavor and odor profile of scotch whiskeys is influenced heavily by the presence and relative concentration of sulfur-containing compounds contained therein, which include dimethyl sulfide, dimethyl disulfide, 3-(methylthio)propanol, benzothiophene, and many others. The aging process affects the concentrations of numerous species, and we will present both the key sample introduction details of our analysis, as well as an aging time-dependent concentration map of some of the principle flavor component sulfur compounds present in a selected set of aged and un-aged whiskeys. Performance data collected using a next-generation pulsed-flame photometric detector (PFPD) will be compared with data from a commercially-available PFPD, which has previously demonstrated good utility for sulfur analysis in other applications.

Abstract Text

Pectin is a high value functional food ingredient widely used as a gelling agent and stabilizer in foods. The aim of this study focus on the microstructure changes in orange and mango peels after essential oil and pectin extraction using conventional heating and microwave (mw). Structural changes of the peels were related with the extraction yield, the degree of esterification and the percentage of free carboxyl groups. Mango and orange fruits were used in this research. Scanning electron micrograph for orange and mango peel before and after of treatment was evaluated. Epicarp of fruits were stored at -20 °C, and cut into sizes of 0.5 x 2 cm. The essential oil extraction was performed in a glass vessel of 2.5 L., coupled to a cleverger device which was cooled at -5 °C in a microwave of 2.45 GHz at 600 W for 10 and 20 min. In pectin extraction with conventional heating, epicarp, was treated with acidulated water (10:1), then the enzyme inactivation was carried put at 80 °C for 10 min. and the extraction conditions were at pH, 2.0 and 80°C, by 55 min, (mango) and pH, 1.5, 85°C, 55 min, (orange). Microwave heating extraction, were performed at the same conditions, but applied 500 W and 600 W for mango and orange. Pectin was precipitated with 96% alcohol (1:1), filtered, and washed with ethanol (70 and 96%); finally, the solid was lyophilized. Scanning electron micrograph for orange and mango peel before and after of treatment was made at SEM JEOL, Model JSM 6490LV. Electron source with tungsten filament (0.3 - 30 kV). Secondary electron detector, a backscattered electron detector and an X-ray detector for ESD. The sample of 1 cm x 1 cm surface area was coated with gold in a thickness of 120-150 amstrong during 75 s, using sputtering technique in coating equipment.

Abstract Text

Hexanal is one of many well-documented aromatic components that contribute to flavor and aroma in common consumer food products containing omega-6 fatty acids. Hexanal content is also used to measure the oxidative status of foods rich in omega-6 fatty acids.

Dynamic headspace sampling differs from static headspace sampling in that the headspace above the sample is swept with a gas onto an adsorbent trap, rather than allowing a sample and its headspace to reach a static equilibrium before transferring the volatile compounds to a gas chromatograph/mass spectrometer (GC/MS). Employing dynamic headspace sampling provides all the benefits of static headspace with the low-level detection capabilities similar to analysis by purge and trap.

The hexanal content of two common consumer food products, rice and infant formula, was evaluated for hexanal content. Dynamic headspace was used to concentrate hexanal from food products, minimizing labor intensive solvent extraction and clean up. The hexanal was then separated from other volatile compounds and quantitated with a GC/MS.

Abstract Text

The analysis of wine aromas is a complex process. A reference to a wine's aroma is indicative of the scents associated with the grapes used to make the wine, while the bouquet is an indication of the aging process of the wine. There are hundreds of compounds that can contribute to the overall aroma of wine. In order to determine the aroma compounds, analysts can use static headspace, dynamic headspace, Solid Phase Micro Extraction (SPME), liquid-liquid extraction, etc... This analysis will compare SPME fibers and the efficiency of the SPME fiber coating for wine aroma analysis.

Abstract Text

There are a large variety of volatile compounds that can be found in alcohol. These volatile compounds can add or deter from the flavor of your drink. Trained analysts can often detect the flavors in liquors by smelling and tasting a sample. However, in order to establish the quality and essence of a liquor sample, further testing is required. Gas Chromatography coupled with Mass Spectrometry (GC/MS) is an effective tool for the determination of the flavor compounds in an alcohol. Utilizing different sampling techniques, the respective efficiency in the determination of flavor compounds in whiskey samples will be investigated.

Entech Instruments, Inc.

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Daniel B. Cardin

Abstract Text

With the introduction of SPME in 1990, Food/Flavor/Aroma/Fragrance Chemists were able to see more compounds than ever before, as strong reactive adsorbents could be avoided. Unfortunately, there are several limitations to this technique, brought about by competitive absorption by the matrix, slow uptake of heavier volatiles, fiber swelling and damage by high alcoholic matrices, excessive carryover, and poor sample throughput when performing high sensitivity SPME analyses.

An improved version of SPME, called "Porous Cartridge Micro Extraction (PCME)" is presented here that eliminates many of the shortcomings of SPME. PCME uses a ceramic coated porous metal cartridge containing far more surface area than a SPME fiber. The cartridge can be coated with adsorbents such as PDMS, and has a 1/8" hollow interior that holds up to 100mg of Tenax TA or other adsorbents. PCME has a flow through design that allows creation of a vacuum after the cartridge is inserted into the sample headspace to vastly increase the diffusion rate from the liquid/headspace boundary to the cartridge. Vacuum extractions can occur 4-8 times faster, especially for heavier aromas or off-odors such as Geosmin and 2-methyl-isoborneol (lake water smell) in drinking water with detection down to as low as 1-2 part-per-trillion. Several PCME cartridges can sample simultaneously for improved sensitivity when performing low part-per-trillion level headspace analysis. Data on Geosmin and 2-methyl-isoborneol will be presented, showing a vast improvement in sensitivity and sample throughput relative to classical SPME analysis.

Abstract Text

Peanut allergens are known to bind to phenolic compounds, hydrophobic surfaces, and molecules with ionic charge such as ferric ion (Fe^{3+}). In this study, we prepared magnetic-bead systems with each of these binding properties in hopes that they could remove peanut allergens from a peanut extract. Magnetic beads covalently linked with the phenolic compound, gallic acid (GA), were prepared by incubating aminoethyl beads with GA in the presence of carbodiimide. Hydrophobic beads were purchased commercially. The GA beads and hydrophobic beads were incubated with a peanut extract. For the ferric iron treatment, plain magnetic beads were incubated with a peanut extract that had previously been incubated with ferric sulfate and dialyzed. After incubations the beads were retrieved by using a magnetic device to separate beads from the extracts. Proteins bound to the beads were eluted using 1 M NaCl. Retrieved extracts and eluted proteins were analyzed by SDS-PAGE and ELISA, using a pooled plasma from peanut-allergic individuals and a microplate reader. Results showed that much of the two major peanut allergens were removed by the GA system, while some of these allergens were removed by the Fe^{3+} and hydrophobic systems. Overall, the allergenic capacity (i.e., IgE binding) of the treated extracts were reduced by 30-56% and GA appeared to be the best. In conclusion, the extent of allergen removal depended on the ligands used. The magnetic beads provide a simple way to remove peanut allergens, and could serve as a model system for the development of hypoallergenic products.

Abstract Title **Small Scale Purification of Constituents from Complex Natural Product Extracts Using sub-2- μ m Chromatography**

Primary Author Andrew J. Aubin
Waters Corporation

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Jo-Ann M. Jablonski, Wendy Harrop

Abstract Text

Extracts from natural product samples can be complex often containing a large number of diverse compounds. Increased separation performance of sub-2- μ m column technology along with low dispersion instrumentation provides a tool that produces sharp, narrow, and more concentrated peaks. When there is a need to collect narrow peaks from these complex mixtures, traditional fraction collection instrumentation designed for preparative HPLC conditions does not provide an adequate solution.

Extracts from several natural product samples were analyzed using sub-2- μ m chromatography. Potential peaks of interest were identified and isolated using a fraction collector designed to overcome the limits of traditional fraction collectors. Collection of narrow peaks generated using modern sub-2 μ m chromatography along with closely eluting compounds is demonstrated using a variety of collection modes including time based and peak detection techniques. Analysis of collected fractions to demonstrate purity is shown using both LC and SFC methodologies.

Abstract Text

Molecularly imprinted polymer(MIP) is very useful in separation and sensing fields. As the MIP is usually prepared by the polymerization of the mixture of template, functional monomer, and cross-linking agent, the rigid polymer should be ground to increase the uptake of the target molecule. This process is very tedious and time consuming. We prepared MIP in the fine powder state by the complexation between polymer anion and metal cation using the process of solvent-nonsolvent treatment. The obtained fine powder has higher uptake of template upto the theoretical value. The polymer was prepared with methymethacrylate(MMA) and acrylic acid(AA), and dissolved in dioxane. Template was added into the solution to bind to the polymer, then added metal cation to form a complex. By the addition of non-solvent, the fine powder of MIP was obtained. This process is relatively easier to increase the uptake.

Abstract Text

Molecularly imprinted materials(MIP) is very useful in the separation process but has the problem how to maximize uptake of the template. To increase the uptake, MIP should be obtained in the fine powder state. In this work, MIP was prepared in the form of star-like polymer on the silica surface. The fine particles of TEOS/3-(methoxysilyl)propyl methacrylate which was obtained by sol-gel method was polymerized together with the mixture of MMA/AA in dioxane. In the solution, there are two types: polymer part of MMA/AA and grafted polymer part on silica surface. After removing the polymer of MMA/AA, the fine particles of sol-gel/polymer was obtained. To the sol-gel/polymer, template was imprinted in THF solvent. Then by the addition of metal ion, sol-gel/polymer MIP was prepared. The uptake was very higher close to the theoretical value.

Abstract Text

Hydrazine compounds are known to exhibit toxicity and can potentially damage DNA with low levels of exposure. Hydrazine and alkylated hydrazines are not easily quantified using traditional liquid chromatography as they lack a chromophore to enable traditional UV detection, and gas chromatographic analysis can be troublesome as well due to the high volatility and reactivity of hydrazines. Derivatization is often employed to enable the quantitative analysis of hydrazine and alkylated hydrazines. The derivatizations undertaken in this study had to be easy, fast, and sensitive. Current work has focused on developing and employing facile derivatization to permit quantitative analysis of hydrazine using traditional chromatographies at parts per billion levels from solid matrices.

Abstract Title **How Scalable are the Dispersion Processes in Real Columns Packed with Solid Core Material?**

Primary Author Tony Edge
Thermo Fisher Scientific

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Luisa Pereira, Monica Dolci

Abstract Text

The improvement in efficiency observed with solid core silica-based substrates comes from the greater uniformity in the particle substrate, which allows for better packing efficiencies, a reduction in the void volume of the column which lowers the longitudinal diffusion and also the reduction in mass transfer effects due to the reduced pore depth offered by the solid-core material. This poster will examine the contributions of all of the three dispersion terms and determine if the current models match the practical gains that have been previously demonstrated.

An investigation on the effects of particle size will also be performed, focussing on three sizes ranging from 4 μm down to sub 2 μm . This will look at how scalable the efficiency gains are in comparison with fully porous materials and also investigate the effects of extra column dead volume. Example separations will be used to investigate the effects that reducing the particle size can have on the selectivity. It has been previously reported that increases in the pressure within a chromatographic system can affect the retention mechanism due to a shift in the equilibrium of the analyte stationary phase complex formation process, and this will be investigated with a range of different compounds to see if this is a phenomena that separation scientists have to consider in the transfer of methods. The use of smaller particles creates higher pressure drops across the columns which will result in increased temperature gradients. This will be investigated to determine the effect that the pressure induced temperature gradients can have on the performance of the separation, and the effects that running the system in a nominally isothermal mode compared to performing the same separation in an adiabatic mode will have on the overall performance of the separation. To establish these two different modes of temperature control a new column oven which allows for forced air heating and still air heating will be employed.

Abstract Text

Core-shell silica has been raising the bar for high efficiency separations in reversed phase for several years now. Currently, other modes of chromatography are attempting to take advantage of core-shell silica as well. To date, almost all core-shell silica based "HILIC" columns are simply unmodified silica. Further, the impact of the mobile phases applied in HILIC on the advantages of core-shell silica have not been well studied. In this work, HILIC stationary phases comprised of specifically designed cyclic oligosaccharides bonded to superficially porous silica particles were developed. Their performance in HILIC was evaluated and compared to fully porous silica particles with 5 μ m and 3 μ m diameters. Faster and more efficient chromatography was achieved. The columns were also evaluated in the normal phase mode. The peak efficiency, analysis time, resolution, and overall separation capabilities in both HILIC and normal phase modes are compared. At higher flow rates, the mass transfer advantage of the superficially porous particles was more pronounced in normal phase separations than in HILIC, demonstrating clearly the influence of the mobile phase in the mass transfer of the analyte. Yet, the minimum reduced plate heights were typically lower in HILIC than NP. Overall, the superficially porous particle based columns showed advantages over the fully porous particle columns, in terms of high throughput and efficient separations at high flow rates, allowing for very fast separations to be performed.

Abstract Title **Retention Behavior of Aromatic Compounds When Using a Fluorophenyl HPLC Stationary Phase Under Highly Aqueous Mobile Phase Conditions**

Primary Author Brittany George
Ursinus College

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Eric Williamsen

Abstract Text

Fluorinated stationary phases are commercially available and are useful in separations of compounds of interest to the pharmaceutical as well as other industries. Although a number of literature studies have appeared, the retention characteristics of these phases are not well characterized, and few comparisons between fluorinated and similar non-fluorinated phases have been reported. Retention of approximately 40 aromatic analytes with phenyl, alcohol, nitro, cyano, halogenated, and other functionality was measured using a fluorophenyl stationary phase at temperatures ranging from 5.0 to 65.0 °C and with a mobile phase composition of 10% methanol/ 90% water (v/v). By analyzing the retention data through van't Hoff and selectivity plots, the effect of temperature and the thermodynamics of the retention process are presented. To demonstrate how this stationary phase is affected by mobile phase composition and how the retention behavior may be different than for other similar phases, similar results will be presented for other mobile phase conditions, such as by changing the organic component to acetonitrile or varying the organic/water ratio, and to using a phenyl stationary phase under the same conditions.

ChromaNik Technologies Inc.

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Shun Kojima, Tomoyasu Tuskamoto

Abstract Text

The feature of superficially porous particle used as a highly efficient material is existence of a core, a thin porous layer and narrow particle size distribution, which lead to higher efficiency than totally porous particle. On the other hand, recently a monodisperse silica gel has been presented to be the almost same particle size distribution as a superficially porous silica and to be higher performance materials than a conventional totally porous silica. In this study, a monodisperse totally porous silica and a superficially porous silica were compared regarding theoretical plate and Van Deemter plot. As a result of a plate measurement, a monodisperse silica showed 16% higher theoretical plate than a conventional totally porous silica, while a superficially porous silica indicated 50% higher. It was led by comparing with Van Deemter plot that only A term of Van Deemter Equation was decreased by effect of narrow particle size distribution and both B and C terms were reduced by effect of a thickness of porous silica layer. It was elucidated that predominance of superficially porous silica over totally porous silica was led by not only low Eddy diffusion due to narrow particle size distribution but also both low longitudinal diffusion and short mass transfer path due to a thin porous layer.

Abstract Text

Recent spectrometric studies have shown that stable nanobubbles, bubbles of submicrometer size, can easily be trapped inside hydrophobic cavities of alkyl-bonded silica. This phenomenon can be explained in terms of capillary effect and the cavity geometry.

It has been reported that aqueous solutions are frequently expelled from the pores of hydrophobic porous materials in reversed-phase liquid chromatography (RPLC). This result is consistent with the observation of spectrometric studies and the pores from which liquid water has been excluded may be occupied by a gas phase.

The separation mechanism in reversed-phase systems has been explained by various models e. g. adsorption of analytes onto the hydrophobic surface and partition into the hydrophobic moieties. On the other hand, Shibukawa et al. showed that separation of inorganic ions and hydrophilic organic compounds in the reversed-phase systems can be successfully explained by the partition between the hydrophobic interfacial water and the bulk water [1]. The nanobubbles fixed in the pores may also act as a separation medium for volatile compounds. This means that we are able to make a hybrid separation medium consisting of the interfacial water, hydrophobic moieties and nanobubbles.

In this paper, we will present a new liquid chromatography with the hybrid stationary phase consisting of the bubbles, the interfacial water and the hydrophobic moiety, surface bubble modulated liquid chromatography (SBMLC). The retention volumes of various compounds and the volume of the interfacial water depend on the back pressure of the column. This indicates that, in aqueous mobile phase systems, the interface between the bonded layer and water or the hydrophobic interfacial water has a key role in retention and that the retention selectivity can be easily manipulated by the applied pressure on the SBMLC column.

Abstract Text

A novel two-dimensional LC (2D LC) has been developed and successfully applied to phospholipids, polyphenols and medicinal compounds in biological, food and crude drug samples respectively. A comprehensive 2D LC is recognized as very effective strategy for both quantitative and qualitative analyses, especially for natural and biological samples in complex matrices. However, the combined effect of the necessity to minimize band broadening in the 1st dimension and the very short analysis time in the 2nd dimension has been a difficulty for spreading this technology. Recent progress in the technology of solvent delivery at very low flow rate and ultra-high speed HPLC (UHPLC) analysis realizes a practical and comprehensive 2D LC. Our new, truly comprehensive 2D LC system, "Nexera-e", combines our latest UHPLC Nexera X2 product line with photo diode array and/or mass spectrometric detectors. Comprehensive 2D LC allows for highly efficient separation of a variety of samples, even in complex matrices, as well as ordinary quantitative analysis. The orthogonal separation selectivity between 1st and 2nd dimensions is a key issue for this technique but difficult to accomplish due to solvent compatibility and column selection in the 1st and 2nd dimensions. In our study for improving the limited orthogonality, it showed dramatic improvement when employing a shifted gradient profile in the 2nd dimension, where initial and final mobile phase composition increase stepwisely, to match the 1st dimension gradient profile. Raw data is mathematically manipulated by dedicated software, resulting in enhanced peak capacity and identification ability compared to those of independent 1D and 2D separations.

Abstract Text

Fluorinated HPLC stationary phases are commercially available and useful in separations of fluorinated compounds and compounds of biological interest. Although the literature contains a number of studies using fluorinated stationary phases, a complete understanding of how fluorinated stationary phases interact with analytes has not been obtained. Retention of over 40 aromatic analytes with phenyl, alcohol, nitro, cyano, halogenated, and other functionality have been measured on fluoro octyl, octyl, phenyl, and fluorophenyl stationary phases. The measurements were made at temperatures ranging from 5.0 to 65.0 °C and with various compositions of organic (methanol or acetonitrile) and water mobile phase mixtures. Differences in retention and how retention changes in response to temperature and mobile phase composition have been observed when using fluorinated and similar hydrocarbon phases. To gain a better understanding of these differences, a number of multivariate analysis techniques, such as cluster analysis and principal component analysis; k-k plots; and linear solvation energy relationships (LSER) have been applied to this data. The cluster analysis and k-k plots emphasize similarities and differences in the retention behavior without providing much direct evidence of the underlying processes that lead to retention while LSER provides more information on the importance of the various interactions that lead to retention. We will discuss the advantages and disadvantages of using these various analysis techniques, show some of the similarities and differences in the retention behavior when using these four stationary phases, and start providing a potential explanation of the interactions that lead to the observed retention behavior.

Abstract Text

A column packed with core shell particles has been widely used on HPLC and UHPLC, because it showed not only excellent column efficiency but also lower back pressure than sub-2 um column. More than 20 kinds of core shell column are available in the market. It is said that two types of core shell silica particle are used. One is a mono-layer structure as a porous silica layer like a core shell silica manufactured by Advanced Materials Technology and another is a multi-layer structure like that manufactured by Phenomenex using so-called layer-by layer method.

In this study, a separation behavior, stability and physical property for Kinetex C18, Accucore C18, Cortecs C18, PoroShell C18 EC, Ascentis Express C18 and SunShell C18 were evaluated. Retention factor, hydrogen bonding capacity, hydrophobicity and steric selectivity were measured using Tanaka method. Not only peak shape of neutral, acidic and basic compounds but also loading capacity of amitriptyline under neutral and acidic conditions were also measured. Furthermore stability under acidic pH1 and basic pH10 conditions was evaluated. Regarding physical property, carbon loading of each C18 packing material, and specific surface area, pore volume, pore diameter of each core shell silica which was deleted alkyl chains by calcination at 600 degree Celsius for 8 hours were measured. As a result, the big difference was recognized among 6 kinds of core shell C18s for separation behavior, stability and physical property. This difference is considered to be due to each manufacturing method and bonding technique as well as fully porous silica C18s. SunShell C18 showed the largest retention factor and the highest stability though its carbon loading is not the highest, while Kinetex C18 showed the lowest retention factor, the lowest carbon loading and the lowest specific surface area.

Abstract Text

Software for identification of unknown materials by comparison against known-sample databases or spectral libraries has been standard for FTIR, MS, and other techniques almost since the introduction of the personal computer. For Differential Scanning Calorimetry (DSC) this has not been the case, perhaps due to the seemingly limitless variables which can affect scan results such as heating rate, purge gas type and flow rate, crucible type, etc. Recently, however, a powerful new DSC curve recognition and interpretation software called "Identify" has been introduced which allows for DSC curve comparison against a built-in database system providing polymer identification with a single click. This is useful for formulation studies and also for quality control and quality assurance. This poster will detail how the new "Identify" software is applied to DSC results to identify the composition of polymeric materials and mixtures.

Abstract Text

The polyethylenes (LDPE, LLDPE, HDPE) are the most industrially produced synthetic polymers in volume with a production of around 75 MT a year. The LLDPE which is produced by coordination catalysis is a copolymer of ethylene with a α -olefin (typically hexene or octene). One of its main advantage is that its structure and consequently its properties are easily adjustable by variation of the co-monomer content (short chain branching). It is thus of high interest to determine the structure of LLDPE. A range of crystalline copolymers of ethylene with α -olefins (propene, hexene, octene, octadecene and norbornene) were prepared using the complexes $\text{Et}(\text{Ind})_2\text{ZrCl}_2$ and $(\text{nBuCp})_2\text{ZrCl}_2$ activated with MAO. The average composition of the copolymers was measured using ^1H , ^{13}C NMR and TREF. The samples were characterized by coupling of the TGA with the GC-MS technique to get information about the structure of LLDPE.

For a clearer understanding of certain reactions, the TGA technique is often coupled to mass spectrometry (MS) and infrared spectroscopy (IR) for identifying the gaseous compounds emitted during thermal decomposition of the sample. When it comes to complex materials such as LLDPE, then gas mixtures are produced but the majority of components cannot be identified precisely with MS or IR. In this case, coupling of the TGA with the GC-MS technique offers interesting advantages. The emitted compounds are first separated by gas chromatography (GC) then identified and quantified by MS. An innovative TGA/IST16/GC/MS coupling is presented that significantly increase the number of data collected and thus provides an efficient way to take advantage of the GC/MS technique. The configuration uses a fractions collector inserted between the TGA and the GC. This coupling is a powerful and versatile tool for interpretation of structure of LLDPE. An example with characterization of several polyethylene samples will illustrate this.

Abstract Text

Although the use of chemical warfare nerve agents (CWNA), such as sarin, and VX is forbidden by the Chemical Weapons Convention, documented cases of the use of these nerve agents exist. For infants and small children, the risk for inhalation and dermal exposure to CWNA may be greater than adults due to greater minute ventilation rates and larger surface area to body mass ratios, respectively. The developing nervous system is particularly vulnerable to xenobiotics that disrupt the cholinergic system. Numerous studies have been done on the developmental neurotoxicity in rats of organophosphate pesticides, such as chlorpyrifos. However, there have been relatively few studies on the developmental neurotoxicity of CWNA exposure. In support of efforts to characterize the behavioral and neuropathological effects associated with developmental exposure to sarin, the biomonitoring of sarin in various biological matrices from rats following whole-body inhalation exposure has been evaluated using the technique of fluoride ion regeneration followed by GC-MS/MS analysis.

Extracts of indicative biomarkers were obtained from blood and tissues from rats exposed to sarin via an inhalation route (60 minutes at 0.6xLC50) using fluoride ion to release bound agent from adduct sites, isolating the agent with a C18 solid phase extraction column, and eluting with ethyl acetate. Prior to extraction, tissue samples were subjected to freeze-fracture pulverization under cryogenic temperatures and homogenized using focused acoustic energy. The extracts were analyzed by chemical ionization gas chromatography tandem mass spectrometry. The multiple reaction monitoring mode was used for detection, and quantitation was accomplished with a deuterated stable isotope as an internal standard.

Results presented will show the successful application of the method to the analysis of blood and tissues from postnatal day (PND) 14, PND 21, and PND 42 rats taken at selected time points following exposure.

Abstract Text

Melamine, a nitrogen-rich chemical, (2,4,6-triamino-1,3,5-triazine) was intentionally added by some company to foods (liquid milk or milk powder) and animal feed to boost the apparent protein content in 2007. Today, pet foods and infant formula products, contaminated with melamine, have created a widespread food safety scare^{1,2}.

The detection of melamine with MIP has been the subject of intense research. In this study, melamine imprinted polymeric films were prepared on Quartz Crystal Microbalance (QCM) chip. Firstly, template molecule (melamine) and functional monomers (acrylamide and methacrylic acid) were preorganized and then, preorganized complex and crosslinker monomer (Methylenbisacrylamide) were polymerized with UV irradiation. The MIP nanofilms were characterized by SEM and atomic force microscopy. After the characterization studies, the imprinted and non-imprinted QCM sensors were connected to QCM system to obtain the kinetic and affinity studies for the target molecule. Imprinted nanofilms showed more sensitivity to melamine than non-imprinted ones. Langmuir adsorption model was found as the most suitable model for this affinity system. In order to show the selectivity of the melamine imprinted nanofilms, competitive adsorption of melamine and cyromazine was investigated. The results showed that the imprinted nanosensor has high selectivity and sensitivity for melamine.

Abstract Text

Identification of drugs of abuse is an increasing challenge for analytical laboratories. Liquid or gas chromatography mass spectrometry (MS) is often utilized for this analysis. Many drugs are structural isomers and cannot be distinguished by MS of the intact ion. Chromatography can often resolve isomers at the cost of increased analysis time. Collisionally induced dissociation (CID) in the mass spectrometer may distinguish structural isomers without use of chromatography. This study was performed to determine if direct sample analysis (DSA) combined with high mass accuracy TOF MS analysis of CID fragments can differentiate isobaric drugs in mixtures. Sample analysis was performed using a PerkinElmer AxION 2 TOF MS fitted with a DSA source. Collisionally induced fragmentation was induced at the capillary exit of the TOF. Analytes were prepared in methanol and applied to a stainless steel mesh for DSA-TOF analysis using AxION DSA Controller AxION Solo software. 12 isobaric drug pairs were analyzed in this study. DSA-TOF analysis distinguished 11 of the isobaric pairs using unique fragment ions. For example, scopolamine and cocaine (C₁₇H₂₁NO₄) were uniquely identified using fragment ions at m/z 138.0918 (scopolamine) and m/z 182.1185 (cocaine). In addition, scopolamine and cocaine were mixed in variable proportions and the diagnostic ions varied with analyte concentrations. One isobaric drug pair, O-Desmethylvenlafaxine and Tramadol, did not produce unique fragment ions but could be distinguished using differences in the relative abundance of a shared fragment ion. These results demonstrate that isobars can be rapidly distinguished without chromatography using DSA-TOF analysis of CID fragments.

Abstract Text

Techniques to interrogate hair samples have proven valuable in detecting human host exposure to drugs of abuse over a long sampling window. The hair matrix is challenging to work with and a number of methods have been reported. This investigation details the feasibility of incorporating an automated bead mill to homogenize the matrix and disrupt non-selective analyte binding on a molecular level by destroying the matrix on a macro-level. It was determined that the bead mill was effective in improving the efficiency of the subsequent digestion familiar to hair testing protocols. Proof of concept was determined using adult human head hair samples (n=5) which were prepared in duplicate using the laboratories standard preparation procedure (cutting the hair into 1-2mm segments using scissors) versus automation in the bead mill at the Center for Forensic Science Research and Education (Willowgrove, PA) using a Biotage BeadRuptor 24. The homogenized samples were incubated overnight in methanol at 40 °C, filtered and evaporated to dryness. The sample tubes were sent to Leco's application lab (Saint Joseph, Michigan) for derivatization and various GC-TOF platform analyses) followed by post acquisition deconvolution software. A GCxGC approach was employed to mitigate a co-eluting peak tentatively identified by PBM software as TMS-urea. Preliminary data suggests alternatives to GCxGC may be found in SPE techniques prior to single stage GC-MS. Additional samples from a range of individuals (age and sex) were similarly prepared and tested via the optimized GCxGC-TOF method showing the method to be effective in separating GHB-2TMS from endogenous interferences. This presentation will have impact on the forensic community by increasing awareness of alternative instrumental techniques that can be used to optimize the determination of silylated-GHB in hair.

Abstract Title **Blood Alcohol Determination Using Static Headspace Analysis with Optimized Sample Throughput**

Primary Author Anne Jurek
EST Analytical

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Kelly Cravenor, Lindsey Pyron

Abstract Text

There are several ways to determine the amount of alcohol that is in a person's system. The most common methods are breath analysis in the field and blood analysis in the lab. Blood alcohol determination in the laboratory is used predominantly when a person refuses a breath test. In order to determine blood alcohol content, a person's blood has to be withdrawn as soon as possible after the occurrence. Furthermore, the blood needs to be collected in duplicate in order to confirm the test results. This application note will examine static headspace sampling of alcohol standards using Gas Chromatography (GC) for separation and Flame Ionization Detection (FID) for analysis. The linearity of the compounds of interest will be examined and compared using a secondary column for confirmation. Additionally, as many forensic labs have an excess of samples to examine, the use of software innovations will aid in optimizing sample throughput.

Abstract Text

Glucose is the essential nutrient in vivo metabolism because the heat released by its oxidation is an important source of energy for human life. Blood glucose level is also an indicator of human health conditions, and it should maintain a certain concentration in order to maintain the body organs and tissues need [1].

Colorimetric biosensing has attracted much attention due to its low cost, simplicity, and practicality. Since color changes can be discriminated by naked eyes, colorimetric biosensing does not require expensive or sophisticated instrumentation and can be applied to field analysis and point-of-care diagnosis [2,3].

In this study, 2-aminothiazole was polymerized via enzymatic polymerization with bi-enzyme system in aqueous solution containing iron nanoparticles (FeNPs). Poly (2-aminothiazole) covered bi-enzyme system was characterized and used for glucose determination by spectroscopic method. Some parameters for glucose determination were also optimized.

Abstract Text

Globular proteins are transformed from the native state into the intermediate states or into the denaturated state under different conditions as low pH, high concentrations of denaturant, heating, etc. Despite some common features, a coherent picture of the intermediate state is still subject of debate and independent investigations are necessary for each case. In this study, pH-induced transition of holo-form of bovine [alpha]-lactalbumin from the native to the intermediate state was analyzed by probing its tertiary and secondary structure using concerted spectroscopic approach. 2D correlation spectroscopy combined with principle component analysis (PCA) can provide deeper insight into the changes developed at level of tertiary and secondary structure of protein. To better understand transition native to intermediate state of [alpha]-lactalbumin, 2D correlation analysis was applied to the pH-dependent IR and Raman spectra of [alpha]-lactalbumin. In this presentation, details of pH-induced transition of [alpha]-lactalbumin will be discussed.

Abstract Title **Assessment of the Stability of Pain-Relieving Components in Children's Nonsteroidal Anti-Inflammatory Drugs by Multivariate Spectrometric and Chemometric Methods**

Primary Author Mark T. Stauffer
University of Pittsburgh Greensburg

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Joshua M. Blaker

Abstract Text

The effects of time, temperature, and humidity on the stability of pain-relieving components in children's nonsteroidal anti-inflammatory drugs (NSAIDs) are the foci of this presentation. To minimize the decomposition of pain-relieving components in NSAIDs, selection of appropriate storage conditions to prolong the effectiveness of the painkillers is essential to the health of infants and young children. Acetylsalicylic acid (aspirin), the most commonly used analgesic, is available in prescription and over-the-counter forms. The degradation of aspirin into salicylic acid and acetic acid renders the aspirin both ineffective for treating pain and harmful to consumers. The goals of this research are: (1) to assess the effects of time, temperature, and humidity on pain-relieving components in children's NSAIDs, and (2) to supply parents and health care providers with information on safe storage conditions for painkillers.

The NSAIDs to be studied will be subjected to storage conditions which span various levels of time, temperature, and humidity. The quality of aspirin in the NSAIDs, in terms of acetylsalicylic, salicylic, and acetic acid concentrations, will be determined by spectrometric (e.g. second-derivative and multicomponent spectrophotometry) and chemometric (e.g. principal component analysis (PCA) and regression techniques such as ordinary least squares (OLSR), partial least-squares (PLSR), and principal component (PCR) regression) methods. Sample preparation, multivariate calibration, and analytical determination methodologies will be presented and discussed, as will the results of the study to date and their significance.

Abstract Text

Acid rain hurts growth of plants, because it damages not only cells/ tissues of plants but also the metabolism such as the activity of the enzyme. Here, we used the optical beam deflection method and absorption spectrometry for investigating effects of acid solution on a plant. Egeria was used as a model plant. In absorbance experiments, a piece of Egeria was put in a beaker with 20 ml HCl solution for a certain time. Then absorbance was measured. In the experiment of the deflection method, a He-Ne laser was used as a light source of the probe beam. The probe beam was focused to a vicinity of Egeria in a culture dish by an objective lens. Deflection signals of the probe beam were monitored by a position sensor. The effects of acidic solutions and the distance between the probe beam and the leaf of Egeria were studied. Absorbance spectra of the HCl solutions with immersing time of the Egeria showed an absorbance peak around 320 nm. This suggested that some compounds were leaked from the Egeria into the HCl solution. Changes of absorbance and deflection signals with immersing time of Egeria were examined for the HCl concentrations with different pH. The changing trends with time of absorbance and deflection signals were similar, but the absorbance changing was delayed for about 2-3 hours. The deflection method was more sensitive than the absorption spectroscopy.

Abstract Title **Studies of Chromium-6 Concentrations in Drinking Water Samples Coming From Three Different Sources of Water: Ground, Surface and Well Waters**

Primary Author Andrea M. Temple
Indiana University Southeast

Date: Thursday, March 12, 2015 - Morning
Time:

Room: Exposition Floor, Hall F, Aisles 390

Co-Author(s) Brian M. Young, Jessica E. Wiggington, Nicholas A. Long, Patty L. Ranaivo, Thomas B. Jorgensen

Abstract Text

Chromium exists in various oxidation states and there are two stable forms of chromium that can be found in the environment: trivalent (Cr³⁺ or Cr[III]) and hexavalent (Cr⁶⁺ or Cr[VI]) chromium. Both forms of chromium can be found naturally in the environment: in air, water or soil; but their existence is pH dependent. Cr(VI) is present in neutral or alkaline environment and can be converted to Cr(III) in acidic environment. Their toxicity level is also oxidation state dependent: Cr(III) is safe and an essential nutrient for humans, while Cr(VI) is known to be toxic and carcinogen.

In this study, the concentration of Cr(VI) in drinking water samples coming from three different types of sources were determined and compared. The sampling sites were within a 50 miles radius and their sources were ground water, surface water and well water. Additionally, the concentrations of Cr (VI) were analyzed from the influent and effluent of waste water treatment plants. A preliminary spectrophotometric method using 1,5-diphenylcarbazide as a reagent to react with Cr(VI) analyte was used and gave the following results: the method detection limit (MDL) ranged from 0.24 to 0.54 µg/L, precision from 0.41 to 0.81% and accuracy from 94.9 to 106.0%. Cr(VI) was detected in all three sources of water. The majority of Cr(VI) concentrations in drinking water samples from ground water were found to be less than the MDL value. Cr(VI) concentrations in drinking water samples from surface waters were from 1.6 to 10.1 µg/L and from 0.6 to 6.6 µg/L in drinking water samples from wells water.

Additional studies will be conducted to better understand the mapping of Cr(VI) concentrations, the origin of Cr(VI) and the correlation between these three sources of water within the 50 miles radius of sampling sites. The study will also include a development of on-site method to analyze Cr(VI) concentration as they are being collected.

Abstract Text

In the present investigation, we synthesize intrinsic and extrinsic MgO₂ nanofilm on glass substrates using chemical dip method. MgO₂ was doped with different dopant concentration (0%, 0.1%, 1% and 10%) of Neodymium and thin films of it was also made using chemical dip method. MgO₂nanofilms are synthesized using chemical dip method because this method is environmentally as well as economically friendly as compared to other methods. Structure and morphology of materials were determined using X-ray diffraction (XRD), Scanning electron microscope (SEM), UV-Visible spectroscopy (UV-Vis.) and particle thickness by ellipsometry spectroscopy . The XRD pattern showed that MgO₂ nano material thin films and thin films of material doped with Neodymium were of amorphous in nature. Reflectance spectra of these samples were carried out in the range of 200-800nm at room temperature. Optical band studies show that the films are highly transparent and exhibit a direct band gap. Band gap of as prepared nanomaterials and doped nanomaterials is investigated using tauc plot. The bandgap of pure MgO₂ thin films has been found to be lie in the range of 3.875 eV. The band gap of MgO₂ thin film increases on doping with Neodymium. Thickness of the prepared nanomaterial MgO₂ and with doped Neodymium thin films on glass substrate were carried out by ellipsometry spectroscopy. It was observed that the thickness of the thin films decreases on doping with Neodymium. SEM images of as prepared pure and rare earth metal Nd doped MgO₂ nanoparticles on glass substrates were taken at different magnification and resolution. SEM images of pure MgO₂ thin films shows grains are of uniform shape whereas on doping with Neodymium, sem shows irregular shape. This study would provides to us useful information about the changes in physical properties when we dope MgO₂ with Neodymium.

Abstract Text

Using raw GC-MS data for chemometric analysis often results in more robust models, as peak detection and integration errors are avoided. One challenge is the enormity of variables especially when high data rate mass analyzers are used. In GC×GC-MS, fast detectors are a necessity due to the narrow second-dimension peaks observed. Consequently huge numbers of variables cannot be avoided in these experiments. This necessitates some variable reduction prior to chemometric analysis.

In an earlier report, we developed a data reduction tool termed unique ion filter (UIF), which provides an objective approach to feature reduction without compromising the multivariate nature of the raw data. This tool is applicable to GC/LC coupled with any multivariate data.

In our current work, we extend UIF's variable reduction capabilities to comprehensive multidimensional separation with multivariate detection data, e.g. GC×GC–MS. GC×GC–MS data is essentially GC-MS data which can be folded into a 3D block using the modulation period and the data rate of the detector. Hence UIF can be applied to the raw data in GC-MS or GC×GC–MS modes.

In this study, we explore a new algorithm for m/z identification for GC×GC–MS data. We also compare the application of the UIF on raw data in GC-MS and GC×GC-MS modes for subsequent chemometric modeling to the use of peak tables obtained from commercial software as a data reduction strategy.

Abstract Text

The National Institute of Standards and Technology (NIST) is a non-regulatory government agency within the Department of Commerce with the mission "To promote U.S. innovation and industrial competitiveness by advancing measurement science, standards, and technology in ways that enhance economic security and improve our quality of life". This mission, guides the separations research at NIST towards improving measurement capabilities via several different routes. (1) A fundamental understanding of separation mechanisms is essential for understanding how to tune conditions to maximize separations. A good example of this is the work performed by Sander and Wise to study and elucidate shape selectivity, which is useful for the separation of geometrically constrained isomers. (2) The application of this fundamental knowledge can be used for the design of stationary phases tailored specific separation tasks. (3) The application of cutting edge separation technologies, such as multi-dimensional separations, is studied to determine the applicability of the new techniques to the determination of analytes in complex matrices. Lessons learned from stationary phase synthesis, column characterization, and multidimensional chromatography will be discussed.

Abstract Title **Development of an Analytical Toolbox for Characterization of Protein and Polysaccharide-Conjugate Vaccine Antigens based on Traditional and Novel Column Technologies**

Primary Author Nathan Lacher
Pfizer Inc.

Date: Thursday, March 12, 2015 - Afternoon

Time: 02:45 PM

Room: 238

Co-Author(s)

Abstract Text

The presentation will describe the development of chromatographic methods that are part of an analytical toolbox that can be utilized for the advancement of vaccine candidates from discovery through commercialization. The vaccine antigens in this case consist of different constructs including protein antigens by themselves, peptides or small molecules conjugated to carrier proteins, or polysaccharides conjugated to a carrier proteins. As part of development, traditional and novel column technologies were evaluated for the characterization of size, charge, purity, and titer as well as other attributes that may impact the immunogenicity of the vaccine candidate. In many cases it is also desirable to discriminate amongst several different antigens included in a drug product that also may include an adjuvant. Since there is quite a bit of diversity in the molecular properties for the vaccines in development, there is currently not a one size fits all approach for vaccines as may be the case for many monoclonal antibodies in development. This presentation will focus on some of the highlights from our recent chromatographic method development activities to progress the vaccine portfolio which utilizes some new instrumentation and novel column technologies.

Abstract Text

Food allergy is a major public health concern that affects up to 8% of children and up to 2% of the adult population. To protect the allergic consumer with accurate food allergen labeling, reliable analytical methods are required for allergen detection and quantification. These methods must be effective in spite of food processing-induced changes in the biophysical and immunological properties of multiple allergen proteins in a food matrix. The present work is focused on the application of analytical techniques used to decipher the chemistry that underlies allergen protein interactions in thermally processed foods.

Combining enhanced solubilization and sophisticated protein fractionation with high resolution mass spectrometry (MS), enables a peptide-specific view of changes in allergen proteins using variable sample extraction and processing conditions. Size-selective GELFrEE fractionation is coupled with liquid chromatography (LC)-MS in a multidimensional platform developed for comprehensive global mapping of the [i]A. hypogaea[/i] proteome. Visualization of allergen peptide molecular distributions by GELFrEE-LC-MS/MS, moreover, aids in the identification of protein rearrangements, modifications, and structural isoforms in peanuts. Expanding upon this work, a comprehensive LC-MS/MS platform is applied for simultaneous multi-allergen detection in thermally-processed food samples incurred with milk, egg, and peanut. Relative quantification of allergens in protein lysates was accomplished by label-free spectral feature (MS1) LC-MS/MS methodologies to identify differentially-abundant peptides resulting from thermally-induced protein modifications. A combined analytical approach incorporating global proteomic screening with qualitative gel-based analyses promotes an advanced understanding of fundamental changes in allergen proteins induced by food processing chemistry, thereby improving the performance of detection methods for allergens in complex food systems.

Abstract Text

Complex samples with multiple compound classes present, compound similarity (isomers), and a wide range of analyte concentrations all present a challenge to conventional gas chromatographic (GC) separation techniques. One powerful technique for the analysis of complex samples is comprehensive two-dimensional gas chromatography (GC×GC). Another is a recently developed vacuum UV (VUV) detector that can be coupled to a GC and is capable of collecting full spectral scans from 125 to 240 nm on the millisecond time scale with less than 1 nm spectral resolution. VUV spectra can be compared to reference spectra, although relatively few are available, compared to known experimental standards, or predicted by molecular modeling to confirm structure. The VUV detector is capable of providing compound quantification as well. The VUV has shown promise in differentiating chemical classes, some of which include: alcohols, aldehydes, esters, acids, glycol ethers, amines, thiols, sulfides, chlorinated aliphatics. Use of specific spectral ranges can aid selective detection of certain compounds or enhance detector sensitivity. The combination of the new VUV detector with a GC×GC instrument may provide the next step towards 'routine' analysis of complex samples in regards to class separation and quantification. In this presentation, the coupling of a VUV detector with a reverse fill/flush flow modulation (RFF) comprehensive GC×GC instrument for selected industrial applications will be presented.

Abstract Text

Metallic nanostructures with their ability of confining and enhancing incident light offer unique possibilities for manipulating light at the nanoscale.[1] Plasmons can efficiently capture incident light and focus it to nanometer sized hotspots which can enhance electronic and vibrational excitations in nearby structures. In this talk, I will discuss how recently discovered fundamental plasmonics effects, plasmonic Fano resonances and quantum plasmonics, can be exploited for surface enhanced spectroscopies. Plasmonic Fano resonances with their characteristic narrow and asymmetric line shapes can provide very large field enhancements making such modes particularly useful in LSPR sensing and surface enhanced spectroscopies such as SERS,[2] Four-wave mixing,[3] and SECARS.[4] Quantum mechanical effects such as electron tunneling[5] and hot carrier generation[6] on the surface of a plasmonic nanostructure can induce charge transfer into adsorbed molecules and change their cross sections.

Abstract Text

The near field enhancement in tip-enhanced Raman spectroscopy (TERS) implicitly relies on the tip-sample interaction as part of the tip's surface plasmon resonance. While this resonance can be considered to be spectrally large as compared to the Raman signature, the exact peak position does significantly depend on the dielectric permittivity of the surrounding media and in particular the local refractive index of the sample environment as part of this media.

Our initial experiments were meant to demonstrate the chemical and structural integrity of ferroelectric nanostructures and while we were indeed able to achieve a spatial resolution below 5 nm, the back-scattered light contained a strong tip signature that was superimposed to a relatively weak Raman signal from the sample. Approximating the surface plasmon resonance by a Lorentzian line shape paved the way to discriminating tip again sample contributions.

We thus demonstrate for the initial case of inorganic nanostructures how residual fluorescence from the apex of the gold tip can be used to determine the relative shift of the surface plasmon resonance which has three immediate implications: first, the quality factor of TERS tips depends strongly on the sample so there is no 'perfect' TERS tip to cater for all samples and second, the peak intensities of the Raman spectrum become a function of the envelope of the enhancing surface plasmon, which depends again on the position on the sample. Last but not least, we demonstrate how to extract local refractive index variations of the sample with a sensitivity of better than 10 percent relative change, which enables detection schemes for local phase transformations, variations of oxidation states or at least a direct optical signature from the tip, which is modulated through the sample in cases where the Raman signature might be otherwise undetectable.

Abstract Text

Intra- and intermolecular coupling and dynamics determines chemical reaction, charge transfer, biological, and catalytic activity of molecules. Spectroscopic access has continued to challenge vibrational photon-echo and its multidimensional spectroscopy implementations to probe the homogeneous system response. In contrast, tip-enhanced Raman spectroscopy (TERS) can intrinsically probe at the homogeneous sample size limit by virtue of its nano-meter spatial resolution and single molecule sensitivity. We perform systematic TERS measurements at cryogenic and variable temperature of dilute malachite green monolayer physisorbed on a template stripped gold surface. The experiments reveal details of the molecular dynamics over a wide range from few 100's fs intramolecular dephasing to seconds for low temperature structural reorientations. Line narrowing, splitting, and the appearance of slow mode hopping with decreasing temperature shows that the inhomogeneous broadening at room temperature is characterized by high-frequency fluctuations of molecular orientation and/or structure. The temperature dependence allows for the separation of a temperature independent dephasing process from an Arrhenius-type activated process with a few 100 cm⁻¹ activation energy indicative of vibrational stretch and combination band coupling to low energy intramolecular bending and torsional modes. Corresponding coupling constant and lifetime of the low frequency modes are consistent with literature values from related photon echo experiments. In the homogeneous sample size limit we observe spectral fluctuations that can be interpreted as discrete orientational changes of the molecules on the surface. The correlation of spectral fluctuations of coupled normal modes provide additional evidence of a single molecule response.

Abstract Text

During the last few years, the study of ultrahigh vacuum tip-enhanced Raman spectroscopy (UHV-TERS) has been raised to an unprecedented level. By using ex-situ laser focusing and Raman collection optics without compromising UHV, multiple vibrational modes for molecular adsorbates on a solid surface have been resolved in TER spectra obtained concurrently with sub-nm resolution Scanning tunneling Microscopy (STM) imaging. In addition, the adsorbate-substrate interactions can be studied. With liquid helium cooling sample, molecules no longer diffuse on the surfaces. New vibrational characteristics of TER spectra can be obtained in R6G / Ag(111) system at 19K. Theoretical analysis of vibrational modes allowed interrogation of the interaction between rhodamine 6G and the Ag(111) surface. Further a substantial progress in TERS application is the integration of ultrafast spectroscopy with TERS. TERS using pulsed excitation in both atmosphere and UHV has been demonstrated. And our results suggest that the UHV environment mediates signal decay. This approach provides the tools to understand the dynamical processes such as – plasmon driven charge transfer with unprecedented temporal and spatial resolution.

Abstract Text

Tip-enhanced Raman spectroscopy (TERS) is a powerful tool for probing the surface of amyloid fibrils with a nanometer spatial resolution. Here we report TERS maps of individual insulin fibrils and a short peptide (LVEALYL) microcrystal, which is expected to mimic the fibril core. Microcrystal TERS spectra measured at different spots are similar to each other and very close to the conventional Raman spectrum. In contrast, TERS spectra of insulin fibrils vary significantly from spot to spot and show very little resemblance with a conventional Raman spectrum. In addition, TERS signal obtained from fibrils is significantly stronger than that of the microcrystal. A hypothetical mechanism of tip enhancement resulting in different Raman spectra acquired for fibrils and microcrystal will be discussed.

Abstract Text

The latch region of the wild-type protein pore α hemolysin constitutes a sensing zone for individual abasic sites in double-stranded DNA (dsDNA). The presence of an abasic site within a DNA duplex, electrophoretically captured in the α HL vestibule and positioned at the latch region, can be detected based on the current blockage prior to duplex unzipping. Variations in blockage current were investigated as a function of temperature and KCl concentration to understand the origin of the current signature and to optimize conditions for identifying the base modification. Optimal resolution for detecting the presence of a furan in the latch region is achieved at lower KCl concentrations, where the noise in the measured blockage current is significantly lower. The noise associated with the blockage current also depends on the stability of the duplex (as measured from the melting temperature), where a greater noise in the measured blockage current is observed for less stable duplexes.

Abstract Text

Single pores have been used as a basis for the detection of single molecules, viruses, particles and cells using the principle of the Coulter counter approach. Each object passing through a pore causes a transient change of the system resistance whose amplitude and duration give information on physical and sometimes even chemical properties of the object. The Coulter counter technique typically involves recording passage of many particles so that appropriate statistics of the translocation time and the pulse amplitude can be obtained. In case however of an unknown and potentially diluted mixture, a different approach might have to be taken. Instead of statistics on an ensemble of particles/molecules, statistics based on one particle studied many times is needed. In the presentation, we will discuss resistive-pulse experiments with polystyrene particles whose transport through pores is controlled by modulating the driving voltage during the process of translocation. Balancing all forces acting on single particles allowed us to observe random walk in a form of ion current fluctuations in time, and diffusion coefficient of individual particles was determined based on variance of their local diffusion velocities. The developed approach is applicable to particles of different sizes, does not require fluorescence labeling or tracking, and is entirely based on ion current recordings. Analysis of particles from mixture will be presented as well. The same technique was used to trap single particles in the pore for tunable time between tens of milliseconds to 40 seconds.

Abstract Text

Lithography-based microfabrication allows creating fluidic devices with well-defined dimensions below 100 nm. We have employed this capability to create nanoscale thin-layer cells and interfacing them to microfluidic channels, thus simultaneously allowing highly efficient redox cycling and independent control of advective mass transport. The electrochemical response of the devices is characterized by stochastic fluctuations associated with the small number of analyte molecules present in the femtoliter detection volume coupled with the random nature of Brownian motion. Analysis of these fluctuations permits extracting information which is otherwise mostly inaccessible, as illustrated by our use of number fluctuations to measure record-low flow rates of order pL/min in nanochannels as well as in-situ potential-dependent adsorption of redox species. The high degree of amplification further allows detecting single redox-active molecules and quantitatively studying the statistics of their individual Brownian trajectories.

Abstract Text

Liquid and gas chromatography have been used as up-front separation approaches for a variety analytical techniques in so-called hyphenated measurement systems. Examples are LC-MS and GCxGC, widely used in the analysis of complex mixtures. In these systems, a segment of the chromatogram is passed to a subsequent device for further analysis. While up-front separation is meant to simplify analysis and/or achieve additional analytical resolution, complications can arise from the segmentation itself. Because component peaks are split between, or among, chromatographic segments, the absolute and relative concentrations of compounds within a segment are not representative of the mixture. Here, we assess how chemical noise, component response factor, and sample load and complexity depend on the width of the passed-on segment relative to a chromatographic peak. Computer simulation studies demonstrate that, for complex mixtures in which the distribution of component concentrations is taken to be lognormal, chromatographic-segment width is a critical parameter that affects the number and distribution of compounds detectable in complex mixtures. We find that chemical noise is greater for short segments than for the whole sample. Additionally, as segment width decreases toward the peak width, the total measured response of each component also decreases, while the chromatographic resolution improves. The resolving power of the subsequent stage and other factors have a large effect on the selection of the optimum segment width.

Abstract Text

Interfacial boundary layer scattering at atomic-scale junction (ASJ) surfaces is a powerful mechanism to sense chemisorption, particularly of Lewis bases, and metallic nanowires are well-matched to the problem of chemical detection of mass-limited samples, such as those handled in integrated microfluidic structures. ASJs at the narrowest constriction are one or a few atoms in the transverse dimension. At open circuit, current conduction in the ASJ is dominated by ballistic transport, and ASJs are exceptionally sensitive to adsorption-induced alterations in electron scattering. Furthermore, fluctuations in the population of surface adsorbates produces chemical noise in the conductance that can be studied by fluctuation spectroscopy of the power spectral density (PSD). The PSD exhibits two main frequency regions: $1/f$ noise originating from resistance fluctuations of the junction itself, and a Lorentzian noise component arising from molecular adsorption/desorption fluctuations at higher frequencies, the latter carrying information about the kinetics of the adsorption/desorption process. Furthermore, studying these phenomena under electrochemical potential control provides a reliable method of regulating the size and stability of these nanojunctions. In general, more anodic potentials decrease junction stability and increase the rate at which conductance decays. Electrochemical potential also plays a significant role in determining adsorption-desorption kinetics of surface adsorbates at steady-state at Au-Ag-Au ASJs, as revealed through fluctuation spectroscopy. Average cutoff frequencies increase at more anodic potentials, as does the width of the cutoff frequency distribution.

Abstract Text

Ambient sample introduction systems for organic compounds are wide spread and have increased the capabilities of various techniques. Elemental and isotope analysis by ICP-MS still suffers from the fact that ambient aerosols cannot be introduced into such instruments. Little amounts of oxygen extinguish the Plasma. Therefore, a gas exchange device (GED-III) was tested for the online analysis of various gas species (airborne and synthetically generated). A particle generation process developed by J-Science was tested to investigate the detection Efficiency by ICPMS spectrometry. The optimization procedure and few selected applications will be reported.

Abstract Text

Inductively-coupled plasma mass spectrometry (ICP-MS) is a vanguard analytical technique, however, new instrumental approaches can unlock even more significant capabilities. Here, a new type of mass analyzer known as the distance-of-flight mass spectrometer (DOFMS) will be evaluated for use in ICP-MS. The DOFMS concept is best explained by comparison with traditional time-of-flight mass spectrometry (TOFMS). TOFMS measures the mass-to-charge (m/z) of an ion by imparting the same energy to all ions and then measuring the time required for each m/z to traverse a distance and arrive at a single detector. In contrast, DOFMS measures the m/z of an ion by measuring the distance each ion travels during a set time period. Simply put, ions of lower m/z traveling longer distances than ions of greater m/z , and their m/z can be determined based upon location.

The DOFMS strategy offers a number of significant benefits for ICP-MS. Like TOFMS, DOFMS is architecturally simple, offers very rapid spectral generation rates, and is capable of simultaneous multielemental analysis. However, DOFMS is able to employ new solid-state array ion detectors to great advantage, providing greater detection efficiency and dynamic range than typical TOFMS, and obviating the need for fast electronics. As important, the DOFMS strategy permits new experiments to be performed. For example, DOFMS focusing strategies can be employed in a typical TOFMS experiment to improve mass resolution over a limited window of the atomic mass spectrum. This technique, known as Zoom-TOFMS, is able to increase mass resolution while simultaneously increasing the S/N of the mass spectrum. Moreover, because TOFMS and DOFMS share a common architecture, a single instrument is able to switch between TOFMS, DOFMS, and Zoom-TOFMS experiments as required. The theory of operation and experimental advantages of DOFMS will be discussed, and the analytical performance of this new type of mass spectrometer will be described.

Abstract Text

Laser ablation sampling provides elemental and isotopic analysis, with minimal or no sample preparation, no consumables, and rapid turn-around time. The ablated mass is analyzed by optical emission from the induced plasma (LIBS – Laser-Induced Breakdown Spectroscopy and LAMIS – Laser Ablation Molecular isotopic Spectroscopy) and/or from the aerosol (particles) that is transported into a secondary source like the ICP (Inductively Coupled Plasma). Every element on the periodic chart, from H to Pu can be analyzed using these technologies.

LIBS has experienced a revival in the past ten years, mainly due to the benefits of no gases, simpler system components and the ability for stand-off applications. With new stable laser sources and intensified detectors, LIBS applications are increasing daily and rugged commercial instruments are available. Chemometric data processing is driving applications further. LIBS has become a workhorse technology for many routine applications; several of which will be mentioned in this talk. By expanding the capabilities of classical LIBS to emphasize the measurement of molecular emission spectra in addition to elemental, LAMIS provides the ability to measure all elements and their isotopes, especially light elements like Li, Be, C, N, O. We developed LAMIS to date by establishing its ability to measure B, C, H, D, Sr and other isotopes. We demonstrated low percent levels for sensitivity and have experimental plans to meet ppm levels. For some isotopes, we achieved < 0.1% precision. The talk will describe the isotope work that has been reported in LIBS plasmas and show how LAMIS expands those capabilities.

Abstract Text

Oceanography is rapidly moving from a sampling science, where measurements are made aboard ship on specimens retrieved from the water column or seafloor, to a sensing science, where instrument systems directly collect measurements in situ, potentially for long periods of time. However, appropriate sensor technologies are required to carry out sensing science, and those for chemical measurements are not as advanced as in other disciplines. Laser-induced breakdown spectroscopy (LIBS) is an existing in situ technique that can potentially address this shortcoming by extending it to the deep ocean aqueous environment. LIBS uses a pulsed laser and gated detector to measure atomic emission spectra from a laser-induced plasma that forms following laser ablation of the sample. A long-range goal of work being carried out jointly by our group at The University of South Carolina and Woods Hole Oceanographic Institute is deploying a LIBS system on Alvin or other deep-ocean submersibles to measure the elemental composition of deep-ocean hydrothermal vent fluids. This talk will include a review of previous work at USC measuring ppm levels of alkali and alkaline metal elements at pressures up to 3×10^7 Pa (~2800 m water depth equivalent), and studies of matrix interactions between different elements. In addition, new work using O and H as internal standards to improve measurement precision will be presented and studies related to the effect of suspended particulates will also be presented. In other applications of LIBS in inaccessible places, planetary applications of LIBS are being investigated. To this end a miniature spatial heterodyne LIBS spectrometer has been developed and used for the first time for standoff LIBS. This instrument uses a 10 mm diffraction grating for light collection at distances up to 20 meters, corresponding to a collection solid angle of less than one microsteradian.

Abstract Text

In recent years, glow discharges have assumed broader and perhaps even greater importance, especially in the form of atmospheric-pressure glows. At atmospheric pressure, the customary spatial structure of the discharge is conserved, but the dimensions are collapsed, the current-voltage behavior is altered, and the distribution of species in the plasma is changed. As a result, the applications of the glow have broadened and it has assumed even greater importance analytically. In this presentation, several examples of novel glow discharges will be described and evaluated. One, the solution-cathode glow discharge (SCGD) is sustained in the open atmosphere directly on the surface of a solution to be analyzed. Material from the solution is then volatilized, atomized, and excited, to yield a source useful for the direct elemental analysis of sample solutions. Even though the SCGD consumes little power (~75W), needs no gas supply, nebulizer or spray chamber, and emits simple spectra, it yields detection limits that rival those of the inductively coupled plasma. In another incarnation, a glow discharge in helium can be used as a source for ambient desorption/ionization mass spectrometry. In this application, sample material need not be introduced into the discharge itself, but only into the effluent from the discharge cell. Also, because the Flowing Atmospheric-Pressure Afterglow (FAPA) heats the flowing helium to selectable temperatures nearing 300C, species can be desorbed directly from the surface of a solid sample, and ionized in the helium stream, to yield mass spectra largely of the parent ion or its protonated counterpart. Here, a recent version of the FAPA source will be introduced and its application featured. Finally, a more conventional glow will be evaluated. Operated at reduced pressure and powered by radiofrequency energy, this pulsed discharge enables the three-dimensional elemental composition of conductive or non-conductive solid samples to be determined.

Abstract Text

Despite the central role of soil microbial communities in the global carbon (C) cycle, very little is known about soil microbial community composition and even less about their metabolic pathways. High throughput sequencing technologies have recently created unprecedented access to the biodiversity of soil microorganisms, allowing characterization of the microbial mechanisms regulating soil C cycling. We coupled soil metagenomic and environmental analyses to identify the “core” C-cycling sequences that are consistently prevalent in soil samples from a fertilized prairie (FP) biofuel cropping system. Of 226,887 sequences associated with known enzymes involved in the synthesis, metabolism, and transports of carbohydrates (the CAZy database), 911 sequences were identified to be consistently prevalent across four replicate soil metagenomes. This core metagenome was functionally and taxonomically diverse, representing five major enzyme classes and 107 enzyme families within the CAZy database and numerous bacteria and fungal phyla. Despite comprising only 0.4% of the cumulative CAZy-associated FP metagenome, the core was found to be functionally representative of the cumulative whole soil metagenome, suggesting that these sequences may represent key C cycling genes in this soil. Comparing the FP CAZy-associated core to other soil metagenomes revealed that the sequences in the FP core are present in multiple other soils, and most similar to soils sharing geographic proximity. Several co-occurring core sequences were identified in functional modules representing distinct metabolic processes in starch and sugar metabolism. In soil ecosystems, where high diversity remains to be a key challenge for metagenomic investigations, these core genes represent a subset of critical functions necessary for carbohydrate metabolism, which can now be targeted to evaluate key carbon cycling organisms and pathways that are relevant to agricultural systems and biofuel reactors.

Abstract Text

Cyanobacteria are found in most types of illuminated environments and the global biomass of these photosynthetic microbes has been estimated to be $\sim 3 \times 10^{14}$ g carbon (C). Although their key role in global C and nitrogen (N) cycling has been widely accepted and significant efforts to advance our understanding of this ecologically important phylum have been made, very little is known about how Cyanobacteria affect and respond to environmental changes. This knowledge gap is mostly due to the fact that, until recently, approaches facilitating [i]in situ[/i] studies of complex microbial systems were rather limited. With the advent of advanced cultivation-independent techniques (e.g. metagenomics, metatranscriptomics, metaproteomics) it is now possible to study microbial communities, their metabolic potential, and their metabolic activity without the need to isolate and grow individual community members or even the complex consortia in the laboratory.

In the project presented here, we took advantage of a suite of unique [i]Omics[/i] capabilities available at DOE's Joint Genome Institute and Environmental Molecular Science Laboratory to [i]i[/i]) obtain a multi-scalar (from molecule to cell to population to ecosystem) understanding of photosynthetic consortia that contain several distinct Cyanobacteria and several heterotrophic microorganisms and to [i]ii[/i]) determine how the community and its individual community members affect the C and N cycle. In addition, our team utilizes the diverse [i]Omics[/i] data generated during this project to develop computational and experimental approaches that will facilitate the isolation of pure cultures of microorganisms that are recalcitrant to current isolation and cultivation techniques. Recent findings will be presented.

Abstract Text

The outcome of a viral infection is influenced by the balance between host defense mechanisms and virus modulation of cellular pathways. We have integrated genomics with proteomics and molecular virology to identify novel host defense factors that can provide new targets for antiviral therapeutics. Currently, most antiviral drugs target specific viral proteins. Consequently, they often work for only one virus and their efficacy can be compromised by the rapid evolution of resistant variants. There is a need for the identification of host proteins with broad-spectrum antiviral functions, which provide effective targets for therapeutic treatments that limit the evolution of viral resistance. Here, we report the discovery that all seven human sirtuins have antiviral properties. Sirtuins are a family of ubiquitously expressed and evolutionarily conserved NAD-dependent deacylases/ mono-ADP ribosyltransferases that regulate numerous cellular and organismal functions, including transcription, metabolism, and longevity. Our results show that sirtuins exhibit defensive properties against a range of DNA and RNA viruses. Furthermore, we show that the sirtuin defense functions are evolutionarily conserved, as CobB, the sirtuin homologue in *E. coli*, protects against bacteriophages. Altogether, our findings establish sirtuins as broad-spectrum and evolutionarily conserved components of the immune defense system, providing a framework for elucidating a new set of host cell defense mechanisms and developing sirtuin modulators with antiviral activity.

Abstract Text

The availability of complete microbial genome sequences for cultured organisms as well as more complex environmental samples has enabled systems biology interrogation of microbial communities by integrating genomic, transcriptomic, proteomic and metabolic information. Our current work seeks to develop and demonstrate advanced “shotgun” mass spectrometry techniques for the comprehensive characterization of complex microbial proteomes. The goal of this research is to enable integration of metagenomics and metaproteomics datasets for a detailed glimpse into the functional state and metabolic activities of microbial systems, spanning the range from single isolates to more complex consortia. The proteome approach is based on multidimensional liquid chromatography interfaced on-line with tandem mass spectrometry. A variety of mass analyzers are employed, ranging from quadrupole ion traps (high throughput) to Orbitraps (high performance, accurate mass measurements). We have focused on integrated experimental/bioinformatic approaches for both qualitative and quantitative proteome measurements. We have optimized a detergent based proteome extraction method which can be combined with high performance LTQ-Orbitrap-Velos measurements to investigate natural microbial communities, such as those involved in carbon cycling in terrestrial (soils, sediments) as well as aqueous (acid mine drainage, deep sea methane seeps) systems. We have extended these MS-based techniques to characterize a variety of microbial species that are involved in bioremediation, bioenergy, human microbiome health, and natural environmental communities.

Research support was provided by the U.S. DOE, Office of Biological and Environmental Research. Oak Ridge National Laboratory is managed and operated by the University of Tennessee-Battelle, L.L.C., for the U.S. Department of Energy.

Abstract Text

Tumors are well known to have poor mass transport, resulting in nutrient-poor regions with high waste concentrations. As a result, the tumor microenvironment can trigger cell survival mechanisms that inhibit apoptosis, a key mechanism for many chemotherapeutic compounds. In an effort to isolate the causes for increased drug resistance in tumor cells, we have developed a "hypoxia chip" to induce hypoxia in cells. This system is based on our low-shear culture design and can accommodate multiple culture types as well as on-chip spectroscopic oxygen detectors. In experiments with hypoxic prostate cancer cells, we observed a marked increase in drug resistance when compared with normoxic controls. We detected apoptosis via fluorescence assays for mitochondrial leakage and membrane rearrangement.

We have shown that short (<60 min) periods of hypoxia are sufficient to impart enhanced drug resistance in cells, and have shown that prostate cells continue to follow a dose-response characteristic curve, albeit at higher concentrations. This work has implications not only in drug testing, but also in the basic mechanisms of cancer cell drug resistance.

Abstract Text

In recent years, there are significant interests in the manipulation of cells using electric, magnetic, acoustic and/or flow fields for separation, characterization, actuation, and assembly of particles. In this talk, a brief overview of electric field driven cell manipulation techniques will be provided. Existing models used to study electric field driven cell manipulation will be highlighted along with their strengths and shortcomings in microdevice. The recently developed hybrid immersed interface-immersed boundary method will be introduced to study electric field driven particle assembly where both electric and hydrodynamic forces are calculated with interface-resolved approach instead of commonly used point-particle method. In this hybrid model, the immersed interface method is employed to capture the physics of electrostatics in a fluid media with suspending cells, while the immersed boundary method is used to study hydrodynamics with rigid or flexible immersed boundaries. Moreover, the Maxwell stress tensor is used to calculate the electrostatic force acting on particles by considering the physical effect of particles in the computational domain. Thus, this method eliminates the approximations used in point dipole methods for calculating forces. Finally, electric field driven cell motions and related fluid flow phenomena will be presented for charged, uncharged and bipolar cells. The self-assembly of cells will be demonstrated for similar and dissimilar types of cells using applied electric fields.

Abstract Text

The ability to correlate single-cell genetic and protein expression information to cellular phenotypes will provide the kind of detailed insight into human physiology and disease pathways that is not possible to infer from bulk cell analysis. This presentation describes a set of single-cell isolation, manipulation, and analysis techniques that we have developed in our lab, including a rare-cell isolation platform we called eDAR, the active manipulation and trapping of single cells using bipolar electrodes and dielectrophoresis, the analysis of single-cell gene expression with digital PCR on a SD chip, and the quantification of expressions of a large set of proteins at the single-cell level.

Abstract Text

Reactive Nitrogen Species (RNS), and in special Nitric Oxide are involved in many biological processes. It has been demonstrated that Nitric Oxide plays an essential role in inflammatory pathway, blood pressure control, cell signaling, neurotransmission, gene expression, coagulation, among other. The study of RNS is difficult due to the reduced concentrations and short lifetime of these species. We have developed strategies to monitor RNS in model cells, such as RAW 264.7 macrophages and lymphocytes, using microchip electrophoresis coupled with amperometric detection. Microchips were built in poly(dimethylsiloxane) and designed to contain one or two separation channels. Samples were injected using gated injection. Calibration procedures for determination of Nitric Oxide can be performed using NO donors compounds, such as NONOates salts. We also demonstrate the viability of cell monitoring using capacitively coupled contactless conductivity detection.

Abstract Text

In the past few years microfluidic devices have begun to change the way cellular analysis is performed. This is because of their ability to integrate cell transport, manipulation, stimulation, and lysis with the separation and detection of the analytes released by the lysis of such cells. The high throughput analysis of single cells is of interest because of their heterogeneous behavior under a variety of conditions. A better understanding of this heterogeneity would improve our understanding of neurodegenerative diseases. Microfluidics might also be employed in the development of early detection systems for these diseases. We have recently developed a microfluidic device architecture to study the expression of nitric oxide (NO) in Jurkat cells. Our experiments compared the production of NO in native and lipopolysaccharide stimulated cells. The cells were labeled with fluorogenic dyes including 4-amino-5-methylamino-2',7'-difluorofluorescein diacetate (DAF-FM DA) which, when hydrolyzed, reacts with NO within the cell. On the microfluidic device, the labeled cells were transported to an intersection where they encountered high voltage that generated cell lysis, injection, and electrophoretic separation prior to laser induced fluorescence (LIF) detection. In all, more than 1000 cells were analyzed, and the average results compared nicely to recently published bulk cell studies performed for the analysis of NO.

Abstract Text

The discovery and identification of a fiber as a particular polymer (e.g., acrylic, cotton, nylon, polyester) may not, of itself, provide much support for a forensic investigation. The probative value of fibers found at a crime scene depends on their uniqueness relative to the fiber background in the absence of the crime. What is required is information that makes trace evidence more specific and discriminating. Based on a collection of 3,000 textile fibers, we have developed a web-based system for storage of microscopy measurements, physical characteristics, and spectral data that facilitates use of multivariate statistics for assessing discrimination and classification of fibers for forensic comparison. Following derivative processing, baseline correction, and normalization, UV/visible and fluorescence spectra from 482 fibers were classified using principal component (PC) and linear discriminant analysis (LDA) in each color and polymer group. The highest discrimination power was obtained from UV/visible spectra, which were correctly classified 89.50% of the time. The transfer of multivariate classification models between laboratories can save time and resources in forensic analyses. Using UV/visible spectra of 12 blue acrylic fibers, collected at five different laboratories, transferability of models was investigated using PCA-LDA and partial least squares-discriminant analysis (PLS-DA). An average classification of 88.06% was found after training the PLS-DA models using data collected at four laboratories and using the information collected at the fifth laboratory as an external test set. For comparison, intra-laboratory studies carried out using PCA-LDA produced an average classification accuracy of 98.33%. These results suggest limitations to the transferability of classification models between laboratories. Researchers are advised to use caution and to follow the traditional adage of "Trust, but verify."

Session Title Statistics and Data Analysis for Forensic Decision-Making

Abstract Title **Statistical Approaches to Decision Making in Fire Debris Analysis**

Primary Author Michael E. Sigman
University of Central Florida

Date: Thursday, March 12, 2015 - Afternoon

Time: 02:10 PM

Room: 263

Co-Author(s) Mary R. Williams

Abstract Text

Chemical analysis of fire debris, as implemented in most US forensic laboratories, involves a relatively easy sample preparation followed by gas chromatography-mass spectrometry with electron ionization. While the analytical methodology is simple, data analysis is more complex and requires the forensic analyst to use visual pattern recognition, coupled with target compound analysis to arrive at a subjective assessment of a sample as positive or negative for the presence of ignitable liquid residue. Although the characteristics of the ignitable liquid classes, as defined by the ASTM E1618 standard method (i.e., gasoline, petroleum distillate, etc.), can assist the analyst in recognizing the presence of ignitable liquid residue in fire debris, the complexity of the sample may be greatly enhanced by the presence of pyrolysis products. Standard classifiers have been used to assign fire debris samples as positive or negative for the presence of ignitable liquid residue, and for class assignment. The performance of classifiers based on linear and quadratic discriminant analysis (LDA and QDA respectively) and soft independent modeling of class analogy (SIMCA) will be discussed. Application of support vector machines will also be discussed along with classification with support vector machines and the incorporation of a Bayesian approach with a verbal scale, which can assist the analyst in decision making and presentation of the results in a legal context.

Abstract Title **Comparative/Compositional Bullet Lead Analyses (CBLA): An Autopsy**

Primary Author Clifford Spiegelman
Texas A&M University

Date: Thursday, March 12, 2015 - Afternoon

Time: 02:45 PM

Room: 263

Co-Author(s) William A. Tobin

Abstract Text

The FBI has used the chemical analysis of bullet lead as a forensic tool for about 40 years. When a bullet(s) is found at a crime scene and in a suspect's possession the trace elements in the bullet can be compared. If the bullets are similar enough a match is declared. The use of this technique in court testimony was the subject of a relatively recent National Academy of Sciences (NAS/NRC) report. The FBI Crime Laboratory subsequent to the NAS report has ceased using the compositional analysis of bullet lead. We discuss how this procedure died. The issues discussed apply broadly to forensic science laboratory management, chemistry, chemometrics, statistics, and the need for straightforward presentation of scientific evidence.

Abstract Title **Class-Conditional Feature Modeling for Ignitable Liquid Classification with Substantial Substrate Contribution in Fire Debris Analysis**

Primary Author Martin Lopatka
University of Amsterdam

Date: Thursday, March 12, 2015 - Afternoon

Time: 04:10 PM

Room: 263

Co-Author(s) Gabriel Vivo-Truyols, Marjan J. Sjerps, Mary R. Williams, Michael E. Sigman

Abstract Text

The detection and classification of ignitable liquid residue in forensic fire debris analysis is complicated by interference from pyrolysis products of the substrate materials present in a fire.

A method is developed to derive a set of class-conditional features for the classification of such complex samples. The use of a forensic reference collection allows characterization of the expected variation in complex mixtures of substrate materials and ignitable liquids even when the dominant feature is not specific to an ignitable liquid. Making use of a novel method for data imputation under complex mixing conditions, a distribution is modeled for the expected variation between pairs of samples containing similar ignitable liquid residues. Examining the expected covariance of variables within the different classes allows different weights to be placed on features more important in discerning the presence of a particular ignitable liquid residue.

Performance is evaluated for an ignitable liquid residue classification task using the total ion spectrum (TIS). These measurements include 119 nominal masses measured by GC-MS and averaged across a chromatographic profile. Ignitable liquids are labeled using the American Society for Testing and Materials (ASTM) E 1618 standard class definitions. Classification is performed in the class-conditional feature space wherein new forensic traces are represented based on their likeness to known samples contained in a forensic reference collection. Classification performance using laboratory prepared reference data applied as a model for real burn data achieves 81.4% accuracy. The demonstrated method uses the culmination of information from forensic reference data as the basis of both hard and soft classification assertions.

Abstract Title **Method Development Using Luminescence for Biodegradable Organic Carbon Measurements in Drinking Water**

Primary Author Lauren Weinrich
American Water

Date: Thursday, March 12, 2015 - Afternoon
Time: 01:35 PM
Room: 264

Co-Author(s)

Abstract Text

A sufficient nutrient supply exacerbates unwanted bacterial proliferation in drinking water systems; however locations exist within the treatment process in which bacterial proliferation can be an advantage. Targeting the fraction of labile or easily assimilable organic carbon (AOC) has been applied in the drinking water industry for decades to monitor and assist in approaches to reduce microbial regrowth in distribution systems to maintain optimum water quality. A novel freshwater luminescent AOC test was developed by genetically modifying the traditional test bacteria *Pseudomonas fluorescens* P-17 (P17) and *Spirillum* strain NOX with luxCDABE operon fusion and inducible transposons to produce bioluminescent strains. Typically measured through serial dilutions and spread plate counts following extended incubation periods, the AOC assay has been improved by utilizing luminescence as the measurement application. A test for seawater was developed using the marine organism *Vibrio harveyi*, which is naturally bioluminescent. Both the freshwater and marine AOC test is automated and use a sensitive, photon-counting, luminometer that allows high throughput, replicate analyses, at a low cost. The AOC test is used in drinking water to evaluate biofouling potential and recently in reclaimed water to evaluate regrowth potential in the distribution system. The presentation will discuss a study of elevated AOC levels ranging from 150 to 1,400 µg/liter (n = 146) in reclaimed water that were primarily responsible for bacterial growth and could contribute to the occurrence of opportunistic pathogens such as *Legionella* and *Mycobacterium*. Another study of biological filters indicated that 42% of AOC was removed between the influent and effluent even in filters that were incidentally biologically active. The level of AOC provides a monitoring tool for efficient drinking water filtration, observe and control impacts of oxidation and chemical addition, and improve biological stability.

Abstract Text

Current approaches to determine the presence of emerging (ECs) and other unregulated contaminants in the water bodies are based on discrete measurements. Targeted chemical analysis has been traditionally employed to quantify the concentration of contaminants in the environment. The main disadvantage of this approach is to overlook the presence of unidentified chemicals in the water. Combined application of targeted chemical analysis by gas or liquid chromatography tandem mass spectrometry with modern analytical techniques based in advanced mass spectrometry, such as quadrupole-time of flight, into environmental monitoring will provide insightful information to environmental specialists to determine the behaviour of ECs throughout water treatment. The current work encompasses the study of the impact of operational conditions during full-scale drinking water treatment on the fate of 8 selected nitrosamines (unregulated disinfection by-products) and their precursors, and 2 selected artificial sweeteners (sucralose and acesulfame K) as indicators of wastewater contamination in the water sources. For this purpose, nitrosamines are analyzed by GC/MS/MS in raw, process and finished water as well in the distribution system from selected American Water (AW) utilities and the sweeteners are quantitated by LC/QTOF in the same locations. Additionally, untargeted ECs are being screened in the source water and samples that undergo in-lab disinfection by the non-targeted analysis capabilities of the LC/QTOF to determine potential transformation pathways involved in the removal/generation of the chemicals under study. In this presentation the results from monitoring nitrosamines and their precursors and other ECs in AW utilities will be shown. The relationship between the concentrations determined in the water and changes in the plant operations and the usefulness of non-targeted analysis to identify unintended consequences of the operational changes will be also discussed.

Session Title Using Analytical Solutions to Target Emerging Issues in Drinking Water Safety

Abstract Title **Monitoring and Optimizing Drinking Water Treatment Processes with Simultaneous Absorbance and Fluorescence Excitation-Emission Mapping**

Primary Author Adam M. Gilmore
Horiba

Date: Thursday, March 12, 2015 - Afternoon

Time: 02:45 PM

Room: 264

Co-Author(s)

Abstract Text

Conventional optical methods for monitoring drinking water treatment are not generally conducive to process optimization because data collection and processing can be imprecise. Further, chemical analyses are often too slow for effective decision making with many tests taking hours to days to complete while the flow-through the plant is on the order of hours. This presentation outlines the advantages of simultaneous monitoring of absorbance and fluorescence excitation-emission mapping (SAFE) with respect to optimizing control of disinfection by-products, coagulant and granulated activated carbon dosing and detection of algae growth with respect to harmful toxins and taste and odor issues. The SAFE technique collects essential information in seconds to minutes and facilitates immediate processing of several key water quality parameters including: dissolved organic carbon concentration (DOC), an aromatic carbon concentration index superior to conventional specific UV absorbance (SUVA), trihalomethane- and halogenated acetic acid- formation potentials (THMFP and HAAFP) as well as information on microbially and chemically oxidizable substrates that determine the bio- and chemical oxygen demands (BOD and COD, respectively). The method can be applied effectively at the point of the organics laboratory where there is continuous access to key process sampling points including the raw inlet, the settled water and the final plant product. Processing of the data for both qualitative and quantitative purposes can be mediated with automated, calibrated multivariate routines capable of correlating the spectral data with other metrics from online and or batch analysis as well as to recognize and adapt to changes from the normal spectral profiles. In conclusion, the case studies used in the report provide clear evidence that the SAFE technique can provide valuable cost- and time-savings in addition to more precise metering of various drinking water processes.

Abstract Text

Despite new polymer based materials increasingly entering our water and energy infrastructure systems, there remains little information about how these products (i.e., pipes, coatings, and liners) age and impact the media they contact. As a result infrastructure owners and operators lack the necessary information to make strategic material selection decisions that weigh both product longevity and environmental impacts. Through a series of bench- and field-scale NSF, EPA, VDOT, as well as water and energy industry funded projects we have applied a range of analytical methods for water characterization coupled with material characterization techniques. This presentation will briefly describe the approach and results of these efforts. Gaps in analytical needs and emerging issues will also be discussed. Projects have included the West Virginia Water Crisis scientific investigation, environmental impacts caused by infrastructure rehabilitation technologies, bottled water drinking water safety, green building plastic plumbing systems, biocompatible crude oil spill dispersants, energy generation facility cooling water pipelines, the fate of fracking waste components in water infrastructure, and infrastructure decontamination.

Abstract Text

During the Summer of 2013 Louisiana experienced the first detection of *Naegleria fowleri* in a treated drinking water system in the U.S. as a result of an investigation of a related death in 2013 and two previous deaths in 2011. Since this discovery Louisiana has issued an emergency rule requiring a minimum disinfectant residual of 0.5mg/l of free chlorine or 0.5mg/l of total chlorine for systems feeding ammonia throughout the water distribution systems. The emergency rule also requires revised monitoring plans for the Total Coliform Rule as well as increased monitoring for disinfectant residuals. In addition, Louisiana is working to develop lab testing capability in coordination with CDC in our Office of Public Health laboratory in order to perform surveillance monitoring in other public water systems to demonstrate the effectiveness of the increased disinfection levels in controlling the presence of *Naegleria fowleri* in our public water systems.

Abstract Text

Chemical safety regulations—such as EPA’s Toxic Substances Control Act (TSCA) or OSHA’s Lab Safety Standard 29 CFR 1950—cover a number of regulatory criteria from hazardous materials management to process safety that require research laboratories to have a detailed understanding of the materials being used in the lab. In addition, many of the regulations also have Chemicals of Interest Lists with very specific requirements about managing and reporting those chemicals if and when a certain threshold limit is reached.

Compliance with most of these regulations is extremely challenging. Worse, the frequency with which national, state and local chemical safety regulations are being updated is not only occurring more often, but also increasing in number and complexity. The Globally Harmonized System of Classification and Labelling of Chemicals, or GHS, for instance, that has been adopted by OSHA requires new labels on just about everything in the lab. And right now the details of the upcoming Chemical Safety Act designed to replace TSCA are being argued in Congress; labs will soon need to become thoroughly familiar with the Act’s requirements when it gets signed into law.

Compounding these challenges is the fact that neither regulatory reporting deadlines nor data are coordinated, meaning that if the lab is subject to 10 different regulations there will be 10 different reporting dates and report formats.

This presentation examines how regulations are driving change at research organizations, and how labs are leveraging technology and changing their processes to ensure compliance and reduce chemical risk.

Abstract Text

In 2007, Yale University purchased the property formerly occupied by Bayer Pharmaceuticals in West Haven and Orange, CT. The site is comprised of 20 buildings on 136 acres and includes 1.6 million square feet of research, office and warehouse space. Branded as "West Campus" in 2008, Yale's ambitious plan is to build a true expansion campus with new and additional programming in basic laboratory research, healthcare, and cultural heritage. To date nearly 1200 faculty, staff, and students call West Campus home and major centers of collaborative academic research have been established on site. Many of these residents are part of West Campus' six multidisciplinary research institutes, Core laboratories, and the Yale School of Nursing.

Being a true expansion effort Yale is taking advantage of a seldom seen perspective in academics and establishing campus-wide protocols for laboratory operations and compliance at the onset of growth. Additionally, a substantial commitment to capital renovation has led to innovative projects that better connect our multi-disciplinary activities. In this respect the West Campus serves as the ultimate site for evaluating new laboratory support systems prior to full implementation. Yale is also cultivating a culture of laboratory safety by supporting applications, e.g. chemical tracking, through University Administration rather than individual research groups.

This presentation will focus on the successful implementation of campus-wide chemical tracking and its role in furthering the efforts of Yale's Office of Research Operations and Technology and Office of Environmental Health and Safety. The entire process, from formulation to deployment, will be presented along with logistical lessons learned during the selection of an appropriate software application and implementation team. Similar campus-wide efforts in compliance and innovation will be presented.

Abstract Text

Research organizations that utilize chemicals in their labs and their manufacturing processes must manage those chemicals in a safe environment in accordance with government regulations. At a minimum, to ensure that this is accomplished, a system for managing information about the chemical safety and inventory data should be established and maintained. Best practices, on the other hand, take this minimum and leverage the management of the chemical inventory by taking full advantage of the people, processes, and technology involved. This presentation delves into chemical inventory management best practices that can optimize chemical safety and inventory data, automate audit trails and regulatory reports, manage and mitigate the amount of chemicals on-site, and reduce inventory management costs.

Abstract Text

Electronic Laboratory Notebooks (ELNs) are becoming common in both industry and academia. Support for and integration of Analytical Information Markup Language (AnIML) files, used to store analytical instrument data, will become important for ELNs to handle as the framework provides a vendor neutral flat file format, for capturing, annotating and archiving data across a wide range of instruments.

This presentation will discuss the ways in which AnIML could be integrated into an ELN workflow, and the advantages and disadvantages of the approaches.

Abstract Title **Evaluation of Standards for Data and Metadata in Analytical Chemistry**

Primary Author Dana E. Vanderwall
Allotrope Foundation

Date: Thursday, March 12, 2015 - Afternoon

Time: 03:20 PM

Room: 274

Co-Author(s)

Abstract Text

Allotrope Foundation is an international consortium of pharmaceutical and biopharmaceutical companies funding a project to develop an innovative Framework (metadata dictionaries, data standards and class libraries) for managing analytical data throughout its lifecycle.

One component of the Framework is a vendor and technique agnostic data standard that defines the structure and format for analytical data and includes rich contextual metadata along with primary instrument data. Another critical and unique aspect of the project is the standardization of contextual metadata (i.e., a core controlled vocabulary which describes key attributes of the experiment and the data) and the mechanism and software tools to utilize that vocabulary in a comprehensive and consistent way throughout analytical workflow. Finally, the Allotrope Framework will provide application programming interfaces (API's) that will enable software developers to implement the standards in a consistent way. The Allotrope Framework and data format leverages current IT best practices, builds on existing standards, is designed to be extensible, to meet performance requirements of modern instrumentation, and to be resistant to technological obsolescence.

The approach taken by Allotrope Foundation is to learn by doing. The evaluation of any kind of standard (including those for analytical data, workflow context, experimental parameters, services, metadata representation) is done in the context of developing pieces of the Framework and proof-of-concept applications that leverage the standard to solve a particular real world problem. This allows for a deep functional and objective understanding of the degree to which a standard meets the requirements of the Allotrope Framework.

The presentation will describe the understanding gained in evaluations of AnIML and other standards, the Framework development to date and discuss plans for the adopted standards and future extensions of the Framework.

Abstract Title **AnIML via SiLA - A Perfect Fit?!**

Primary Author Devon Johnston
SiLA

Date: Thursday, March 12, 2015 - Afternoon

Time: 03:50 PM

Room: 274

Co-Author(s) Niklaus Graber

Abstract Text

The SiLA Consortium aims to establish global standards to make laboratory automation more efficient and profitable. SiLA is a non-profit, international consortium and joins companies, research institutions and individuals in a global community. Among our SiLA members working together in various working groups are leading device manufacturers, software companies, system integrators and Pharma/Biotech enterprises as well as lab automation experts from all over the world.

What is the basic idea of SiLA?

SiLA defines standardized interfaces for device control and communication such that users can easily integrate and rearrange instruments following a "plug and play" philosophy. By using a SiLA interface, there is:

- Less effort in integrating devices from different vendors
- More flexibility to reuse lab equipment in various setups
- Efficient and cost-effective use of laboratory automation systems over the entire lifecycle

With increased lab efficiency, scientists are able to run more experiments in shorter time frames, generating larger amounts of data than ever before. SiLA goes beyond just standardizing device communication interfaces and extends its standardization philosophy to data handling through its partnership with the "best in class" data handling solution, AnIML.

"AnIML via SiLA" uses SiLA as the standardized "Transport Vehicle" for "AnIML Containers" of data. The combination of both standards results in an even more complete solution to be applied in labs right now!

SiLA is quite excited about the past years of progress and is gaining momentum! There are already many vendors that supply systems compliant to the SiLA Device Control and Interface Standard. Making them "speak" AnIML would be a major leap forward for both standards and most of all for users and scientists in the labs!

In this workshop, we would like to provide some more insights on SiLA and discuss real world applications of "AnIML via SiLA". We hope to see you there.

Abstract Text

Analysis of trace level of ions in the presence of high levels of matrix ions is challenging.

In recent years, a new ion chromatography analysis methodology termed two-dimensional Matrix Elimination Ion Chromatography (MEIC) has been introduced to meet this specific challenge. MEIC takes advantage of large capacity columns and stationary phase selectivity to minimize the interference from the common ions in the first dimension. The analytes of interest are refocused in a concentrator column and reanalyzed in the second dimension using a smaller format column with a different separation phase to achieve better sensitivity and selectivity in the second dimension. The second dimension column can thus be a microbore format column or a capillary column.

In this presentation, we will show the application of MEIC for the analysis of various trace contaminants in drinking waters. Overall the method is automated and eliminates the tedious manual processes currently employed and provides improved analysis from a sensitivity, precision and recovery perspective.

Abstract Text

On February 11, 2011, the United States Environmental Protection Agency (USEPA) initiated development of a national primary drinking water regulation (NPDWR) proposal for perchlorate. There are several published methods for the analytical determination of perchlorate in raw and finished drinking waters. The robustness of these methods is limited by interferences, false positives, ionization suppression, and detector inlet or column fouling. This work discusses a single laboratory validation of EPA Method 314.2. Calibration model, precision, accuracy, single laboratory lowest concentration minimum report (LCMRL) limit in DI water and detection limit were evaluated. The calibration model was determined by analysis of six calibration levels over six days. Residual values were examined to determine if weighting was necessary. ANOVA calculations were performed to determine the appropriate order of calibration model. A lack of fit test was performed as a final evaluation of the calibration model. Precision was determined by examination of relative standard deviation for eighteen replicates at three levels in both DI water and synthetic matrix. Accuracy was determined by analyzing samples spiked with the analyte. Additional considerations are given to analysis of matrices containing high ionic strength and a comparison between first dimension and second dimension data.

Abstract Text

Aquariums are an important part of modern society, as they provide both a way to explore the wonders of the aquatic world and a source of entertainment. Assaying aquarium water is essential for the proper maintenance of aquariums in order to provide fish and other sea creatures with the healthy environment they need to thrive. These water samples offer a significant analytical challenge in that they often contain a wide variety of dissolved salts and/or organic molecules at greatly differing concentrations. Common anion/cations are found at very high concentrations, and contribute significantly to the overall salinity of sea water. Other ions, such as strontium (an essential element used by reef-building invertebrates) or iodide (also crucial to a variety of marine life) are found at much lower, or even trace, levels. Ion profiling of artificial seawater using ion chromatography followed by suppressed conductivity detection was investigated as a means to ensuring proper tank condition. Maintaining stable water chemistry of aquarium systems requires frequent sampling and, as a consequence, high throughput is a desired analytical characteristic. The goal of the project was to improve, optimize, and validate a currently-in-place method for the determination of cations and anions in artificial seawater. Variables such as mobile phase composition, column/cell temperature, and injection loop volume were studied in order to achieve better peak resolution in a shorter time period. The impact of a validated ion profiling method on aquarium maintenance is an important contribution to the zoo and aquarium industry.

Abstract Text

Ion chromatography (IC) is one of the most popular techniques for the separation and analysis of inorganic and small organic ions. Normally, chromatographers expect perfectly Gaussian peak shapes in liquid chromatography. With the introduction of high efficiency phases and small particle sizes excellent peak shapes with high efficiency phases are commonly seen. However, many challenging and real samples contain disproportionate amounts of analytes in the sample. Such samples can cause mass overload. In such cases, non-Gaussian peak shapes are seen. These fronting and tailing peaks shift the retention times of minor components and are therefore important in two dimensional liquid chromatography.

Our efforts are directed at understanding the fundamental basis of peak shapes with special reference to ionic analytes. This talk will discuss simple practical and predictive rules for determining the peak shape of a given ion on a modern high efficiency IC column. These simple ideas will allow chromatographers to predict the peak shapes without knowing the actual column chemistry and without resorting to complex numerical analysis. Finally, we will present two interesting cases (1) "Is it possible to see both fronting and tailing on the same IC column using the same mobile phase?" and (2) Can fronting and tailing peaks shift the retention times of other components under mass overload?

Abstract Text

Although ion chromatography is a relatively mature science, research into the development of new stationary phases for ion chromatography continues at an active pace more than 35 years after the introduction of ion chromatography as an analytical technique. In this work I will review the latest developments in new ion exchange phases developed specifically for ion chromatography. We will cover a variety of different stationary phase architectures and include examples illustrating their application to water quality and environmental analytical challenges.

Abstract Text

We describe an admittance detector for high impedance systems (small capillary bore and/or low solution specific conductance). Operation in the low frequency range (<1 kHz, much lower than used heretofore) provides optimum response to conductance changes in capillary id <20. The detector design was based on theoretical studies. The highest S/N for detecting 100 μ M KCl injected into water carrier (5.5 μ M peak concentration, \sim 0.8 μ S/cm) in a 15 μ m i.d. capillary was observed at 500-750 Hz. A low bias current operational amplifier in the transimpedance configuration permitted high gain (1 V/nA) to measure pA-nA level currents in the detection cell. Aside from an oscillator, only one more chip, a RMS-DC converter that can also provide offset, formed the complete detection circuitry; an additional operational amplifier can provide for added gain and further offset capabilities. Limits of detection (LODs) of KCl scaled inversely with the capillary cross section and were 2.1 and 0.32 μ M injected KCl for 2 and 5 μ m id capillaries, respectively. Used as a detector on a 16 μ m id polymethylmethacrylate capillary in a split effluent stream from a suppressed ion chromatograph, the LOD was 27 nM bromide (Vex 22 V p-p), compared to 14 nM observed with a commercial bipolar pulse macroscale conductivity detector with an actively thermostated cell. We also show applications of the detector in capillary electrophoresis in the smaller capillaries. Efficient heat dissipation permits high concentrations of the background electrolyte and sensitive detection because of efficient electrostacking.

Abstract Text

The utility of a suppressor in Ion Chromatography is well established. From the introduction of the packed bed suppressor to the continuously regenerated suppressors there has been significant progress in this arena. The development of a continuously regenerated suppressor paved the way to a more robust analytical platform for pursuing ion analysis. Advances in regeneration such as by electrolysis resulted in a more easy to use suppressor system. The recycle mode made it even more convenient and for the first time ion analysis was feasible with just an eluent containing reservoir. Advances in the eluent generation technology resulted in a system that today could be operated purely with a deionized water stream.

In the first part of this presentation we review the suppressor technology from a historic perspective. In the second part of this presentation we discuss a newly introduced electrolytic suppressor called the Electrolytically Regenerated Suppressor (ERS 500). We will discuss the design details along with the key benefits. Other designs of the suppressor particularly geared towards improving the chromatographic performance will be discussed. A new chemical suppressor design will also be discussed. We will also show example performance characteristics of the new suppressors. Results from analyzing real life samples such as drinking and waste waters will also be shown.

Abstract Text

Although SFC-MS has been around since the late 1980s, it has not become as prevalent as LC-MS in the pharmaceutical industry because, until recently, most of the work was in the form of preparation SFC chromatography for isolating compounds (usually chiral). However, with more sensitive instruments coming online, the analytical interest in SFC has reawakened and along with that has come an increase in SFC-MS activities. This review follows the progression of SFC-MS technology, the types of interfaces, back pressure regulators and analyzers that have been coupled to SFC. An overview of chiral SFC-MS and prep SFC-MS in the pharmaceutical industry is presented.

Abstract Text

In recent years, core shell particles have gained interest for use in HPLC and SFC applications. The hallmark of core shell particles are their relatively rapid mass transfer properties, making them ideal for high speed analytical separations. Good mechanical stability (strength) of the particles also lends itself to these fast and often high pressure separations in HPLC. While core shell materials have received a lot of attention for UHPLC application, less work has been done in the SFC realm. This is mainly due to the lack of variety of stationary phases available on core shell supports and the inherent "speed" already built in to SFC separations with traditional porous silica based stationary phases. However, as our industry trends to smaller particles and faster analysis times, even SFC users can benefit from core shell materials. We will present comparative data on three SFC stationary phases, bonded both to a core shell support and an analogous porous silica support. We will examine chromatographic similarities and differences over a wide range of commercially applicable test compounds. The data will illustrate in many cases that porous silica stationary phases, if properly optimized for SFC, can challenge core shell separations with respect to speed and selectivity.

Abstract Text

Process analytical chemistry serves as a critical function in the drug development process. A variety of analytical techniques are needed to support the analytical research and development activities. Supercritical Fluid Chromatography (SFC) has been used in process analytical chemistry to meet the increasing demand for better efficiency. In this presentation, the typical applications of Supercritical Fluid Chromatography (SFC) in process analytical chemistry will be discussed with highlighted examples, especially in the area of chiral separations.

Abstract Text

The aggressive pace of pharmaceutical drug discovery programs has placed increasing emphasis on implementing innovative technologies for processing new compounds in a rapid and efficient manner. The chromatographic efficiency of supercritical fluid chromatography (SFC) has enabled our group to rapidly characterize and isolate lead candidates for screening and development since early 2012. A mass-directed preparative SFC system is suitable for fast compound separations and same-day recovery of both chiral and achiral compounds at high specificity and sensitivity. The orthogonality of SFC enables successful separations of complex mixtures or chiral isomers that often limit the use of traditional techniques such as normal or reversed phase chromatography. Timely chiral purity checks for multiple projects have ensured a compounds' purity and identity to alleviate toxicity concerns.

This presentation will cover the implementation of SFC, instrument design optimizations, and strategies for successful small molecule separations in an automated high-throughput laboratory setting. Examples highlighting the benefits of SFC in pharmaceutical achiral-chiral separations and analysis will be discussed, especially for solving critical program challenges in large scale purifications and chiral separations of drugs and related metabolites.

Abstract Text

Chiral Chromatography has become essential for the pharmaceutical industry since there is a new focus on homochiral drugs. There are three different modes of chromatography that are utilized for nearly all of these chiral applications. Each mode: Super Critical Fluid Chromatography (SFC), Normal Phase Chromatography (NP), and Reverse Phase Chromatography (RP), has its own strengths and weaknesses. Since enantiomers are mirror images of each other and practically all of their physical properties are exactly the same. The development and execution of the chromatographic separations of chiral compounds are very different than for any other chromatographic methodology. It is virtually impossible to predict chiral resolution for a particular pair of enantiomers without some prior knowledge.

Chiral chromatographic method development always starts with screening the chiral compounds on columns capable of chiral separations. This is where the differences between the modes of chromatography become important. SFC is capable of screening compounds and columns much faster than NP or RP because the mobile phase can run at high linear velocities due to the eluents low viscosity and the columns equilibrate rapidly. However, the equipment used for SFC has the install base out of these three modes in the pharmaceutical industry. RP is easily the most common mode of chromatography used in the industry and NP uses the same equipment as RP but sometimes needs small changes due to solvent compatibility. There are reasons why someone might want chiral methodology for the same compound on several chromatographic modes. It might have to do with equipment availability, their regulatory environment, or in what solvent their samples solutions arrive in. The work described here will use real examples to demonstrate how chiral methodology can be screened in one mode and switched to another mode of chromatography.

Abstract Text

On occasion an analytical chromatogram presages a preparative separation. The purpose of the preparative separation may be to purify the main component from impurities found in the analytical chromatogram, to isolate enantiomers from a racemate or to isolate small amounts of impurities for identification. The equipment and procedures involved greatly depend not only on the object but also on the scale of the separation.

Scale-up from the analytical separation to preparative use is straightforward providing some simple rules are followed. This may involve not only a change in column size but also a change in packing material – both its dimensions and perhaps its nature. Guidelines in making this transition – when it is appropriate to redevelop a method and when to use one as close as possible to the existing one – are given.

The isolation of impurities should not be done in a single stage. A pre-purification step is essential to make the economics of the project viable. One approach is the supercritical fluid extraction of the impurities from the product; an illustration using extraction of a sample as an injection procedure to concentrate and make an initial purification of the sample is presented.

The question of the appropriate size of the preparative equipment can be approached by analysis of the costs of the operation. If one takes into account the operating costs, the costs of manpower, facilities and services as well as the cost of amortization of the equipment it is clear that there is an optimum size system for any specific project size. Data are presented demonstrating that where a single system is to be used to cover all scales of separation in a laboratory, it is usually best to choose a unit appropriate for the larger scale separations; the costs of running a small separation on a large system, although not optimum, are in general less than those of running a large separation on a small one.

Abstract Text

Human metabolites are a carrier of comprehensive information on the status of the entire metabolism with regard to nutrition, diseases and progress of a therapy, medication, drug abuse and nutrition. However, in general sampling, enrichment and adsorption steps are required before transport to a laboratory for analysis. Therefore, results are available only with a delay and quantification is limited. We want to present a method using ion mobility spectrometry coupled to rapid gas-chromatographic pre-separation and combined with appropriate sampling which enables the on-site, non-invasive sampling and analysis of the volatile metabolites in exhaled breath or sweat. When the focus is on semi-volatile or non-volatile metabolites this could be realised with the same analytical technique but coupled to e.g. laser desorption or electro spray ionisation. As a data base with the relevant compounds and suitable software algorithms for data evaluation are available, the results of such an analysis are available after few minutes and can be used e.g. for diagnosis.

Abstract Text

Dispersion that occurs during flow injection (FI) was investigated earlier by our research group to detect and correct for matrix interference in inductively coupled plasma time-of-flight mass spectrometry. The concept is straightforward: in the absence of an interferent, the dilution that occurs during FI should be the same for all sample constituents. As a result, the ratio of any two elemental signals should be constant. However, when an interferent is present, the signals from individual elements are affected differently, so the signals deviate from a constant value, especially at the peak of the FI curve where the interferent concentration is greatest. The drawback of this earlier method was that dispersion, and therefore dilution, was element-specific, causing the ratios to wander even when no interference existed. Here, we employ a gradient HPLC pump to overcome this drawback. With longer gradient runs and smaller gradient steps when compared to flow injection, the dispersion variation between elements is negligible and difficulties associated with it are eliminated. Importantly, when an interference exists, the optimal dilution factor to reduce the interference to an acceptable level can be found from the gradient curve as the point where the signal ratio between two elements becomes constant.

Abstract Text

We present a high-throughput device designed for large-scale aptamer selections, characterization and optimization of the selection process. This versatile device is also capable of performing chromatographic processes, including group exclusions and charge-based separations. This device, Microplate-based Enrichment Device Used for the Selection of Aptamers (MEDUSA), is an extension of our previously developed microcolumn technology and comprises 96 microcolumns arranged with the dimensions of a 96-well microplate, allowing it to be coupled directly to a microplate. It is a layered device fabricated using CO₂ laser machining, which enables it to be customized or reconfigured, with the ability to be assembled such that the microcolumns are connected in series or in parallel. MEDUSA has been used to characterize aspects of the aptamer selection process, including the specificity and partitioning efficiency of specific aptamers. A smaller customized version of MEDUSA was used to perform RNA aptamer selections to 12 protein targets with a single aliquot of nucleic acid library using the columns connected in series for the initial binding step, and in parallel for the subsequent steps. The results of these experiments, as well as chromatographic separations using the microcolumns will be discussed. MEDUSA's plate-based format allows easy integration with other plate-based systems for downstream biochemical processes and analysis.

Abstract Text

Multistep assays are often performed by using either magnetic beads or filter plates with a vacuum manifold. Magnetic beads are a popular tool for such assays, however they suffer from several disadvantages including the aggregation of the magnetic beads, the need for powerful magnets and the possibility of bead loss during washing steps. Vacuum based systems suffer from difficulties regulating vacuum pressure well-to-well and plate-to-plate. In addition, they have difficulty adapting to solvents of various polarities and viscosities.

We have devised a method for optically gating the passage of fluids through microtiter plate filter floors by functionalizing the floors with photochromic spiropyran derivatives. Spiropyrans are a class of organic compounds known for their photochromic properties; they are reversibly isomerized between a closed, hydrophobic form and an open hydrophilic form upon irradiation with UV and visible light, respectively. Photo-controlled gating of the filter floor allows for more rapid, efficient assays and a reduction in sample loss by enabling automated reagent transfer out of the wells between treatment steps.

The bottom surfaces of the wells are functionalized by covalently bonding spiropyrans to the membranes. Photogating is accomplished by irradiating the floor of the microtiter plate with the appropriate wavelength of light to open or close the spiropyran, rendering the floor hydrophilic (enabling passage of aqueous solutions) or hydrophobic (effectively "closing" the filter floor to passage of aqueous solutions). This presentation provides an overview of methods and applications of the innovation, along with surface characterization data.

Abstract Text

In recent years, laboratory managers have faced challenges in procurement and management of funds due to decreasing budgets, and as a result, there is an urgent and ongoing need to improve laboratory efficiency. Instrument manufacturers are challenged to provide researchers with higher-throughput analytical methods that do not compromise the quality of results but still meet budget requirements. An automated sampler handling system (EasyPREP) was acquired to reduce labor costs and to improve precision and accuracy, thereby increasing laboratory efficiency. The EasyPREP system allows for automated preparation of calibration standards, addition of multiple reagents, and internal standard additions and is suitable for many solvents. The instrument was procured to perform routine extractions of PM_{2.5} air samples collected on Nylon and Teflon filters. Prior to acquiring the EasyPREP system, PM_{2.5} samples were extracted using manual air displacement pipettes.

Samples were extracted using both the manual and automated delivery methods, and results were evaluated for precision and accuracy. The precision for samples extracted using the EasyPREP automated system was nearly 40 times better than the precision calculated for samples extracted using manual pipettes. Accuracy of the EasyPREP automated system was within 0.5% for 25.0 mL volume deliveries and 0.3% for 20.0 mL volume deliveries. Precision and accuracy were evaluated in a year-long study to determine consistency of the automated system and found to be reliable and steady throughout the year.

In conclusion, the EasyPREP automated system has been demonstrated to be a more reliable and effective method than manual pipetting. It reduced labor costs, increased efficiency and throughput, and maintained high precision and accuracy.

Funding for this research was provided by Research Triangle Institute.

Abstract Text

Selected Ion Flow Tube Mass Spectrometry (SIFT-MS) (Smith & Spanel, 2005) is a real-time analytical technique that detects volatile organic compounds (VOCs) and certain inorganic gases to low part-per-trillion concentrations (by volume; pptv) without sample preparation or preconcentration (Prince et al., 2010). These characteristics mean that SIFT-MS has traditionally been applied to real-time detection of VOCs in air.

This paper presents the very recent development of a swab desorber inlet that has for the first time enabled SIFT-MS to be applied to detection of diverse semi-volatile organic compounds (SVOCs) swabbed from surfaces. Very low nanogram quantities of SVOCs are readily detectable from a single swab, with greater selectivity than ion mobility spectrometry (IMS) due to the use of three instantaneously switchable reagent ions (H_3O^+ , NO^+ and O_2^+) coupled with mass spectrometric detection.

Compounds detected using the swab-based SIFT-MS analysis include explosives, explosives taggants, drugs of abuse and their precursors, and pungent odor compounds. A detailed presentation will be made on detection of taint compounds (such as dichlorophenol and tribromoanisole) that permeate through packaging materials and taint food and pharmaceutical products. This example also illustrates how readily SIFT-MS can be applied as a turn-key application.

Abstract Text

Many plasma-based sources for ambient desorption-ionization mass spectrometry (ADI—MS) perform best with helium as a supporting gas. The flowing atmospheric-pressure afterglow (FAPA) source is one such example, and uses around 1.0 L He/min. Unfortunately, even this modest flow rate can be cost-prohibitive, especially in some countries, and is best to avoid everywhere, since helium is a non-renewable resource. To address this problem, we have explored several strategies to reduce helium consumption; one successful strategy includes pulsing the gas flow on for only short periods and just when samples are immediately present in front of the source. Due to residual He in the discharge cell, the plasma can be sustained between He pulses with no gas flow for several minutes. When the helium flow is then restarted, the plasma quickly returns to its original state for a selected analysis period. Accordingly, helium is conserved as a function of the effective duty factor of gas-flow pulses. Gas flow, current-voltage characteristics, and helium pulse rate and duration have been studied and optimized. Sensitivity, repeatability of measurement, plasma behavior, and mass-spectral characteristics of this system will be discussed and advantages and drawbacks of pulsing the helium flow will be considered.

Abstract Text

Buffer capacity (β) is a superior parameter to pH because it is an estimation of the stability of pH at a particular time as opposed to just a static reading of the hydrogen ion activity. Physiologically, a blood pH of 7.4 is considered normal but there are no indications of how stable that pH is or how fast it will change. Buffer capacity is simply defined as the total acid or base influx a system can sustain without causing a pH change. The body's overall β is accounted for through contributions predominantly from the carbonic acid – bicarbonate buffer system, phosphates and plasma proteins. Acid is one of the major by-products of normal physiological activity and the blood's total β protects the body against this acid influx and aids in the removal of these toxins. Patients with sickle cell disease (SCD) and traumatic injuries have compromised homeostatic adaptations that cause an acid build-up and eventually reduce β . From the point of view of diagnostics, no point-of-care technologies exist that quantify β reliably and the systems that do present an estimation of the blood's overall ionic composition are multi-parametric, expensive, time-consuming and not portable. This project focuses on engineering a lab-on-chip device to quantify β of small whole blood samples (<1 μ l) ex-vivo whilst addressing key challenges of preserving sample integrity by preventing clots and atmospheric gas effects. A unique coulometric titration device was developed to generate a constant proton flux required to systematically titrate all buffering sources in whole blood. A comparative understanding of the time taken to reach the buffer's titration end point generates an understanding of the titration curve and an estimation of the total β in a matter of minutes. The device is intended to aid clinicians attending to patients with traumatic injuries to effectively reduce multi-organ failure rates and also help clinicians prevent vaso-ocular episodes in patients suffering from SCD.

Abstract Text

An electrochemical nucleic acid biosensors for the purpose of detection of microRNAs from cell lysates will be discussed. The fabrication of the system has been done via immobilization of complementary antimir-microRNA to graphene (GRP) modified pencil graphite (PGEs) electrodes prior to solid phase hybridization with either synthetic or microRNA contained total RNA. Enhancement of the signal due to GRP and the existence of GRP on PGEs have been investigated via electrochemical impedance spectroscopy (EIS) and differential pulse voltammetry (DPV). Intrinsic guanine oxidation signal recorded via DPV and charge transfer resistance, R_{ct} values determined via electrochemical circle fit option of EIS. Designed biosensor with its LOD of 1 pmole is applicable to analysis of certain miRNAs from total RNAs isolated from cell lysates. Many studies have been done in our lab related to microRNAs[1-4].

GRP modification of bare PGE ; optimized amount of GRP has been added to the acetate buffer solution (ABS) and sonicated for 20 minutes at room temperature. The bare PGEs are activated in the ABS (with 20 mM NaCl, pH:4.8) by applying +1.40 V for 30 s. A novel, ease-of-use, rapid, reproducible and selective graphene based electrochemical microRNA biosensor has been developed. To optimize hybridization conditions ,parameters affecting the process of immobilization and hybridization time, buffer pH, concentration of probe and target sequences have been studied.

Abstract Text

The increasing prevalence of antibiotic resistance challenges researchers to better understand infection, propagation of disease, and innate immunity. Group B streptococcus (GBS; *S. agalactiae*) is a beta-hemolytic Gram-positive bacterium that asymptotically colonizes approximately 20-30% of healthy women; however, it can cause severe disease in elderly, immunocompromised adults and neonates resulting in pneumonia, septicemia, and meningitis. Although GBS can be screened for and treated prior to delivery, GBS infections remain a leading cause of chorioamnionitis, preterm birth, stillbirth, and neonatal sepsis throughout the developing world. To understand the metabolic differences between a hypervirulent neonatal invasive strain (GB37) and an asymptomatic maternal vaginal colonizing strain (GB590), the multianalyte microphysiometer (MAMP) was utilized to dynamically measure glucose and oxygen consumption, lactate production, and extracellular acidification simultaneously. In addition to monitoring the differences between invasive and colonizing strains, further studies were performed to elucidate the effect of prostaglandin E2 (PGE2), an immunomodulatory lipid molecule found in high concentrations in the pregnant uterus and thought to mediate inflammatory responses throughout gestation. To simulate the macrophage-rich placenta, a murine macrophage-like cell line, RAW 264.7, was exposed to both strains of GBS, with and without the presence of PGE2. These studies provide real-time measurements of GBS exposure to macrophages and highlight the differences between strain virulence, enhancing the understanding of GBS infection and proliferation, which may eventually lead to accessible and early diagnostic tools for future screening.

Abstract Text

Octopamine is an endogenous biogenic amine that plays important roles as neurotransmitter, neurohormone, and neuromodulator in invertebrates, and has functional analogy with norepinephrine in vertebrates. In the past, fast scan cyclic voltammetry (FSCV) has been used for real time detection and characterization of rapidly changing dopamine and serotonin in the [i]Drosophila melanogaster[/i] larva ventral nerve cord (VNC). Release of neurotransmitters has been controlled by optogenetic activation of blue light sensitive channel, Channelrhodopsin (ChR2). Blue light causes a false peak near the upper (switching) potential of the FSCV waveform, which is close to where the octopamine oxidation peak is observed. This non-faradaic false peak could be due to tissue damage or ionic changes, and makes it difficult to detect blue light mediated octopamine release. We have characterized evoked octopamine release with two new stimulation methods, the ATP sensitive channel, P2X2, and a newly discovered channelrhodopsin, CsChrimson, which is red light sensitive. On average, a 5.0s stimulation with CsChrimson evokes 0.11 μ M of octopamine release in the larval VNC. Current due to evoked octopamine decreases upon repeated stimulation, and varying the inter-stimulation time does not change the magnitude of current decrease. The release is reduced by reserpine, demonstrating that it is vesicular. Overall, the ability to stimulate and detect octopamine release will allow a more thorough characterization of this important neurotransmitter in [i]Drosophila[/i].

Abstract Text

In recent years there has been considerable interest in the development of continuous physiological monitoring technologies for assessing physical performance in athletes. Measurement of metabolites is of particular interest as it provides information about the metabolic state of the tissue.

We are developing a wearable microfluidic analysis system that uses biosensors to quantify key metabolic markers of exercise. Microdialysis is used to sample the subcutaneous tissue during various levels of cycling and during the post-exercise recovery period, and the resulting dialysate is monitored for changes in glucose and lactate levels. The system consists of microelectrode-based amperometric biosensors [1] within a 3D-printed microfluidic flow-cell. Using this system we are able to continuously monitor the metabolic state of subcutaneous tissue in real-time.

Results will be presented from cyclists during and after various levels of exercise. These will be compared to results obtained using our existing human rsMD system [2,3].

Abstract Text

Cerium oxide nanoparticles, also known as nanoceria, have been proposed as potential radical scavenger, an abrasive catalyst in chemical polishing, a catalyst in fuel cell and as therapeutic molecules. The autocatalytic and therapeutic properties of nanoceria are derived from its redox chemistry. Ceria exists in both +3 and +4 states due to oxygen vacancies created during their formation. The redox value is sensitive to pH; however, its redox chemistry is not readily assessed using conventional electrochemical techniques such as cyclic voltammetry or chronoamperometry. This paper presents the ac electrochemical impedance spectroscopy (EIS) characterization of nanoceria. The effect of the maximum phase angle (ϕ_{max}) the interfacial charge transfer resistance (R_{ct}) and capacitive charge transfer (C_{dl}) at varying concentrations, sizes and pH will be presented. The impact of these parameters on the catalytic properties of nanoceria will be discussed.

Abstract Text

Our understanding of the underlying mechanisms of action of anesthetic drugs, and their influence on neural transmission, is relatively limited. Understanding how anesthetics affect neuronal activity would be advantageous in studies exploring brain circuits. Here, we investigated the influence of isoflurane or urethane on basal dopamine levels within several brain regions including the nucleus accumbens (NAc), the anterior cingulate cortex (ACC), and the caudate putamen (CPu) using fast-scan controlled adsorption voltammetry (FSCAV). Fast-scan cyclic voltammetry (FSCV) was used to measure dopamine release with millisecond resolution in the NAc following electrical stimulation in the medial forebrain bundle. Evoked release was determined in the absence or presence of cocaine (20 mg/kg, i.p.). Urethane was given intraperitoneally at 1-1.5 gm/kg and isoflurane was constantly administered at 1.25%; level of anesthesia was monitored in individual rats by monitoring respiration rate and by presence of reflex response to nociceptive stimuli. Basal dopamine concentrations were lower in the ACC, than in the CPu and NAc in isoflurane anesthetized rats but similar across regions in urethane anesthetized rats. In the presence of cocaine, tonic [DA] was increased similarly in all anesthetized animals but showed an extended duration in urethane over isoflurane, anesthetized rats. Additionally, electrical stimulation in the presence of cocaine produced a greater increase in NAc phasic dopamine release in urethane, than in isoflurane, anesthetized rats (135 and 84% over baseline). These findings indicate differential effects of anesthesia on dopamine dynamics and provide a basis for standardizing conditions of anesthesia in experimental settings.

Abstract Text

We present an origami paper-based electrophoretic device ([i]o[/i]PEpD), which achieves rapid (< 5 min) separation of fluorescent molecules and proteins at a voltage of 10 V, more than 10 times lower than that in a regular electrophoresis apparatus. [i]o[/i]PEpDs use multilayer origami paper as supporting medium for electrophoresis, which significantly shortens the distance between anode and cathode (e.g. ~2 mm thick for an 11-layer origami paper) and thus, generates a strong electric field > 1 kV/m even with a few volts input. In addition, the multilayer structure of [i]o[/i]PEpD enables convenient sample introduction by a slip layer, as well as easy product reclamation and analysis after electrophoresis by unfolding the device and cutting out desired layers. These advantages—low cost, low voltage, speed, and ease of use—make the [i]o[/i]PEpD a potential platform for point-of-care (POC) analysis. The use of [i]o[/i]PEpDs for simple separation of proteins in bovine serum is also demonstrated, which indicates its potential applications in diagnostic testing.

Abstract Text

Preterm birth (PTB) is the leading cause of infant death. Although the etiology is unknown, 6 protein and 3 peptide serum biomarkers were identified in association with spontaneous PTB. Even though no single biomarker had the specificity and sensitivity to diagnose PTB, a panel of these 9 has the predictive power to greatly aid clinicians in diagnosing PTB risk¹. We are focusing on creating a timely, accurate, inexpensive, miniaturized, and automated device that can selectively concentrate, label, separate, and quantify PTB biomarkers. Our approach entails a microfluidic lab on a chip that combines selective extraction on an affinity monolith column, labeling with a fluorescent species on a reverse-phase monolith column, electrophoretic separation, and quantitation by laser-induced fluorescence detection. We are currently optimizing conditions for on-chip labelling, elution of the unreacted dye and electrophoretic separation of the biomarkers. These devices should allow diagnoses of PTB risk prior to contractions and membrane rupture, which increases intervention and treatment options.

Funding was provided by the National Institutes of Health (R01 EB006124) and an Undergraduate Research Award from the Department of Chemistry and Biochemistry at Brigham Young University.

Abstract Text

Microfluidic systems allow integration of sampling, reagent mixing, and rapid electrophoretic analysis, and also are useful for culturing cells. Pancreatic islets—containing insulin secreting β -cells—have insulin oscillation with 3-5 min frequency or even longer rhythm. Deficiencies in such rhythms have been observed on Type 2 diabetes patients. To continuously monitor single islet insulin secretion patterns would be a helpful approach to understand them.

We have developed a microchip based electrophoresis assay allow such applications. The system incorporates two independent syringe pumps loaded with low and high concentration glucose. By mixing both pumps' contents—with different flow rates, arbitrary glucose gradients can be generated. Insulin secreted from the islets is measured at 5-10 s intervals by an electrophoretic competitive immunoassay. The integrated system can perform 14000 electrophoresis assays in 24 h and automatically control culture condition. Online calibrations are also incorporated to improve quantification.

The system has been applied to investigate a few projects.

1) Long term secretion dynamics

The islets are alternately perfused with high and low glucose on chip. Preliminary data shows expanded 1st phase response after the 1st glucose period.

2) Effect of toxic agents on secretion such as H₂O₂ and elevated glucose

The islets pretreated with H₂O₂ have elevated insulin secretion rather than the normal insulin oscillations. Islets would be cultured in high glucose to find if excess glucose leads to similar results.

3) Effect of incubation conditions on glucose sensitivity

Preliminary results have found that islets pre-cultured in 2.8 mM glucose have slower glucose response than normal cultured islets, but those co-cultured with 100 μ M diazoxide have faster response.

The results reveal the versatility of the islet workstation and its use for routine cellular monitoring. It would further be applied for adipocytes-islets interaction studies.

Abstract Text

Miniaturization is of interest as a tool for biochemical studies and holds the promise of portable, rapid, sensitive, integrated, and inexpensive analysis for point-of-care diagnostics. Herein, pressure actuated microfluidic devices for electrophoretic separations were developed using soft lithographic techniques. Each device has three-layer poly(dimethylsiloxane) (PDMS) construction. The fluidic layer with a T-shaped design has injection and separation channels. To carry out sample movement the control layer has an on-chip peristaltic pump and four different valves. An unpatterned PDMS membrane layer was sandwiched between the control and fluidic layers. Devices with different valve locations from the T intersection were tested with colored dye by selectively applying the actuation pressure. Currently, we are studying the separation and detection of fluorescently labeled model compounds and a mixture of pre-term birth biomarkers. Future work will involve testing of thermoplastics such as cyclic olefin copolymer or poly(methyl methacrylate) for the fluidic and control layers. We plan to integrate separation with on-chip labeling to develop next-generation microfluidic devices for pre-term birth analysis. This novel, state-of-the-art technology should provide a clinical diagnostic tool to assess pre-term birth, enabling therapeutic interventions.

Abstract Text

Heavy metals such as Cd and Pb are threat to human health due to the fact that they are not biodegraded. Although various high sensitive methods such as ICP and AAS have been reported, electrochemical analysis is advantageous since this method requires short time and the system can be miniaturized for on-site analysis. Anodic stripping voltammetry (ASV) has been commonly used for determination ppb level metal ions because the preconcentrate of metal ions on to electrode surface can improve the sensitivity and detection limit. We have previously developed an sp² and sp³ hybrid carbon film electrode by employing the electron cyclotron resonance (ECR) sputtering method. The carbon film electrode was utilized for ASV measurement of Cd at ppb level concentrations.⁽¹⁾ Recently we employed Unbalanced Magnetron sputtering (UBM) method which can fabricated carbon film with similar properties with that formed by ECR sputtering with lower equipment cost.⁽²⁾ In this work, we optimized sp² to sp³ ratio of UBM carbon film by mainly considering S/N ratio in ASV analysis for Cd and Pb.⁽³⁾ After optimizing measurement solution and carbon film structure, we incorporated the carbon film electrode in a radial flow-cell and integrated the pre-processing system including pre-column to remove Cu ion and on-line optical decomposition devise to remove organic interferents. With our UBM carbon film electrode, low detection limits of 0.5 ppb and 5 ppb could be archived for Cd and Pb ion, respectively, despite of relatively low current signal due to extremely low noise level compared with GC electrode. With our integrated system, we cloud measure ppb level Cd ion even in the presence of 100 ppb Cu ion and 0.1 mM EDTA.

Abstract Text

Cloud point extraction (CPE) is a well-established technique for the pre-concentration of hydrophobic species from water without the use of organic solvents. Subsequent analysis is then typically performed via atomic absorption spectroscopy (AAS), UV-Vis spectroscopy, or high performance liquid chromatography (HPLC). However, the suitability of cloud point extraction for electroanalytical methods such as stripping voltammetry has not been reported. We have developed a CPE procedure for the determination of cadmium (Cd^{2+}) by anodic stripping voltammetry (ASV) with bare and modified glassy carbon (GC) working electrodes. This extraction method was performed without the use of chelating agents, but using iodide to neutralize the charge on Cd^{2+} . This novel combination achieved a detection limit of 1 ppb when using a mercury-coated glassy carbon electrode. Applicability of this procedure to tap and river water samples was also demonstrated. The method can potentially be applied to a wide variety of transition metals as a simple, versatile, and cost-effective detection method.

Abstract Text

The hydraulic fracturing procedure typically involves a high pressure injection of water, a propping agent and different chemical additives into underground bedrock formations for the extraction of oil and natural gas. The chemistry of these fracturing fluids are often a complex proprietary blend designed for a variety of different purposes dependent on the specific type of well being fractured.

The analysis of fracking fluids by inductively coupled plasma optical emission spectroscopy (ICP-OES) may pose difficult challenges. Fracking fluids contain high levels of total dissolved solids which can cause interferences for the analytes of interest. These high concentrations may suppress the signal for the analyte and the internal standard due to plasma loading effects. To minimize plasma loading effects, minimal sample volume (<0.5 mL) was delivered into the system with analysis times of approximately 30 seconds per sample. The minimal sample volume and fast analysis times allowed for high sample throughput and minimal torch devitrification. For extended torch life of fracking samples, a hybrid torch was utilized in analysis increasing torch lifetime approximately 10 times.

Minimal sample dilutions (10x) were prepared to ensure reproducible trace metal detection. Typical precision obtained was $\pm 2\%$ RSD for 3 replicates. Typical matrix spike recoveries of $\pm 15\%$ were attained and stability over a 300 sample analysis achieved internal standard (Y 361.38 nm) recoveries from 89% to 105%, indicating a robust method with optimized plasma conditions. Additional data visualization was carried out using data analysis software, Tibco Spotfire.

Abstract Text

Silver nanoparticles, Ag NPs, are widely used in many consumer products. As a result, they can leach into the environment during product usage, raising concern about their toxicity in the ecosystem. Natural organic matter, NOM, is abundant in water supplies, soil, and sediments, and can bind with Ag⁺ that is released from Ag NPs. This results in formation of silver-species with altered bioavailability and toxicity. Using fluoros-phase Ag⁺ ion-selective electrodes (ISEs), we studied Ag⁺ binding to NOM and showed that Ag⁺ binding to NOM is favored by a higher pH. Moreover, effect of NOM chemical composition on kinetics and extent of binding was investigated. While only weak Ag⁺ binding was found for Suwannee River humic and fulvic acid, which are NOM samples with a low sulfur and nitrogen content, stronger binding was observed for Pony Lake fulvic acid, which has higher amounts of these elements. Fast kinetics of Ag⁺ and NOM binding was confirmed and Ag⁺ reduction by NOM was shown to cause slow decreases in free Ag⁺ activity in presence of Pony Lake fulvic acid. More generally, this work has shown that fluoros-phase Ag⁺ ISEs are effective tools for in situ studying of Ag⁺ binding to

Abstract Text

The use of nanoparticles in consumer products is showing a tremendous increase over time. The National Institute of Standards and Technologies reported that nanotechnology-based consumer products are currently entering the market at a rate of 3 to 4 per week, and it is estimated that \$2.6 trillion in manufactured goods will contain nanotechnology by 2014[1].

In spite of their beneficial properties, possible risks for humans and the environment need to be thoroughly investigated, and multiple key characteristics need to be assessed. Detailed information about the quantity, shape, size, size distribution, structure, composition, surface charge and functionality need to be studied and addressed in order to perform an appropriate and reliable risk assessment.

This work presents Single Particle Inductively Coupled Plasma Mass Spectrometry (SP-ICP-MS) as a tool in assessing the fate of engineered nanoparticles in environmental sample types [2,3]. The technique allows for the differentiation between ionic and particulate signals, measurement of particle sizes and size distribution, and assists in monitoring agglomeration.

Abstract Text

Metal burden in [i]Eudrilus eugeniae[/i] (earthworm) and [i]Pachybolus ligulatus[/i] (millipede) as bio-indicators of toxic metals impaction of soils in Akwa Ibom State, in the Niger Delta region of Nigeria were investigated. The study involved collection of [i]Eudrilus eugeniae[/i] and [i]Pachybolus ligulatus[/i], and their site soil samples from different impacted and non-impacted soils in ten locations spread over four Local Government Areas. Toxic metals (Pb, Fe, Zn, Ni and Cd) in soils and bio-indicator organisms were analysed using Atomic Absorption Spectrometry after acid digestion. Geo-accumulation Index (Igeo) was used to measure the extent of soil pollution, Bio-Accumulation Factor (BAF) to compute the metal uptake from soil by bio-indicators, and multivariate statistics to identify interrelationships among metals and the pollution sources. Metals in all soils were higher than the background levels, and were classified unpolluted to very strongly polluted. Pb, Fe, Zn and Cd were higher in [i]Eudrilus eugeniae[/i] and Ni in [i]Pachybolus ligulatus[/i] at 0.05 level. The organisms absorbed all metals (BAF<1), but [i]Eudrilus eugeniae[/i] accumulated Cd and Fe and [i]Pachybolus ligulatus[/i], Ni and Fe (BAF>1). Metals were clustered into three ([i]Eudrilus eugeniae[/i]) and two ([i]Pachybolus ligulatus[/i]) dissimilar groups. Two principal components extracted each for *Eudrilus eugeniae* and *Pachybolus ligulatus* accounted for 64% and 72% of total variations respectively. [i]Eudrilus eugeniae[/i] and [i]Pachybolus ligulatus[/i] could be used as bio-indicators in toxic metals impacted soils; and [i]Pachybolus ligulatus[/i] in particular, as indicator of soil Ni pollution due to oil and gas activities in the Niger Delta Region of Nigeria.

Abstract Text

In recent years, 1 in 6 Americans have been infected by foodborne pathogens, which each year on average have resulted in ~50 million illnesses, ~130,000 hospitalizations, and 3000 deaths. Preventing distribution and consumption of contaminated foods is challenging because just 100 bacterial cells can rapidly multiply to millions, reaching infectious doses within a few days. Unfortunately, current methods used to detect these few cells rely on similar growth steps to multiply the cells to the point of detection, which also takes a few days. Consequently, there is a critical need for an analyzer that can rapidly extract and detect foodborne pathogens at 100 colony forming units per gram (cfu/g) of food in 2-4 hours (not days), and with a specificity that differentiates indigenous microflora, so that false alarms are eliminated. In an effort to meet this need, we have been developing an assay that extracts such pathogens from food, selectively binds these pathogens, and produces surface-enhanced Raman spectra (SERS) when read by a Raman analyzer. Measurements of E. coli in ground beef, Listeria in cheese and Salmonella in cantaloupe at 100 cfu/g using this assay will be presented.

Abstract Text

Although Surface-enhanced Raman scattering (SERS) is a powerful technique for the sensitive and selective detection of low concentration analytes, the quantitative detection of target in real matrices using an optimal substrate is still a challenge. But the main problem in homogenous SERS immunoassay system is the difficulty in surface modification of nanoparticle. One of the solutions of this problem is to use a thin polymer film to immobilize the high amount of biomolecules.

In the present study, a simple and highly selective homogeneous sandwich assay was developed for fast and ultrasensitive detection of toxins such as SEB and ricin using a combination of aptamer functionalized hybrid magnetic nanoparticles and aptamer immobilized gold nanoparticles as the recognition and surface-enhanced Raman scattering (SERS) component, respectively. The magnetic hybrid particles were first coated with poly(N-acryloyl-L-valine) via surface-mediated RAFT polymerization and then biofunctionalized with appropriate aptamer, which are both specific for target toxin and can be collected via a simple magnet. After separating target toxin from the sample matrix, they were sandwiched with the SERS substrate composed of aptamer and 5,5-dithiobis(2-dinitrobenzoic acid) on gold nanoparticles. The optimization strategies for avoiding aggregation and the analytical performance of the SERS-based assays will be presented.

Abstract Text

Viability of standoff Raman technique is demonstrated by detecting contamination/adulteration in food items like grain flour, olive oil and milk from a distance of several meters. We have characterized standoff Raman technique with reference to parameters like, nature of food item, standoff distance, nature and concentration of contaminants, ability to make quantitative measurements, and sensitivity.

The equipment involves a portable Raman system with a 785 nm laser. The Raman system is coupled to a 2-inch refracting telescope and can be operated in the field either with batteries or a gas-powered generator. This set-up has been used to detect adulteration in powder and liquid-foods.

Results include detection of agrochemicals like fertilizers in wheat-flour. Nitrate contamination can be detected in flour from a distance of up to five meters. Likewise Alum is used for refining flour and has been detected by the standoff Raman technique. Contamination of Olive Oil with cheaper edible oils has been detected from a distance of 1 meter. We have detected Ammonium Nitrate by stand-off Raman technique at distances of up to 100 meters. This serves as a proof of concept that we may be able to detect food contaminants at very large distances.

Stand-off Raman technique can detect food contaminants/adulterants which could be toxic or laced with biological pathogens from a safe, non-contact distance of several meters. The results show a potential to solve issues related to monitoring food-supply chain and characterize the nature of vulnerability.

Abstract Text

The kinetics for the in vitro reactions of acrylamide (AA), a potentially toxic food contaminant formed during elevated-temperature food preparation, with captopril (CapSH), L-cysteine (CySH) and glutathione (GSH), were determined under basic conditions and constant ionic strength (pH 7.10 – 9.10; $I = 0.2 \text{ mol dm}^{-3}$, NaCl), and pseudo first-order conditions with respect to AA. The second-order rate constants, k , and activation parameters (E^\ddagger , S^\ddagger , and G^\ddagger) were determined over the ranges of 293 – 303 K for CySH and 303 – 315 K for GSH and CapSH. Comparison of experimental second-order rate constants at 303 K for CapSH, CySH, and GSH were: 0.13 ± 0.01 , 0.34 ± 0.02 , and $0.18 \pm 0.02 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$, respectively and DFT calculations show evidence of diminished intra-molecular hydrogen abstraction reaction in aqueous solution specific only to GSH. An isokinetic plot of E^\ddagger versus S^\ddagger yields an isokinetic temperature of $260 \pm 24 \text{ K}$ and an intercept, G^\ddagger , of $71 \pm 4 \text{ kJ mol}^{-1}$ indicating that AA reacts with all three thiols via the similar reaction mechanism. Theoretically determined G^\ddagger values in aqueous solution (DFT-BVP86/Ahlich-TZVP/COSMO-RS) for CapSH, CySH, and GSH, including their zero point vibrational energy, are 212.2, 217.8, and 253.4 kJ mol^{-1} , respectively at 298 K.

Abstract Text

The need for highly selective, efficient protein separations continue to rise due to the costs associated with downstream processing of biopharmaceuticals. Affinity chromatography is considered a fast, simple, highly selective method for biomolecule purification. This is evident in the rise of new affinity ligands including aptamers, antibodies, metal ions, etc. These methods are so useful that biomolecules have been designed with affinity tag modifications to exploit these powerful interactions. A problem associated with these methods is the cost associated with functionalizing these support phases. Novel lipid tethered ligands (LTL) can allow for a quick and easy method to functionalize hydrophobic surfaces with affinity ligands. LTLs work by strongly adsorbing the lipid to hydrophobic surfaces, while leaving the modified head group exposed in the bulk flow. Biotin functionalized LTL demonstrated the ability of capturing streptavidin labeled with Texas Red (SAv-TR) while adsorbed to polypropylene capillary-channeled polymer fibers.

A comparative study is underway evaluating the robustness and efficiency of LTLs for the functionalization of polystyrene-divinylbenzene (PS-DVB) micro-beads. PS-DVB packed columns are exposed to biotin functionalized LTL containing solutions of 50% ethanol:water. The functionalized biotin LTL PS-DVB column was evaluated for selective capture of SAv by breakthrough curve analysis. Addition of 0.1% Tween 20 is added to the SAv containing buffer to prevent non-specific binding of the SAv to the PS-DVB beads.

Further evaluations of LTLs will be done to evaluate elution conditions and robustness of PS-DVB columns functionalized with LTLs. LTLs with fluorescent head groups will be used to evaluate conditions necessary to elute the LTLs from the PS-DVB. At times it is easier to separate the ligand from the surface, than overcome the affinity interactions. This is used when regeneration of the stationary phase is easy and cost effective.

Abstract Text

Capillary-channeled polymer (C-CP) fibers (polypropylene, nylon and polyethylene terephthalate) have been used as stationary phases for HPLC separation in this laboratory for over a decade. Considerable research has been conducted to employ C-CP fiber stationary phases for downstream protein processing. Protein A modified polypropylene (PP) C-CP fibers have been shown to be a promising affinity phase for efficient capture of IgG. PP C-CP fibers have been modified by head group-functionalized lipids to introduce different functionalities. Ion-exchange separations are another crucial step in protein downstream processing. In this study, polyethylenimine (PEI), a highly branched and positively charged polyamine, was covalently attached to the surface of polyethylene terephthalate (PET) C-CP fibers. Initial results showed that the PEI modified PET C-CP fiber stationary phases were capable of capture and elution of bovine serum albumin (BSA) under weak anion exchange (WAX) conditions. By choosing the optimized modification process, PEI modified PET C-CP fiber stationary phases showed little reversed phase characteristics, indicating extensive coverage of the hydrophobic surface of native PET C-CP fibers with PEI. The inexpensiveness of PET C-CP fibers and the simple, low-cost modification process make PEI modified PET C-CP fibers a promising choice as stationary phase in protein downstream processing.

Abstract Text

A heart-cutting two dimensional liquid chromatographic method for the isolation and quantification of amino acid enantiomers from rat brain tissue is demonstrated. Evidence to support the occurrence of D-amino acids in high concentrations in physiological samples has spurred studies toward the elucidation of their importance and function. In this work, the level and regional distribution of select amino acids were determined by achiral-chiral LC/LC. The free amino acid extracts were analyzed as their 9-fluorenylmethyloxycarbonyl derivatives and separated in the reverse phase on superficially porous C18. In the second dimension, enantiomers of selected amino acids were resolved on Chirobiotic-T as it exhibits excellent selectivity. This study focused on D-ser, D-ala, D-leu, D-asp, and D-pro as they hold relevancy as highly functional neurological molecules. Total concentration of amino acids were determined through the use of internal standards and enantiomeric ratios were determined with high sensitivity using fluorometric detection. Because the selected D-amino acids have utility in development and neurotransmission, their potential as disease biomarkers is concurrently being investigated.

Abstract Text

Drugs are often reversibly bound to carrier agents such as serum proteins in the circulatory system, causing these drugs to exist in a free or protein-bound form. Because the free drug fraction is generally thought to be the biologically-active form, there is increasing interest in developing methods to estimate the free drug fractions and to study drug-protein interactions in clinical samples. However, commonly-used methods such as equilibrium dialysis and ultrafiltration generally need large amounts of sample and/or long analysis time. Moreover, separate experiments are required to measure both the kinetics and thermodynamics of a drug-protein interaction. To overcome these limitations, a new approach was created based on ultrafast affinity extraction and affinity microcolumns to measure free drug fractions and to study the drug-protein interactions. Human serum albumin (HSA), the most abundant serum protein in the blood, was used as a model soluble protein for this work. Several drugs were examined, such as warfarin, verapamil, chlorpromazine, and sulfonylurea drugs. It was shown this approach could simultaneously determine both the binding and rate constants for drug interactions with soluble proteins. A modified approach based on a multi-dimensional affinity system was also created to simultaneously study the binding of two enantiomers in racemic warfarin with HSA in serum. The same general approach was used to investigate how glycation of HSA, as found in diabetes, may alter the free fractions and affinities of sulfonylurea drugs with normal HSA or glycated forms of this protein. The results indicate that this method can be a powerful tool for the study of drug-protein interactions and can provide information on free drug fractions in serum or in samples with clinically-relevant concentrations of drugs and proteins.

Abstract Title **Modification of Polyethylene Terephthalate Capillary-Channeled Polymer (C-CP) Fiber Stationary Phase for Affinity Separations**

Primary Author Liuwei Jiang
Clemson University

Date: Thursday, March 12, 2015 - Afternoon

Time: 03:05 PM

Room: 254

Co-Author(s) R Kenneth Marcus

Abstract Text

Capillary-channeled polymer (C-CP) fibers have been under investigation and development as stationary phase for high performance liquid chromatography (HPLC) separations for over ten years. They are unique due to the eight capillary channels extending the whole length of the C-CP fiber. This unique shape offers them ~3x greater surface area than that of circular cross-section fibers with the same nominal diameter. When packed into a column, C-CP fibers self-align, yielding a monolith like structure of 1-5 μm open, parallel channels. As a result, C-CP fiber stationary phases exhibit excellent fluid transport properties. A traditionally sized HPLC column packed with C-CP fibers can be operated at high linear velocity ($> 100 \text{ mm s}^{-1}$) with low backpressure ($< 2000 \text{ psi}$). In this study, a polyethylene terephthalate (PET) C-CP fiber packed microbore HPLC column was sequentially functionalized. The coupling strategy of solid phase peptide synthesis (SPPS) was employed for the attachment of ligands. The common biotin-streptavidin affinity pair was used as a demonstration of the basic methodology, wherein biotin was the immobilized ligand. The subsequent streptavidin binding homogeneity and binding capacity were studied by breakthrough curve experiments and frontal analysis. The biotin functionalized PET C-CP fiber column was shown to be able to affinity capture streptavidin from an enhanced green fluorescence protein (EGFP)-spiked *E. coli* cell lysate with high selectivity and efficiency. The SPPS coupling method used here yields PET C-CP fiber stationary phases with great potential for further functionalization by a variety of affinity ligands and used for affinity chromatography applications.

Abstract Text

Capillary-channeled polymer (C-CP) fibers have been studied in this laboratory as stationary phases for protein separations in high-performance liquid chromatography (HPLC). C-CP fibers are uniquely shaped so as to include eight continuous capillary channels which interdigitate once packed into a column. The packed column resembles a monolithic structure of unobstructed flow through capillary channels which reduces backpressure and increases linear velocity, reducing separation time. Fibers are effectively nonporous for macromolecules, resulting in rapid mass transfer and high sample recovery. C-CP fibers made from polypropylene (PP) yield a fairly homogenous hydrophobic surface suitable for reversed phase (RP) chromatography. In a microbore C-CP column, separations can be done very quickly, in less than ten minutes, even at low flow rates, saving time as well as money in column cost, solvent cost and waste generation. Presented is a fast liquid chromatographic separation of a multi-protein suite analyzed by electrospray ionization mass spectrometry (ESI-MS).

Electrospray ionization mass spectrometry (ESI-MS) analysis provides more analytical information than multi-wavelength detectors. However, the low flow rates needed (<0.5 mL/min) for optimal spectral clarity generally imply low linear velocities and slow separations if liquid chromatography mass spectrometry (LC-MS) is desired. To this end, decreased C-CP column diameters (0.5 mm i.d.) are employed to increase linear velocity, and therefore speed separation time, without the need to increase flow rates. Ribonuclease A, cytochrome c, and transferrin were loaded in phosphate buffered saline. Matrix was removed using a water wash before applying a gradient of ACN to elute proteins by hydrophobicity into ESI-MS.

Abstract Text

Oxidative stress occurs due to a disturbance of the body's natural balance between oxidants and antioxidants due to an overabundance of reactive oxygen species (ROS). During a stress event, the overproduction of ROS will disrupt the function of many biological molecules and processes. One example is lipid peroxidation, where ROS attack polyunsaturated fatty acids and result in the secondary production of reactive aldehyde species, such as 4-hydroxynonenal (HNE), malondialdehyde (MDA), and acrolein. These species can then be used as biomarkers of oxidative stress. A method was developed for the separation and simultaneous detection of these three analytes using liquid chromatography with fluorescence detection. The aldehydes were derivatized with dansylhydrazine for 20 minutes at 50 °C to form a fluorescent product with a maximum excitation and emission wavelength of 250 and 550 nm, respectively. No other preparation was required before injection. Separation was achieved on a reverse-phase column with a C18-based stationary phase in 20 minutes. This method resulted in LODs of 660 nM for HNE, 1.7 µM for MDA, and 2.4 µM for acrolein. Additionally, this method was used to quantify levels of these reactive aldehyde species in rat urine following a stress event. Epileptic-like seizures were induced in the animals through the use of a chemical agent, 3-mercaptopropionic acid, and the change in concentration monitored. A rise in acrolein concentration after seizures was observed, while HNE and MDA stayed near basal levels. The current method was also validated by comparison to a previously-published method for the detection of malondialdehyde.

Abstract Text

Goldenseal has emerged today as one of the 20 most popular herbal supplements used worldwide. The major alkaloids in goldenseal are berberine, hydrastine and canadine, which are believed to be the main bioactive compounds with various pharmacological effects. Most previous researchers have used LC-UV methods to quantify berberine, canadine and hydrastine in goldenseal. LC/MS techniques are extremely powerful tools for the quantification of alkaloids in medicinal herbs. Quantification using LC/UV or LC/MS techniques requires the standard compounds to have a known purity to construct calibration curves. The quantitative high-resolution proton nuclear magnetic resonance method (^1H -qNMR) method is rapid, highly specific, linear, can provide traceability through use of well characterized, internal or external standards of very high purity.

In this study, the ^1H -qNMR method has been developed with external standards to determine the purity of berberine, canadine and hydrastine, which are used for quantification of those compounds in goldenseal extract. We have developed a LC-MS/MS using selected reaction monitoring (SRM) to quantify these three alkaloids in goldenseal extracts. The purity results of berberine, canadine and hydrastine are 93.35; 99.36 and 99.32% (respectively). To date, berberine, canadine and hydrastine have been quantified at mg/g levels powdered goldenseal extract.

In conclusion, the current ^1H -qNMR and LC-MS/MS using SRM option methods are rapid, highly specific and can assign the purity of standard compounds and quantify the three major alkaloids of goldenseal root and will provide a useful tool in understanding the bioactivity of this medicinal plant.

Abstract Text

The chemical industry: a data industry. Yes, we make products, tens of thousands of them, from the fuel that powers our cars, to lifesaving medicines, to key components of the food we eat every day. We transform raw materials into the products that make modern society possible; it's pretty amazing when you think about it. But in each company, in every chemical sector, we also make and manage vast amounts of data that underpin the discovery, development, manufacturing, quality, safety and efficacy of our products.

It all starts with the data. No data, no products. And our data is in a sad state.

We live in a world where millions of us can find any song we want on our phones and then listen to it from our car stereo in seconds. Yet finding and assembling data to support a scientific decision, regulatory or legal query can take hours, days, weeks, or longer. We can share our thoughts, a song, a playlist or pictures with our friends in seconds, yet sharing scientific observations, a fundamental scientific endeavor, is inefficient, hindered or sometimes impossible.

What's going on?

Bluetooth, WiFi, MP3, HTTP, and HTML are standards we use nearly every day because our devices (e.g., phones, cars) seamlessly implement these standards using software toolkits like those provided by iOS, Windows and Android. You don't even think about the standards— the toolkits do the heavy lifting. Yet no such common standards or software toolkits exist for our devices at work, our laboratory instruments.

In this talk we describe a software toolkit being created to embed standards for analytical data. We also discuss why this approach addresses fundamental root causes of our data challenges rather than treating symptoms of the problem. Finally, we describe how such a community-driven approach can transform how we create, use, share and manage scientific data to create innovative products; how it will simplify and enhance productivity in our industry. After all, we are a data industry.

Abstract Text

“Laboratory Information Management Systems (LIMS) have evolved significantly over several decades to help end-users achieve their lab management requirements. Some LIMS platforms have provided very flexible systems in terms of configurability, but the reality is that most of the systems still need to be customized to meet specific end-user requirements. This customization, whatever technology is used, always involves some degree of programming. The programming tools or integrated development environments within LIMS platforms mostly require vendor tool specific programming skills. Even an experienced programmer still needs to know the programming language and the underlying database structure in order to make changes or modifications to the system. This leads to increased total cost of ownership and validation challenges.

Now for the first time in the LIMS world there is a fully developed non-programming solution. QuaLIS Studio allows users to make changes to the LIMS behaviour, to the business rules it uses and to create completely new functional capability without writing code. Additionally it has minimal requirements to understand the underlying database structure. QuaLIS Studio is designed using object oriented technology which simply allows users to drag and drop user interface components and interact with server-side class objects which in turn perform transactions. Extra functionality can be added by re-using existing class objects or by creating new classes using the business rule definition tool which in turn generates the underlying code for the server-side class. QuaLIS Studio provides a significant speed increase for customization and does not require an IT professional to implement modifications and enhancements to the system. Regulated industries will benefit from using this new programming-free approach and all industries will benefit from the speed and ease of configuration without customization.”

Abstract Title **Safe Energy-Efficient Chemistry Labs – Challenging the Assumptions**

Primary Author Greg Muth
Wilson Architects

Date: Thursday, March 12, 2015 - Afternoon
Time: 01:30 PM
Room: 255

Co-Author(s)

Abstract Text

There are a lot of assumptions around chemistry labs that have shaped the way that these facilities have been designed for decades, but some of these assumptions are now coming back to haunt us. There is a growing trend among research institutions to renovate or replace their existing chemistry labs. We are seeing these spaces being moved out of the upper floors of research towers. Old unsafe facilities are being replaced and inefficient spaces are being overhauled. New chemistry teaching and research pedagogies are changing the program requirements and new technologies are allowing us to challenge the old assumptions and build energy efficient spaces that are safe and flexible.

In this presentation we will look at assumptions around safety, program, building codes, equipment loads, ventilation rates and, of course, fumehoods. We'll investigate what are the possible payoffs for challenging them and what are the costs for not challenging them. We will look at the new technologies that are available and see which are safe and can save you money and which will be a waste of your facilities dollar.

Key Points

1. Safety is paramount in chemistry labs. We have learned a significant amount about the dangers posed by hazardous chemicals over the past few years and this is now reflected in building codes and the plan review process.
2. Reducing CFM doesn't have to mean reducing safety. Targeting where how and when you reduce your flows can actually make your lab safer.
3. Chemistry labs don't have to be energy hogs if everyone works together from the beginning and challenges the assumptions.

Abstract Text

For decades helium ionization detectors have been the detector of choice for the analysis of high purity and ultra high purity gases for atmospheric impurities. In some cases these detectors have not evolved since their inception, others have become obsolete, but those designs are for a bygone era, when the cost and availability of helium was not a concern.

However, with greater industry demand for helium, changes in the politics of helium, global supply chain risks, rising prices, and a growing international awareness of the limited supply of helium, it is both economically and environmentally responsible to consider how this resource can be used more efficiently and to consider options that exist which can greatly reduce helium consumption and perhaps to recycle as a means of further reducing waste and cost.

This presentation will provide comparisons of older techniques and emerging methodologies, and where the greatest opportunities for improving analysis, reducing time and helium consumption all of which help in reducing cost of ownership, while simultaneously improving our stewardship of one our limited environmental resources.

We will compare detector systems, chromatographic techniques and system considerations which can drastically reduce your helium footprint.

Abstract Text

We will deliver an analysis of the critical components of a company's overall enterprise manufacturing intelligence (EMI) strategy, plan, structure backed by real cases. We will delve into the criteria that impacts manufacturing operations and the requirements involving the real-time analysis of data from any and all processes in order to react with quick, educated decisions to reduce costs, increase yields and improve quality.

Manufacturers, LIM providers and LIM users will learn how to use enterprise manufacturing intelligence (EMI) and integrate, analyze and visualize information from data sources across operations for better, faster results. LIMs Providers and Users of LIMS will get an in-depth understanding and the resulting impact of using mission-critical data that is collected and managed by LIMS as part of the greater EMI environment.

EMI the fastest growing technology investment segment in manufacturing according to analysts. LIMS managers need to be proactive to ensure their LIMS is a key part of the overall EMI plan. By getting involved now, laboratories greatly mitigate the risk of having integration plans dictated to them or worse - their companies start considering alternatives to LIMS. This session will explain the role of LIMS in the overall EMI environment, best practices integrating LIMS with other process information systems, and the importance of taking a leadership role in an EMI roll-out.

Abstract Text

A recent revolution in chromatography is the development of porous polymer monoliths (PPMs) as stationary phases. Compared to traditional silica-based stationary phases, PPMs have very different structures. Monoliths can be customized by changing polymerization conditions, porogens, or monolith components. Small changes in polymer recipes may result in dramatically different structures and separation performances. A lauryl acrylate porous polymer monolith was synthesized in fused silica capillary columns with different linkers, with and without an anionic electroosmotic flow modifier. Cross-sections of polymers were coated with gold or platinum and imaged using secondary electron SEM in order to provide morphology information for better understanding of the behavior of the lauryl acrylate PPM. The highly porous, interconnected network of globular polymer clusters enable the mobile phase and analyte to interact. The clusters are randomly shaped, however, the globular particles are similar in size and thus used for quantitative comparison. To eliminate imaging artifacts, commercially calibrated nanoparticles were imaged in situ with our polymers. These high-resolution SEM images enabled direct visualization and comparison of different polymer compositions. Measurements of particle size and edge thickness were also taken from images and analyzed statistically. The results provide insights for understanding the relationship between structure and properties of lauryl acrylate porous polymer monoliths.

Abstract Text

A separation of rhodamine laser dyes is accomplished through the use of an electrospun polymeric nanofiber mat acting as the stationary phase in planar electrochromatography (PEC). A solution composed of silica nanoparticles and polyvinylpyrrolidone (PVP) was dispersed/dissolved in reagent alcohol and electrospun to create a mat of nanofibers. The nanofiber mat was then cross-linked to reduce the solubility of PVP in common solvents used in mobile phases. The silica/PVP mat was previously shown as an effective stationary phase in ultra-layer chromatography (UTLC). Cross-linking parameters were studied to show chromatographic performance with optimization under different reaction conditions. The influences of ternary mobile phase conditions, applied potential, and development time on analyte migration distances were studied. The laser dye separation utilizing PEC will be compared with UTLC analysis in terms of efficiency and analyte order of retention. Time of analysis is decreased for PEC (60-120 seconds) and occurs faster than in UTLC separations.

This research was funded by the National Science Foundation.

Abstract Text

Monolithic stationary phases include both silica and polymeric types. Both of these phases behave differently from traditional particle based stationary phases. We are examining the behaviour of organic, porous polymer monoliths used in capillary electrochromatography so that these materials and their performance as stationary phases can be better understood.

In order to compare the performance of porous polymer monolithic stationary phases to traditional stationary phases, the relationship between analyte diffusion and retention is explored and modeled with Eq. 1, first published by Knox and Scott in 1983.

$$D_{eff} = (\frac{\eta D_m + k \tau D_s}{1 + k}) \quad \text{Eq. 1}$$

$$(1 + k) D_{eff} = (\eta D_m + k \tau D_s) \quad \text{Eq. 2}$$

This relationship links D_{eff} , analyte diffusion in the presence of a stationary phase; with D_m , the diffusion coefficient of the analyte in the mobile phase; η , the column obstruction factor; τD_s , the kinetic parameter; and k , the retention coefficient. When rearranged as is shown in Eq. 2, this relationship predicts a linear result if D_{eff} is plotted versus k . However, literature examples of studies of traditional stationary phases show negative and curved deviations from the predicted linear relationship.

We are applying this approach to studies of a lauryl acrylate porous polymer monolith (PPM). Diffusion studies were carried out with a homologous series of alkyl benzenes (toluene through 1-phenyl octane). The lauryl acrylate PPM was prepared in situ as stationary phase in a capillary column. The peak parking method was used to measure the axial diffusion of analytes (D_{eff}) within this stationary phase at after allowing the analytes to diffuse for various times. The rate of diffusion in mobile phase (D_m) was also measured in an open column. After treating the data according to Eq. 2., a linear relationship was obtained. Our results show significantly less deviation from an ideal Knox plot compared to literature reports of other stationary phases. This linear relationship is due to the very low internal porosity which results from the unusual structure of the polymer monolith. Characterization of this new stationary phase on a fundamental level provides useful information for its development.

Abstract Text

We have recently reported the preparation of microfabricated, carbon nanotube(CNT)-templated SiO₂ nanowire thin layer chromatography plates. One of the principle challenges in this work has been to find a suitable method to conformally coat carbon nanotubes with the desired stationary phase material. Here we present an overview of our fourth microfabrication process. In this development, true atomic layer deposition (ALD) in commercially viable equipment is used to coat the CNTs with SiO₂ for the production of robust plates capable of performing rapid, high-efficiency, normal phase separations.

Abstract Text

The work presented in this talk evaluates silicon nano-pillars for use as planar chromatographic platforms. Electron beam lithography (EBL) and Dewetting (DW) protocols were used to create nano thin layer chromatography (NTLC) platforms. With these wafer level fabrication methods we are able reduce the size of separation medium beyond ultrathin-layer chromatography (UTLC). The pillar heights for all systems investigated are 1-2 micron. The pillar diameter/pitch is 400/550-700 nm for the EBL arrays. The stochastic DW systems have an average pillar diameter/pitch of 230/640 nm. A porous silicon oxide layer (25 nm) was added to each of the pillar array types and then a C18 stationary phase created. Flow was studied and the values for the permeability constant (K0) for the EBL cases were $\sim 8 \times 10^{-7}$ and for the DW arrays $\sim 5 \times 10^{-7}$. These values are slightly better than our prior report for UTLC pillar arrays. The experimental plate height using Sulforhodamine test dye was ~ 0.1 micron and reproducible for an EBL platform. However, this was done with a slow-evaporating benzyl alcohol mobile phase and there was probably considerable band focusing during the drying process. The same test dye yielded a plate height of ~ 1 micron with the DW array when a more traditional solvent system was used. Separations of fluorescent dyes, environmentally significant derivatized-amines, and anti-tumor drugs are illustrated.

This research is supported by the National Science Foundation under Grant CHE-1144947 with the University of Tennessee and a portion was conducted at Oak Ridge National Laboratory.

Abstract Text

Nanoporous gold (NPG) is an attractive material for such applications as catalysis and immunoassays due to its ease of fabrication and large surface area density. The nano-scaled features and bicontinuous geometry, however, suggest that NPG might also find practical use as a membrane towards (bio)molecular separations. The small constrictions not only demonstrate size-selective behavior, but also promote electroosmotic flow (EOF) effects through the pores. Furthermore, the amenability of Au surfaces towards self-assembled monolayer (SAM) formation allow for precise control over of the surface charge of the NPG. In effect, dynamically tuning the strength and direction of EOF is possible through modulation of this surface charge.

Herein, NPG was prepared through free-corrosion de-alloying of an Au-containing alloy with a concentrated nitric acid bath. Average pore sizes of 50 nm were obtained for the as-prepared NPG, as determined using scanning electron microscopy. The pore sizes were tuned to a desired average diameter by electrodepositing Au monolayers following a surface limited redox replacement approach. Further modifications to the surface charge of NPG were made using standard SAM techniques by immersing the NPG in various omega-functionalized alkanethiol solutions. A custom reservoir assembly coupled to a UV-visible absorption spectrometer was used to monitor the translocation of tracer molecules, such as sodium benzenesulfonate and methyl viologen in the presence of an electric field. The surface charge and pore size was found to have a direct effect on the rate at which these analytes transited the NPG membrane.

Support for this work was provided through the University of Illinois at Urbana-Champaign and the National Science Foundation Graduate Research Fellowship Program (NSF DGE-1144245).

Abstract Text

Porous polymer monoliths (PPMs) are recently developed new stationary phases that have many advantages over traditional phases. However, fundamental characteristics of these polymers haven't been fully studied. This work examines the thermodynamics of analyte retention on lauryl acrylate PPMs used as stationary phase for capillary electrochromatography (CEC).

For an alkyl benzene series (toluene through octyl benzene) of analytes, the effect of temperature on retention was examined using CEC. Temperatures ranging from 25 °C to 60 °C in 5 °C increments were tested and a clear and expected trend was obtained indicating a reduction in retention as temperature increases. Thermodynamic parameters such as entropy and enthalpy were derived from the Van't Hoff equation.

While the enthalpy of retention is taken from the slope of a Van't Hoff plot, determination of the entropy of retention relies on obtaining the value for phase ratio. Nanoflow HPLC was used to measure the volumes of mobile and stationary phases. It is also crucial to determine if the phase ratio is a function of temperature. Precise measurements of the flow rate enabled accurate calculation of phase ratios at a variety of temperatures. These studies were expanded by varying the amount of acetonitrile in the mobile phase. In addition, columns with different linkers, with and without anionic electroosmotic flow carriers were investigated and compared.

Abstract Text

Ionic liquids are a class of nonmolecular ionic solvents with low melting points. These liquids are unique combination of cations and anions and can provide a variety of different selectivities when used as stationary phases in capillary gas chromatography. The majority of the polyionic ionic liquid phases that we have been evaluating all provide polar and highly polar selectivities similar to polyethylene glycol based our biscyanopropylpolysiloxane phases. These phases will provide unique selectivity for the evaluation of a number of variety of different samples including petrochemical, environmental and food and beverage. The purpose of our studies is to determine the effects changing the cation and spacer groups on the selectivity and stability of the phases. Selectivity was determined and compared using various isothermal and temperature programmed test mixes. Particular cation and anion combinations appear to provide very unique selectivity by the shifting of normal alkane relative to aromatic and other chemical species. New combinations of cations and anions have been evaluated which provide unique selectivity and stability to the phases. We will also demonstrate the effects of the various functional group combinations on the overall stability of the ionic liquid stationary phases.

Abstract Text

Water and alcohol are found in many pharmaceutical products, both are used for their solubilizing properties or are residuals from the synthesis process, in addition water is absorbed due to the hygroscopic nature of the compounds, whereas alcohols are added for their antimicrobial properties. Since one or both of these are found in tablets, syrups and excipients they must be measured, monitored and controlled. Moreover, water content can lead to microbial growth, hydrolysis and affects dosing. Alcohols while important to solubilizing compounds both as intermediates and end products can have harmful effect and undesirable interactions with other drugs. Current analytical methods have difficulties due to the wide varieties of drugs functional groups. There is also a lack of a method which is able to simultaneously detect both water and a range of alcohols. Karl Fischer titration (KFT) is used to detect water due to it being precise and specific to water, however its specificity means it is unable to measure alcohols. In addition, KFT is known to have solubility issues and side reactions. The ethanol content is determined by a few different methods, density measurements, distillation, or refractive index depending on the state of the sample. These methods are time consuming, not sensitive for trace analysis of ethanol or require benzene or toluene extractions. We have developed an easy, fast and accurate headspace gas chromatographic method to simultaneously determine the water and alcohol concentrations. This method works for both liquid and solid samples and does not have side reactions with the working media.

Abstract Text

The detection and quantification of residual solvents present in clinical and commercial pharmaceutical products is necessary from both patient safety and regulatory perspectives. Head-space gas chromatography is routinely used for quantitation of residual solvents for small molecule APIs produced through synthetic processes; however residual solvent analysis is generally not needed for protein based pharmaceuticals produced through cultured cell lines where solvents are not introduced. In contrast, Antibody Drug Conjugates and other protein conjugates where a drug or other molecule is covalently bound to a protein typically use solvents such as N,N-dimethylacetamide (DMA), N,N dimethylformamide (DMF), dimethyl sulfoxide (DMSO), or Propylene Glycol (PG) to dissolve the hydrophobic small molecule drug for conjugation to the protein. The levels of the solvent remaining following the conjugation step are therefore important to patient safety as these parental drug products are introduced directly into the patient's bloodstream. We have developed a rapid sample preparation followed by a gas chromatography separation for the detection and quantification of several solvents typically used in these conjugation reactions. This generic method has been validated and can be easily implemented for use in quality control testing for clinical or commercial bioconjugated products.

Abstract Text

Developing a method to analyze and detect piperazine compounds (ca. BZP and TFMPP), will aid in the screening for emerging synthetic piperazine drugs on the market. The objective of this research is to optimize the conditions and parameters for a method to detect and screen for piperazine-derived compounds, by using gas chromatography (GC) coupled to mass spectrometry (MS), a flame ionization detector (FID) and a nitrogen phosphorus detector (NPD). Due to the amine group of the piperazine, an NPD has higher sensitivity than a FID and a single quadrupole MS system, therefore providing a lower limit of detection. Additionally, the NPD is likely to exhibit less instrumental drift than the MS, potentially making it a better choice for quantification.

A challenge to the analysis of piperazines is their chemical reactivity in the GC sample pathway. A series of commonly used piperazine drugs were evaluated as part of a study to investigate the chemical reactivity. During the course of this research, the impact of the deactivation chemistry of the inlet liners and columns was evaluated, with results ranging from poor to excellent. This method increased the accuracy of the analysis by comparing the chemical reactivity in the GC pathway and increased the sensitivity and selectivity by coupling MS, FID and NPD. This complete investigation of the chromatographic variables as directed to both native piperazines, and their relevant metabolites, in both recreational drug samples and human urine will allow for a consolidated analytical methodology that is more efficient.

Abstract Text

In an effort to increase the mass loading of crude phyto-extracts in a relatively rapid fractionation process, we are fabricating a large-scale spiral countercurrent chromatograph. The scale of instrument will be suitable for the research laboratory and the parameters determined in this study will be applied to further scaling to pilot and even larger process. Equally important is to develop the various solvent systems to be easily applied for all types of natural product molecules. In the last few years, spiral separation columns (rotors) have been discovered that can retain much better the stationary phases of all 2-phase solvent systems than other separation column-coils utilized in planetary centrifuges of countercurrent chromatography. A new bench-top chromatograph carrying 2 balancing spiral tubing support rotors (20-cm OD) with 2.1 mm ID FEP tubing will be operated at increased RPM. New active metabolites such as flavonoids and glycosides will be isolated from extracts of *Lessertia frutescens* and *Harpagophytum procumbens* plants of So. Africa. Solvent systems will be designed to maximize the isolation and recovery of targeted compounds in a separation.

Abstract Text

In this presentation we introduce some new approaches on the development of new methods for drug screening of active components from Chinese medicine in our research group [1-3]. We have successfully developed a capillary electrophoretically mediated microanalytical technique for screening aromatase inhibitors from Chinese medicines [2] and an neuraminidase-immobilized enzyme microreactor for screening of neuraminidase inhibitors for anti-avian influenza virus from Chinese medicines by capillary electrophoresis. In addition, these novel methods can also be well used for studying the molecular interaction between drug and target enzyme and measuring the enzyme dynamic parameters such as Michaelis constant. Injection procedure of EMMA and electropherograms for screening the aromatase inhibitors are shown in Figure A and B.

Abstract Text

It is well known that it is necessary to separate enantiomers in order to show the true effectiveness of chiral drugs. Often, especially at the early stage of drug discovery, it is necessary to quickly separate enantiomers in order to evaluate the pharmaceutical activity of a specific candidate. Among all possible separation tools, capillary electrophoresis (CE) is by far the best and fastest method of choice for this purpose. The primary reason behind this is the combination of the high resolving power of CE and the availability of a wide choice of chiral selectors (CSs), especially cyclodextrin (CD) based CSs including [alpha]-, [beta]- and [gamma]-CDs. However, it is hard to pick and choose specific CDs as the selectivity of those individual CD based CSs are unknown. Thus, it is necessary to further develop new CSs that can offer a quick and fast separation mechanism for quick and dirty start work. For this reason, we have developed a new class of CSs using various sulphated CDs as the constituents to form a polymer CSs. On the basis of polymerizing sulphated [alpha]-, [beta]- and [gamma]-CDs, we further developed mixed CDs as well as other CSs to form unique polymers. We will present our results from synthesis of those new CSs and the separation results for chiral drugs.

Abstract Text

Incidents involving release of chemicals into the environment often require rapid response, which includes testing to determine the extent of the contamination. Sometimes there are no established environmental test methods for the chemicals involved. For example, the chemical spill which took place in the Elk River in West Virginia in 2014 involved two chemicals, 4-methylcyclohexane methanol (MCHM) and propylene glycol phenyl ether (PPH) which are not included on compound lists of any US EPA test methods. One approach in testing for odd compounds such as these is to use pieces of conventional methods such as purge & trap, soxhlet and liquid/liquid extraction techniques. An alternative approach to consider is solid phase microextraction (SPME), a sampling technique which was commercialized in the early 1990's. It has found utility in the testing of a wide variety of compounds from many different types of sample matrices. SPME is a fast, easy, and highly sensitive technique which uses no solvent, making it "greener" than conventional methods. It can be used for field sampling in some cases, and when combined with GC-MS analysis, for non-routine testing such as environmental forensic investigations, or screening related to chemical releases. We will present data showing the application of SPME to non-routine environmental testing. Its utility to the extraction of MCHM and PPH from water will be presented as well as other applications.

Abstract Text

Environmental laboratories have been pushed to the limit to keep costs low since a downward price spiral in the 1990's made profits hard to maintain. The market contraction has made it very difficult for laboratories to do much beyond that required for the tasks at hand, although some laboratories have been able to focus on a greener approach to their work.⁽¹⁾

Recent changes have caused laboratories to take a second look at air emissions, mostly arising from solvent evaporation of organic extracts. Through Title V and State Implementation Plans up to 10 tons of chlorinated solvent and up to 25 tons total of solvent may be emitted with a valid permit. For extremely small emitters, no permit is required if they are not at risk of exceeding the limit. Some states, such as Massachusetts have reduced the limit to one ton and recently found several laboratories were exceeding this and fined them. ⁽²⁾

This paper will talk about several ways to reduce solvent emission, including reducing sample size to reduce the solvent amount that may be required for extraction. Since chromatographic techniques have improved tremendously over the years, the full capability of the chromatograph is not taken advantage of with older environmental methods. The use of solid phase extraction (SPE) can also be used to reduce the solvent needed for elution. Solid phase extraction is well established and offered as an alternative to liquid-liquid extraction in many US EPA methods. The third technique to help reduce solvent emissions is recapture of the solvent after the evaporation step. The requirements for this process will be examined and the feasibility evaluated.

Abstract Text

Large temporal and spatial variability of the concentrations of air contaminants makes current health risk assessment practices questionable because of the short duration of air sampling. The best way to improve the quality of risk assessment is to collect data on pollutant concentrations over longer periods, either through multiple sampling events, or through sample collection over a long time. Such procedures would provide better estimates of the long-term average concentrations, and thus better evaluation of health risks. Passive sampling is capable of meeting the above requirements in principle, yet quantitative passive sampling of volatile organic compounds from air lasting more than a few weeks has never been reported. In this study, the suitability of a modified version of a permeation passive sampler known as the Waterloo Membrane Sampler (WMS) for long-term sampling has been evaluated.

The study showed that a simple modification involving increasing the permeation membrane thickness from 0.75 μm to 1016 μm made it possible to use the WMS to collect long-term VOC samples from humid atmospheres over prolonged periods. Six different sorbents were tested (Anasorb 746, Tenax TA, Carbopack B, Dowex Optipore, XAD-2, Carboxen 1016) to reveal the differences in the strength of each sorbent towards specific analytes. The results indicated that WMS filled with Anasorb 746, Tenax TA or Carbopack B could provide 3-month time-weighted average concentration measurements for most compounds of interest. For these samplers, good correlations between linear temperature-programmed retention indices and the calibration constant values were obtained, as predicted by the theory. In addition, a good agreement between experimental and theoretical uptake rates, as well as low variation coefficients within and between months, were achieved. Consequently, a WMS customized in this way could be an invaluable tool for better assessment of risks associated with VOCs present in air.

Abstract Text

The new SPME Arrow represents a promising alternative to traditional SPME instrumentation, offering mechanical robustness and increased sorption phase volumes for improved sensitivities.

While all commercially available SPME Fiber coatings may be realized as well for SPME Arrow, phase volumes of up to 15.3 μL in comparison to 0.61 μL with traditional 100 μm SPME-fibers enable an improved performance and potentially novel fields of application. The required changes to the utilized analysis-system are marginal, allowing injector-penetration by the larger diameter of the SPME Arrow (1.15 - 1.5mm). The specially designed tip of SPME Arrow minimizes septum wear to levels below traditional SPME-fibers.

In the presented results, we compare the new SPME Arrow with traditional SPME-fibers using polycyclic aromatic hydrocarbons (PAH) as analytes, PDMS as sorption phase and GC/MS detection. Reported literature results typically contain calibrations down to 10 ng L⁻¹ with satisfactory linear correlations and reproducibility in higher concentration ranges.

Our results demonstrate how sensitivity and reproducibility benefit from the increased sorption phase volume of SPME Arrow, enabling calibrations down to the pg L⁻¹ range, even in real-world groundwater matrices. Furthermore, the enhanced mechanical reliability of SPME Arrow is a considerable benefit to the robustness of the overall analytical technique.

Abstract Text

Nitric oxide (NO) and calcium ion (Ca²⁺) are important biological active species in regulating fundamental physiological functions. NO is continually produced by various NO synthases (NOS) from cells under normal condition. The activity of constitutive NOS (cNOS), which is one of the NO synthases, is known to be dependent on Ca²⁺ ion and calmodulin. Due to the close linkage between NO and Ca²⁺, it is of great interest to measure NO and Ca²⁺ concurrently in living biological system. In this presentation, we demonstrate the simultaneous real-time NO and Ca²⁺ measurements by using electrochemical dual microsensor. A NO/Ca²⁺ dual microsensor possesses two working electrodes (WEs) and two Ag/AgCl counter/reference electrodes for each working electrode: one porous Pt micropore-disk electrode (diameter of disk 25 [micro]m, WE1) is used for amperometric NO measurement and the other Ag microdisk electrode modified with ionophore membrane (diameter of disk 76 [micro]m, WE2) is used for potentiometric Ca²⁺ measurement. For a sensor feasibility test, the prepared dual sensor is applied for real-time simultaneous measurements of the dynamic change of NO and Ca²⁺ levels in living rat organs (e.g., brain, kidney). This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT & Future Planning(2014R1A2A2A05003769).

Abstract Text

Stochastic nanopore sensing, a resistive-pulse, single molecule detection technology, presents a promising strategy to develop biosensors for quantitative measurements of target analytes. Specifically, the utility of bio-inspired nanopore sensors has found significant use in a variety of applications, including nanomedicine, environmental monitoring, nanoelectronics, and sensing. However, most biological nanopore-based sensors have been limited to the utility of well-behaved protein channels with open conductance states, but lack chemical specificity to target molecules of interest. In this study, we report on the use of the ion-channel activity of heat shock cognate 70 (Hsc70) as a means to specifically and quantitatively detect ATP. Hsc70 reconstitutes into artificial lipid bilayers and forms multi-conductive, ATP-regulated ion pathways, but does not remain in an open, conducting state; rather, requires ATP to induce formation of ion pathways through an artificial membrane. To account for this multi-conductance behavior, we introduce the measurement of 'charge flux' to characterize the ATP-regulated channel activity of Hsc70, which enables sensitive quantification of ATP (100 μ M - 4 mM) using a traditional bilayer chamber set-up. Furthermore, we demonstrate the ability of Hsc70 as a new biorecognition element in developing an ATP-specific, nanopore-based biosensor supported on a glass nanopore (GNP) membrane, which shows comparable sensitive detection of ATP in the millimolar range (1 - 4 mM). This provides the very first demonstration of the suitability of the GNP biosensing platform in performing small-scale ATP measurements using a naturally occurring pore with high specificity for ATP. We believe that this new class of biosensors will present a rapid and simple analytical methodology in detecting ATP with unprecedented sensitivity, specificity, and spatiotemporal resolution; thus, will add to the growing toolbox enabled by biological nanopore-based sensors.

Abstract Text

The electrocatalytic reaction between catechol and the antioxidants, glutathione, cysteine, homocysteine and ascorbic acid is studied at a nanocarbon paste electrode and used to measure the total antioxidant concentrations in aqueous solution. Two different approaches were studied: one in which catechol is dissolved in solution and the second in which catechol is dissolved into the nanocarbon paste electrode. Similar limits of detection of $2.0\mu\text{M}$ and $1.9\mu\text{M}$ and sensitivities of $8.8 \times 10^{-3} \mu\text{A}/\mu\text{M}$ and $0.11 \mu\text{M}^{-1}$ are reported, respectively at nanocarbon and nanocarbon-catechol paste electrodes. Three different commercial multivitamin drug samples were analysed and the results were in a good agreement with those from independent analysis.

Abstract Text

Graphene, the most attracting 2-D nanomaterials, possesses broad applications because of its excellent electronic, mechanical, optical and chemical properties. Particularly, by coupling metal nanoparticles onto the surface of graphene sheet, multifunctional nanocomposites have been proposed for metal-based graphene catalysis, surface-enhanced Raman spectroscopy, enhanced photothermal effect, etc,. Here, a general, environmental-friendly, one-pot method for the fabrication of reduced graphene oxide (RGO)/metal (oxide) (e.g. RGO/Au, RGO/Cu₂O, and RGO/Ag) nanocomposites was developed using glucose as the stabilizer and reducing agent. The RGO/metal (oxide) nanocomposites were characterized using STEM, FE-SEM, EDS, UV-Vis absorption spectroscopy, XRD, FT-IR and Raman spectroscopy. The reducing agent, glucose, not only reduced the GO to form RGO, but also reduced the metal precursors to form metal (oxide) nanoparticles on the surface of RGO. Moreover, the RGO/metal (oxide) nanocomposites were stabilized by glucose on the surface of RGO. To demonstrate the utility of these materials in electrochemical sensing, the RGO/Au nanocomposite was used for the simultaneous detection of L-ascorbic acid (L-AA), dopamine (DA) and uric acid in natural matrices with detection limit of 0.1 mM, 1 μM and 5 μM, respectively.

Abstract Text

The online combination of thermogravimetry with mass spectrometry (TG-MS) is widely used for evolved gas analysis (EGA). In recent years, also hyphenated systems featuring an additional gas chromatographic (GC) separation to form a TG-GC-MS were available. A newly developed system, which is presented in this study, expands the possibilities of common TG-GC-MS by implementing new features.

A novel modulator system and a fast-GC were developed. In combined use, it allows a short separation within a 30 s-temperature-programmed GC run. Advantages are the enhanced signal intensities, due to accumulation of the evolved gases in the modulator and the possibility to differentiate between isobaric and isomeric compounds on the basis of different retention time.

Furthermore, a time-of-flight (TOF) mass spectrometer with a maximum mass resolution of 5000 M/ m was applied. It ensures high acquisition rates and enables the distinction of isobaric compounds, which is not possible with low resolution mass spectrometers.

Additionally, fast switching between hard electron ionization (EI) and soft single-photon ionization (SPI) is possible and allows quasi-simultaneous acquisition with both ionization techniques. This offers standard ionization energy mass spectra for library search in EI mode and mass spectra where the molecule ions are most abundant at the same time in SPI mode.

The new system was applied to characterize various petrochemical samples such as crude oils, oil shales, algae- and other bio-feedstock-based oils and fuels. The gained multi-dimensional data sets facilitate the determination of elemental compositions and give further insights into these highly complex matrices.

Abstract Text

Evolved gas analysis using mass spectrometry (MS) is an established analytical technique in thermal analysis (TA) to further characterize the samples causing the mass loss. With current instruments, usually electron ionization (EI) is employed. As the kinetic energy of the electrons thereby is typically far beyond the ionization energies of the assayed samples, the interaction of electron and molecules effects fragmentation particularly of organic compounds, hampering the correlation of the ion signals to the gaseous compounds. This applies for complex mixtures in particular.

Fragmentation can be reduced using so-called soft ionization techniques. In the course of the presented setup, single photon ionization (SPI) is employed.

For the instrumentation, a STA (Simultaneous Thermal Analysis) system has been coupled to a SPI-oaTOFMS (oaTOFMS: orthogonal acceleration time-of-flight mass spectrometry) system using a heated transfer capillary in order to detect semi volatile organic substances from the gas flow of the thermo balance with high temporal resolution.

In this work the thermo-analytical data and the SPI-MS information on the released organics is presented and discussed for various samples. Namely biomass (soft and hard wood), fossil fuel (crude oil and coal) as well as a complex polymer (ABS) are investigated. A first commercially available Setup will be presented and the general potential of hyphenating thermal analysis and soft photo ionization mass spectrometry (SPI-MS) for fundamental and applied research and material analysis is discussed.

Abstract Text

Polytetrafluoroethylene (PTFE) is, of course, well known as a non-stick coating for cookware. Because PTFE is very unreactive and provides a high chemical resistance, it is also used for medical applications and for industrial applications such as containers for reactive chemicals and for corrosion-resistant pipe liners. Also parts like bearings, bushings and gears, where sliding action is needed, are made from PTFE. In this paper, thermal characterization of a PTFE material was carried out using various thermal analysis and thermophysical properties testing techniques. Measurements were carried out between 170[degree]C and 700[degree]C (depending on the method). The thermal expansion and the density changes were determined using pushrod dilatometry (DIL). Dynamic mechanical analysis (DMA) was used to analyze the viscoelastic properties (storage and loss modulus). Thermal diffusivity was measured using the laser flash technique (LFA). Combining thermal diffusivity data with specific heat and density allows for calculation of the thermal conductivity of the polymer. The decomposition behavior was studied using simultaneous thermal analysis (STA). Evolved gases were analyzed by a mass spectrometer (QMS) and Fourier transform infrared spectroscopy (FTIR). In this paper, various thermophysical and thermomechanical properties were tested to get a better understanding of PTFE. The solid-solid transition could be identified by all the thermal analysis techniques that were used. Only dynamic mechanical analysis was able to detect transitions related to the amorphous phase.

Abstract Text

Wood and wood pellets are important energy sources with a zero carbon dioxide balance. This means the carbon dioxide produced during combustion was originally captured by the plants. Instead of firing the wood in air, it could also be heated up in inert gas atmosphere to produce charcoal and also gaseous organic products. The pyrolysis of wood material was investigated by a thermo balance connected to a gas chromatograph with mass spectrometer (TGA-GC-MS). This instrument combination facilitates measuring the mass change of the substances versus temperature and time. The GC-MS allows the identification of gaseous products in real time (quasi-continuous), meaning direct correlation to actual temperature/time/mass. Alternatively, the gas products condensable at -50°C were collected in a cryo-trap and analyzed after the TGA measurement by high resolution GC-MS analysis. In this contribution, the principle of the TGA-GC-MS will be explained along with the measurement modes employed for these investigations. The TGA-GC-MS results will be shown and explained for selected wood samples.

Abstract Text

The hyphenation of a simultaneous thermogravimetry/differentia scanning calorimetry device (STA) to single photon ionization/electron ionization time-of-flight mass spectrometry (EI/SPI-TOFMS) for evolved gas analysis (EGA) is a fast thermal analysis technique for chemical characterization of thermal processes in natural products. Extended by a modulated rapid gas-chromatographic separation step (GC) an additional dimension is generated.

After a single run, multidimensional information is available: The data set contains the thermal information for a chosen heating program from the STA and substantiates these with the correlating mass spectra. Detailed chemical information can be extracted from corresponding mass spectra. It is possible to operate MS in a fast switching modus between EI and SPI. The SPI mass spectra are dominated by the molecular ions of the evolved gases, due to the soft character of this ionization technique, while the molecular specific fragment pattern is available in the EI mass spectra. By CO₂-modulation the evolved gases are trapped and remobilized in 30 s cycles to the column of the rapid GC. With regard to enduring repeatable complete rapid GC, runs a chromatographic separation of isobaric molecules is possible.

Quality control and process optimization in food industry are applications where STA-GCxEI/SPI-TOFMS can be employed. This is a challenge, as hundreds of molecules evolve from natural food products like tobacco, coffee or peanut, evolves simultaneously hundreds of molecules. The aim of this study was to show, that it is possible to simulate the roasting processes in the micro scale to track specific products or to gain specific chemical information of raw products.

Abstract Text

It is well known that bile salts form micelles, but the precise understanding of the structure and dynamic behavior of the aggregation of bile salt monomers to form larger aggregates remains elusive. In this work, isothermal titration calorimetry (ITC) is used to characterize the thermodynamics of the sodium cholate bile salt micelle system, providing significant information about the stability and stoichiometry of this system. Furthermore, ITC experimentation should be well suited to measure the difference in micelle-binding energetics between the R- and S- enantiomers of 1,1'-bi-2-naphthol (BN) and 1,1-binaphthyl-2,2'-diylhydrogenphosphate (BNDHP), molecules that are known to bind to cholate micelles with differing affinity. Chiral resolution appears to be enthalpic controlled: these experiments should provide the first direct measurement of thermodynamics of stereo selective guest solubilization of binaphthyl substrates by bile micelles. Our early data suggest that the presence of BNDHP in high concentrations (2.0 mM) facilitates the micellization process and documents a significant difference in the binding energies between the two enantiomers of BNDHP. Interestingly, the temperature dependence of the demicellization enthalpy (ΔH_{demic}) yields a positive change in heat capacity of demicellization (ΔC_{pdemic}), suggesting that the dissociation of the aggregates of sodium cholate in water leads to the exposure of additional hydrophobic surface area. In all, ITC data that systematically investigate that cholate micelle system, as well as cholate binding of BN and BNDHP, will be presented.
